DICTIONARY OF CHEMISTRY.

CONHYDRINE. $C^8H^{17}NO$, or $C^6H^{17}NO^2$. (Wertheim, *Wien. Akad. Ber.* xxii. 113.)—This alkaloid, which has the composition of a hydrate of conine ($C^8H^{15}N.H^2O$), exists, together with conine, in the flowers and ripe seeds of hemlock (*Conium maculatum*). It is extracted by a process which will be described under CONINE, and purified from adhering conine by pressing the product after it has been submitted to a low temperature (by means of a freezing mixture), and subsequently by repeated recrystallisation from ether. 100 kilogr. of fresh flowers yield 6 grammes of pure crystals.

Conhydrine crystallises in laminae having a pearly lustre and splendid iridescence; they melt at a gentle heat and sublime below $100^\circ C$. It has a slight odour, which increases when the substance is volatilised, and closely resembles that of conine. Its aqueous and alcoholic solutions have a strong alkaline reaction. Its physiological action is narcotic, but less powerful than that of conine.

1 pt. of conhydrine, heated to $200^\circ C$. for an hour and a half with 3 pts. of anhydrous phosphoric acid in a glass tube, decomposes into conine and water.

Conhydrine neutralises acids, expels ammonia from its compounds, but appears to be separated from its salts by conine. The hydrochlorate is uncrystallisable.

Chloroplatinate, $C^8H^{17}NO.HCl.PtCl^3$.—An alcoholic solution of conhydrine neutralised with hydrochloric acid is mixed with alcoholic dichloride of platinum, care being taken to avoid an excess of the latter, and the whole is placed over sulphuric acid in vacuo; when crystals begin to form, the solution is removed to the air and allowed to evaporate, and the crystals are washed, first with ether-alcohol, then with ether. The salt crystallises in hyacinth-red tablets, from 1 to 4 millim. in length, belonging to the trimetric system. It gave by analysis 27.58 per cent. C, 5.31 H, 4.55 N, and 28.04 Pt, the formula requiring 29.47 C, 5.15 H, 4.01 N, and 28.33 Pt.

CONICALCITE. An arseno-phosphate of copper and calcium, containing also a small quantity of vanadic acid, found at Hinajosa de Cordova in Andalusia. It forms reniform masses of pistachio-green colour inclining to emerald green, and yielding a streak of the same colour. Hardness = 4.5. Specific gravity = 4.123. Subtranslucent. Brittle. Fracture splintery. It contains, according to Fritzsche (*Pogg. Ann.* lxxvii. 139), 30.68 per cent. As^2O^5 , 8.81 P^2O^5 , 1.78 V^2O^5 , 31.76 Cu^2O , 21.96 Ca^2O , and 5.61 water, whence it may be regarded as

$\frac{1}{2}Cu^2O \left\{ \frac{2}{3}As^2O^5 + \frac{3}{2}H^2O, \text{ or } \frac{1}{2}Cu^2O \right\} \cdot 2 \left[\frac{1}{2}Ca \right]^3 \left\{ \frac{2}{3}As \right\} O^4 + \frac{3}{2}H^2O$, a small quantity of the arsenic or phosphoric acid being replaced by vanadic acid. (Dana, ii. 421; Rammelsberg, p. 376.)

tity of the arsenic or phosphoric acid being replaced by vanadic acid. (Dana, ii. 421; Rammelsberg, p. 376.)

CONINE.* *Coniine*, *Cicutine*, $C^6H^{15}N$, or $C^6H^{15}N$.—A volatile alkaloid which forms the poisonous principle of hemlock (*Conium maculatum*). It was discovered in 1827 by Giesecke (Brandes' *Arch. Pharm.* xx. 97), but was first prepared in the pure state by Geiger in 1831 (*Mag. Pharm.* xxxv. 72, 259; xxxvi. 159). Ortigosa (*Ann. Ch. Pharm.* xlii. 313) assigned to it the formula $C^6H^{16}N$; Blyth (*Chem. Soc. Qu. J. i.* 345) regarded it as $C^{17}H^{17}N$. The formula $C^8H^{15}N$, according to which conine is isomeric with cyanide of œnanthyl or capronitrile, $C^7H^{15}.CN$, was proposed by Gerhardt and adopted by v. Planta and Kekulé (*Ann. Ch. Pharm.* lxxxix. 129),

* See ADDENDA, p. 964.

who have shown that conine exhibits the characters of a secondary monamine $\left(\begin{smallmatrix} \text{C}^{\text{H}^{14}} \\ \text{H} \end{smallmatrix}\right)^{\text{N}}$, or perhaps $\left(\begin{smallmatrix} \text{C}^{\text{H}^7} \\ \text{H} \end{smallmatrix}\right)^2 \text{N}$.

The last formula, which represents conine as containing the radicle butyrosyl $\text{C}^{\text{H}}\text{H}'$, is rendered probable by the frequent production of butyric acid in the oxidation of conine.

Conine exists in combination with acids in all parts of the hemlock plant, but most abundantly in the fruit a little before maturity. The leaves contain a much smaller quantity, and appear to lose nearly the whole of it in drying, whereas in the fruit the quantity is little, if at all, altered by desiccation. It occurs also in the flowers. According to Walz, conine is probably also contained in the ripe seeds of fool's parsley (*Æthusa Cynapium*). According to Wagner, it appears to exist in the root of *Imperatoria*. In all these plants it exists in combination with acids, and must therefore be separated by the action of a stronger base. It then distils over easily with vapour of water.

Preparation.—1. The seeds of hemlock are distilled with carbonate of potassium or slaked lime, and the yellowish distillate, upon which oily drops float, is neutralised with sulphuric acid and evaporated: it then becomes red, violet, and lastly brown, and deposits brown resinous flakes, which are separated by filtration. The filtrate is evaporated to the consistence of thick syrup, and the residue is treated with a mixture of three parts absolute alcohol and one part ether, as long as it continues to grow turbid. A precipitate of sulphate of ammonia is thus formed, from which the liquid is filtered and then distilled; and the residue is heated in a water-bath and repeatedly moistened with water, until no more alcoholic vapours are perceptible. On cooling, the mass is found to contain a number of micaceous laminae, which cannot be separated. The whole is, therefore, distilled with potash in a chloride-of-calcium bath, whereupon a clear yellowish oil first passes over, containing alcohol (probably from ethyl-sulphate of potassium), and smelling strongly of conine. If this product is rendered turbid by mixture with the following distillate, the receiver must be changed, and the distillation continued till the residue is almost dry, when it is again to be mixed with caustic potash and water, and distilled as long as conine continues to pass over. The distillate, consisting of a watery liquid and oily conine, which still contains water in solution (*for which reason it becomes turbid when heated*), is mixed with chloride of calcium as long as the latter continues to absorb water, and then distilled; ammonia is then evolved, and there remains a brown resinous residue. The distillate is again treated with chloride of calcium and distilled in a sand-bath, and the product, which is almost colourless, is rectified alone; it then leaves a small resinous residue. 6 lbs. of fresh green, unripe seeds, or 9 lbs. dry ripe seeds, yield 1 oz. conine. (Geiger.)

2. The ripe seeds are exhausted with alcohol, the alcohol is distilled off, and the residual syrup is mixed with an equal volume of water and a little hydrate of potassium, and distilled in a chloride-of-calcium bath. (Christison.)

3. When the fresh flowers (or seeds) of hemlock are exhausted with hot water to which a little sulphuric acid has been added, and the extract supersaturated with lime or hydrate of potassium and distilled as rapidly as possible, a strongly alkaline distillate, containing ammonia, conine, and conhydrine passes over. The distillate is neutralised with sulphuric acid, evaporated on a water-bath to a thick syrupy consistence, and then treated with absolute alcohol, which precipitates sulphate of ammonia. The solution is removed from the deposit and placed on a water-bath, in order to evaporate off the alcohol; the residue is allowed to cool, then strongly supersaturated with concentrated potash and mixed with ether, the whole being shaken for a considerable time. The brownish red ethereal solution thus obtained is separated from the aqueous solution and evaporated on a water-bath, till the ether is completely driven off; it is finally heated to 100°C ., and then distilled in a stream of hydrogen, at a very slowly increasing temperature, in an oil-bath. Conine rendered impure by a little water and ether, first passes over, and afterwards colourless oily conine, which may easily be purified by neutralising with hydrochloric acid, pouring off the mother-liquor from the crystals of hydrochlorate of conine, and recrystallising the salt from alcohol. Conhydrine remains in the retort, and, on heating, sublimes in the upper part and neck of the retort in crystalline laminae; if very slowly heated, it sublimes at 150°C ., otherwise between 190° and 210° . (Wertheim.)

Purification.—Conine, obtained by Geiger's process, may still contain ammonia. To remove this impurity, the product is shaken in a long glass tube with water, and after a few hours, the conine is decanted off. The wash-water becomes milky on being shaken up with chlorine-water, but does not evolve nitrogen gas if free from ammonia (Boutron-Charlard and Henry). The ammonia is removed by placing the conine in vacuo over sulphuric acid; the evolution of gas-bubbles causes ebullition (Liebig). If the conine contains water, it is mixed with fused hydrate of potassium: the conine

then separates out, after a time, in an oily stratum, which is removed and rectified alone. Commercial chloride of calcium cannot be used for this purpose, as it generally contains alumina.

Properties.—Conine is a limpid oily liquid of specific gravity 0·89 (Geiger), 0·878 (Blyth). It boils at 168°—171° C. (Blyth); at 187·5° C. (Geiger); 189° C. (Christison); 212° C. (Ortigosa); and when carefully but rapidly heated, distils almost without decomposition (Geiger). It volatilises in vacuo at ordinary temperatures, and distils without residue (Liebig, Ortigosa). It may be carried over with vapour of water at 100° C., but not without slight decomposition. It has a highly penetrating, repulsive, peculiar, and suffocating odour, like that of tobacco, and somewhat resembling that of hemlock; at a distance, and in small quantity, it smells like mice; if closely inhaled, it attacks the head and provokes tears (Geiger). Its taste is sharp, repulsive, and persistent, like that of tobacco. It is a violent poison, small quantities of it rapidly causing death, attended with tetanus. When outwardly applied, it does not dilate the pupil, even if introduced into the eye itself (Geiger). (On the action of conine, see Christison, J. Pharm. xxii. 413; J. Chim. med. xii. 461. Kuhlmann, N. Br. Arch. xxiii. 38.) It has a strong alkaline reaction, but only in the presence of water (Geiger). The alkaline reaction disappears from turmeric paper on application of heat, and slowly from litmus paper. (Blyth.)

The composition of conine is as follows:

			<i>By calculation.</i>	<i>Ortigosa.</i>	<i>Blyth.</i>
Carbon	8 atoms	.	96	74·59	75·11
Hydrogen	15 "	.	15	12·00	13·06
Nitrogen	1 "	.	14	11·20	
			<u>125</u>	<u>100·00</u>	

Conine is slightly soluble in *water* at ordinary temperatures; it is also capable of dissolving one-third of its weight of water, and at low temperatures an equal weight; if it be then heated, it becomes turbid, from separation of water (Geiger). It is very soluble in *alcohol*, and when dissolved in 4 pts. of alcohol, may be mixed in all proportions with water. It is easily soluble in *ether*, in *oils*, both fixed and volatile, and in *acetone*.

Conine dissolves *sulphur* in large quantity, forming a dark orange-coloured solution, which yields crystals of sulphur by evaporation. It is slightly soluble in *sulphide of carbon*. It does not appear to dissolve phosphorus.

Decompositions.—1. Conine is very inflammable, and burns with a bright smoky flame, like volatile oils, leaving only a small residue of carbon. (Geiger.)

2. When kept from the air, conine remains colourless, but, on exposure to the air, it rapidly turns yellow, brown, and viscid, and becomes less soluble in water. The aqueous or alcoholic solution undergoes the same decomposition, especially if the conine is impure; both rapidly turn brown, while the aqueous solution becomes turbid, and deposits resinous flakes (Geiger). In the decomposition of conine by the air, resin is formed and ammonia evolved (Christison). Conine, placed in a shallow dish, and exposed to the action of oxygen for some weeks, turns dark red, becomes thicker, and is finally converted into a stringy resinous mass, which smells strongly of conine, and has an alkaline reaction. This resin dissolves in strong hydrochloric acid, and is precipitated by carbonate of potassium. If this operation be repeated, and the product washed with water, a resin is obtained which is free from conine, smells of butyric acid when burnt or exposed to moist air, and contains nitrogen. (Blyth.)

3. On distilling conine, a portion is always decomposed, ammonia being evolved and a resin formed. The purer the conine, the less decomposition takes place. Heated for some time to a temperature near its boiling point, it is much more decomposed than when it is rapidly heated to boiling, in which case the greater part distils over unchanged; ammonia and a resin are formed, and perhaps also carbonic and acetic acids (Geiger). Moist conine, evaporated in vacuo over substances which attract moisture, leaves a resinous pitchy residue (Charlard and Henry, Ann. Ch. Phys. lxi. 337). Moist conine leaves a resin on distillation; the dry substance does not (Ortigosa, Ann. Ch. Pharm. xlii. 513). When conine is heated above 172° C., the boiling point rapidly rises, decomposition takes place, and white fumes are evolved. (Blyth.)

4. In the *oxidation* of conine, butyric acid is generally formed, as when conine is boiled with *nitric acid* (a resin is formed at the same time, which is precipitated from the solution by potash on cooling); also on evaporating hydrobromate of conine in vacuo with a slight excess of *bromine*, or by evaporating sulphate of conine to dryness, and by treating conine with acid chromate of potassium and sulphuric acid (Blyth). An odour of butyric acid is perceptible during the evaporation of the platinum- or mercury-salts of conine, and of its basic substitution-products (v. Planta and Kekulé). Conine reduces silver-salts. (Ortigosa.)

5. When conine is neutralised with *dilute mineral acids*, it is not decomposed by spontaneous evaporation, but if evaporated with the aid of heat, its solution becomes dark, and a salt of ammonia and a resin are formed. The same reaction is produced, even in the cold, by an excess of acid, or by *acetic or tartaric acid*. (Geiger.)

6. Alcoholic tincture of *iodine* acts violently upon moist conine, the solution becoming turbid and yellow for a few moments, and then colourless, and ultimately drying up to an uncrystallisable mass (Geiger.) A weak tincture of iodine added drop by drop to alcoholic conine, produces a dark brown precipitate, which dissolves and forms a colourless liquid. When tincture of iodine is added as long as the liquid remains colourless (if an excess of iodine is added, a different decomposition takes place), and the solution evaporated in vacuo, there remains a brownish mother-liquor, containing crystals of a similar form to those obtained by the action of bromine upon conine; they are easily soluble in water, alcohol, and ether (Blyth). Anhydrous conine becomes heated in contact with iodine, and forms thick white fumes and a readily fusible mass, which is at first blood-red, and afterwards turns olive-green; this body dissolves in water, forming a nearly colourless solution, and depositing a thick black resin. (Geiger.)

7. When conine (distilled at 169° C.) is exposed to vapour of *bromine*, it immediately solidifies into a mass of crystalline needles. If too much bromine is used, the chief product is a gummy mass; if conine is employed which distilled over below 168° , a red liquid is formed. The purer the conine, the more abundant is the formation of crystals. Conine which has passed over between 98° and 136° does not at first form any crystals with bromine, and when evaporated in vacuo, becomes dark red, or, if more bromine is added, black. This product, dissolved in water, boiled with animal charcoal, then filtered and evaporated in vacuo over sulphuric acid, yields transparent colourless needles and a brown mother-liquor. The crystals, after washing with ether, contain 48.52 per cent. C, and 8.98 H; they are readily soluble in water and in alcohol, but much less in ether; when purified by treating them with ether, and recrystallised from water or from alcohol, they form needles which are permanent in the air and melt into an oil at about 100° C., giving off a little conine vapour. On cooling, the oil solidifies into a striated mass. (Blyth.)

8. Anhydrous conine, acted upon by *chlorine gas*, gives off dense white fumes, becomes hot and thick, and forms a dark brown mass, which has a peculiar odour, something like that of chlorine, but not like that of conine, and when suspended in water and treated with caustic soda, diffuses an odour of conine and turpentine. With hydrated conine, chlorine gas produces a whitish turbidity, separation of oil drops, and a smell of chloride of nitrogen; if potash be then added, an odour of conine is evolved (Geiger). Moist conine, free from ammonia, does not evolve nitrogen when shaken with chlorine-water (Charlard and Henry). When chlorine gas is passed over conine which has distilled at 130° C., the conine becomes hot, assumes a dark red colour, and emits heavy white vapours which smell somewhat like oil of lemon. If the action of the chlorine be continued and the oil cooled, it becomes colourless again and thicker, ceases to evolve white vapours, and becomes covered with white crystals, into which it is completely converted after the chlorine has been passed over it for a long time. The crystals are like those formed by the action of bromine, and are very volatile. If stirred up with water, they readily dissolve; they are very soluble in alcohol and ether, from which they crystallise.

9. Anhydrous conine poured upon dry *chromic acid*, takes fire immediately. (Hofmann, Ann. Ch. Pharm. xlvii. 85.)

10. *Phosphomolybdic acid* (obtained by precipitating molybdate of ammonium with common phosphate of sodium, evaporating the solution to dryness, igniting till the ammonia is driven off, and dissolving the residue in water containing nitric acid) forms with conine and its salts, a bright yellow bulky precipitate. The precipitate is scarcely soluble at ordinary temperatures in water, dilute acids (with the exception of phosphoric acid), alcohol, or ether; it is however readily taken up by the carbonates, borates, and phosphates of the alkalis, and decomposed, though with difficulty, with separation of conine, by the alkaline earths and their carbonates, as well as by the oxides of lead and silver and their carbonates. (Sonnenschein, Ann. Ch. Pharm. cv. 45.)

11. Conine is rapidly attacked by *bromide of ethyl*, and forms a crystalline product (Hofmann, Ann. Ch. Pharm. lxxiv. 175; lxxix. 34). Commercial conine mixes with iodide of ethyl, and forms at first a clear liquid; but a reaction quickly takes place, whereby a brown oil is formed, which sinks to the bottom of the vessel. If the mixture is heated in a sealed tube to 100° C., till the stratum of ether at the bottom no longer decreases, there is formed, if the conine is pure, a viscid oil (hydriodate of ethyl-conine); but if the conine contains methyl-conine, there is formed, besides hydriodate of ethyl-conine, the hydriodate of ethyl-methyl-conine, which solidifies in part immediately, and completely on cooling. (v. Planta and Kekulé.)

12. *Cyanate of ethyl* dissolves conine, with evolution of heat, forming a compound urea, the crystallisation of which causes the mixture to solidify on cooling. (Wurtz.)

SALTS OF CONINE.—Conine is a strong base, and neutralises acids completely; forming salts in which 1 at. conine is united with 1 at. of a monobasic acid, 2 at. conine with 1 at. of a dibasic acid, &c. These salts may be obtained in the solid state by leaving their solutions to evaporate in vacuo, but they are difficult to crystallise. They dissolve easily in water, in alcohol, and in a mixture of alcohol and ether, but are insoluble in pure ether. Many of them are deliquescent. They have a disagreeable, bitter, and acrid taste, like that of tobacco. In the dry state they are odourless, but the aqueous solutions always smell of conine. They are decomposed by heat.

The aqueous solutions of conine-salts form, with *iodine-solution*, a saffron-coloured precipitate, which soon redissolves. They yield flocculent precipitates with *tincture of galls* and *dichloride of platinum*. With *alkalis*, they give off the peculiar odour of conine; and when shaken up with a solution of *sulphate of magnesium*, they form a crystalline salt. The solutions, when exposed to the air, gradually change, from the decomposition of the conine, acquiring a beautiful red or violet colour, which afterwards changes to green or dark blue, and disappears again on addition of alkalis; if quite neutral, they often become yellow or brownish. A much more rapid decomposition takes place when the solution of a conine-salt is evaporated by heat and in contact with the air, the conine appearing to suffer the same alteration as when exposed to the air in the free state; the solutions become brown, and deposit brown flocks, and if an alkali be then added, ammonia and conine are set free, and a dark-brown, bitter, resinous substance is separated, which does not exert any poisonous action.

According to Geiger, conine-salts are less poisonous than the base itself; according to Christison's experiments, on the contrary, the poisonous action of conine is greatly intensified by neutralisation with acids. Five grains of conine, neutralised with hydrochloric acid, and introduced into the vein of a small dog, killed it in a few seconds.

Acetate of Conine dries up, by spontaneous evaporation, to a brown varnish-like mass, which dissolves in water.

Hydrochlorate of Conine, $C^8H^{15}N.HCl$.—Hydrochloric acid gas colours dry conine red and then blue. When conine is placed under the receiver of an air-pump, beside a vessel containing fuming hydrochloric acid, crystals of the hydrochlorate are formed in both vessels, having the form of beautiful, colourless, transparent laminae (Liebig). According to Wertheim (Ann. Ch. Pharm. c. 335), conine evaporated with hydrochloric acid, yields rhombic crystals from 2 to 4 millimetres long, and having a rather strong fatty lustre; they are easily purified by recrystallisation from alcohol. The salt dissolves easily in water, and becomes moist in contact with the air. If the solution be left to evaporate in contact with the air, the salt again crystallises in laminae, but turns brown from decomposition.

Chloroplatinate of Conine, $C^8H^{15}N.HCl.PtCl_2$, obtained by mixing an alcoholic solution of conine with dichloride of platinum, and evaporating in vacuo over oil of vitriol, is an orange-yellow crystalline powder, soluble in water and in boiling alcohol, insoluble in ether-alcohol (Ortigosa); decomposed at $100^\circ C$.

Nitrate of Conine is obtained, by spontaneous evaporation, as a brown deliquescent mass, having the consistence of an extract, mixed with small needles and crystalline granules.

Sulphate of Conine.—Conine, saturated with dilute sulphuric acid, assumes a brownish colour on evaporation, and leaves a thick gummy mass, with traces of crystallisation. According to Charlard and Henry, the salt is crystallisable, deliquescent, and dissolves in all proportions in alcohol. Potash separates the conine. If the evaporation be carried too far, decomposition takes place, and the odour of butyric acid becomes perceptible. Sulphate of conine forms with *sulphate of aluminium*, a double salt which crystallises in octahedrons (conine-alum).

Tartrate of Conine.—The solution, left to evaporate in the air, becomes turbid, acquires a green and then a brown colour, and leaves an extract-like mass, containing small granular crystals. On heating the mass with water, a few brown flakes remain undissolved.

Conine forms crystallisable salts with iodic, oxalic, and phosphoric acids.

Substitution-derivatives of Conine.

Conine is a secondary monamine, $N.H.(C^6H^{11})''$, or $N.H.(C^4H^7)^2$, containing only one atom of replaceable hydrogen: for when it is treated with iodide of ethyl, hydriodic acid is formed, and the ethyl takes the place of 1 at. hydrogen in the base, the product being *hydriodate of ethyl-conine* ($N.C^2H^5.C^6H^{11}).HI$); but on treating ethylconine with iodide of ethyl, no further substitution takes place, but the two bodies unite directly, forming *iodethylate of ethylconine* ($N.C^2H^5.C^6H^{11}).C^2H^5I$), or rather *iodide of diethylconinium* [$N.(C^2H^5)^2.C^6H^{11}]I$].

METHYL-CONINE. $C^8H^{17}N = N.CH^3.C^6H^{14}$.—This base is often contained in commercial conine. It is also produced by the action of heat on ethyl-methyl-conine. It is a colourless oil, smelling like conine, lighter than water, and sparingly soluble in water, imparting, however, a strong alkaline reaction. Iodide of ethyl converts it into iodide of ethyl-methyl-coninium.

ETHYL-CONINE. $C^{10}H^{19}N = N.C^2H^5.C^8H^{14}$. (v. Planta and Kekulé, Ann. Ch. Pharm. lxxxix. 131.)—The hydriodate of this base is obtained by heating conine with iodide of ethyl in a sealed tube to $100^{\circ}C$. for about half an hour; and by dissolving the product in water, removing the excess of iodide of ethyl by decantation, and gently heating the solution with caustic potash, ethyl-conine separates, and may be rectified in a current of hydrogen after being dried over fragments of chloride of calcium and solid potash.

Ethyl-conine is a volatile, almost colourless, strongly refracting oil, lighter than water, smelling like conine, partially decomposed by distillation. Iodide of ethyl converts it into iodide of diethyl-coninium.

Ethyl-conine is sparingly soluble in water, but dissolves readily in acids, with considerable evolution of heat. Its salts do not crystallise by evaporation.

The *hydrobromate* and *hydriodate* are uncrystallisable. The *hydrochlorate* is obtained, as a mass of white deliquescent crystals, by leaving anhydrous ethyl-conine under an exhausted receiver beside a vessel containing fuming hydrochloric acid. The *chloro-aurate* is precipitated as a yellowish oil which solidifies and crystallises; from a hot dilute solution it sometimes separates in beautiful yellow crystals. The *chloromercurate* is obtained by precipitation, as a white resinous substance, which melts in the liquid at the boiling heat, and if dilute solutions are used, separates in rhomboidal tablets. The *chloroplatinate*, $C^{10}H^{19}N.HCl.PtCl_2$, is a yellow crystalline powder easily soluble in water and in alcohol.

DIETHYL-CONINIUM. $C^{12}H^{24}N = N.(C^2H^5)^2.C^6H^{14}$. (v. Planta and Kekulé, Ann. Ch. Pharm. lxxxix. 146.)—Known only in combination. The iodide, $C^{12}H^{24}NI$, is obtained by the action of iodide of ethyl on ethyl-conine in the cold. This mixture, left to itself for 12 hours, forms a crystalline mass; and on heating this product in a sealed tube to $100^{\circ}C$., the iodide of diethyl-coninium melts to a liquid which floats on the iodide of ethyl. The crystals are softer than those of ethyl-methyl-coninium, dissolve easily in water and alcohol, less readily in ether.

The *hydrate* is obtained in solution by decomposing the iodide with oxide of silver. The solution is inodorous, has a bitter taste, and strong alkaline reaction.

The *chloride*, obtained by saturating the base with hydrochloric acid, forms, with *chloride of mercury*, a white flocculent precipitate, which melts when heated, and separates from the hot solution after some time in microscopic crystals; with *trichloride of gold*, a sulphur-yellow semi-fluid precipitate which dissolves when heated, and separates on cooling in oily drops which become solid and crystalline; and with *dichloride of platinum*, on evaporation, a crystalline salt containing $C^{12}H^{24}N.Cl.PtCl_2$.

ETHYL-METHYL-CONINIUM. $C^{11}H^{22}N = N.CH^3.C^2H^5.C^6H^{14}$. (v. Planta and Kekulé, Ann. Ch. Pharm. lxxxix. 135.)—This base also is known only in combination. The *iodide* is produced by the action of iodide of ethyl on methyl-conine. When commercial conine, containing the latter compound (ii. 5), is treated with iodide of ethyl, it yields, besides the syrupy hydriodate of ethyl-conine, crystals of the iodide of ethyl-methyl-coninium. The reaction takes place even in the cold, and is completed in a few minutes at the heat of the water-bath. On dissolving the product in water, removing the mass of iodide of ethyl, and adding caustic potash, a brown oil separates which divides into two layers, the upper, which consists of ethyl-conine, remaining liquid, while the lower, consisting of iodide of ethyl-methyl-coninium, separates in splendid needles, which may be purified by washing with ether containing a little alcohol.

Hydrate of Ethyl-methyl-coninium is obtained in solution by decomposing the iodide with recently precipitated oxide of silver. The solution is colourless, inodorous, very bitter, strongly alkaline, and when concentrated acts on the skin like caustic potash. It absorbs carbonic acid quickly from the air. It may be boiled without decomposition, but when concentrated and distilled, it is resolved in methyl-conine, water, and ethylene gas:

Heated in a sealed tube with iodide of ethyl, it is converted into alcohol and iodide of ethyl-methyl-coninium.

The *chloride, sulphate, nitrate, carbonate, oxalate, and acetate* of ethyl-methyl-coninium are crystallisable, very soluble in water, and, for the most part, deliquescent.

The *iodide*, $C^{11}H^{22}NI$, forms colourless needles very soluble in water and in alcohol, insoluble in ether and in alkaline liquids. It may be boiled with caustic potash without decomposition.

Chloro-aurate, $C^{11}H^{22}NCl.AuCl_3$.—Precipitated by chloride of gold from a solution of the base in hydrochloric acid, in yellow flakes which soon become crystalline. From hot solutions, the salt is deposited in fine needles on cooling. The dry salt melts below $100^\circ C$. (Gold, by analysis, 38.67 per cent., by calculation 38.86 per cent.)

Chloro-mercurate, $C^{11}H^{22}NCl.6HgCl$.—White crystalline precipitate, moderately soluble in water, alcohol, and ether. Gives by analysis, 59.15 per cent. Hg. and 24.53 Cl, the formula requiring 59.03 Hg, and 24.45 Cl. When heated with water, it melts and dissolves, and the solution, on standing, deposits another salt containing $C^{11}H^{22}NCl.5HgCl$. (Analysis, 14.25 per cent. C, 2.70 H, and 55.78 Hg; calculation, 14.98 C, 2.50 H, and 56.75 Hg.)

Chloroplatinate, $C^{11}H^{22}NCl.PtCl_3$.—Precipitated as a yellow crystalline powder, or from dilute solutions, gradually, in fine octahedrons. It is sparingly soluble in cold water, more soluble in boiling water, insoluble in alcohol and ether. (Mean of analyses, 35.49 per cent. C, 6.54 H, and 26.43 Pt; calculation, 35.37 C, 5.85 H, and 26.45 Pt.)

CONISTONITE. A name given by R. P. Greg (Sill. Am. J. xvii. 333) to a hydrated oxalate of calcium in crystals of the trimetric system, from Coniston in Cumberland; afterwards, however, found not to be a natural mineral (*ibid.* xxii. 252).

CONITE, or *Konite*. Compact dolomite.

CONIUM MACULATUM. *Hemlock*.—This very poisonous plant contains the two alkaloids, conine and conhydrine. It loses its activity by drying, and, according to Müller, by keeping for twelve months. The extract loses its activity with equal facility, the alcoholic sooner than the aqueous extract. According to Landerer, the green parts of the plant contain also a small quantity of an extremely intoxicating oil. 100 pts. of the dry leaves contain, according to Wrightson (Pharm. J. Trans. v. 40), 6.8 pts. nitrogen, and 12.8 ash, consisting, after deduction of carbonic acid, sand, and charcoal, of 21.7 per cent. potash, 9.6 soda, 14.9 lime, 8.3 magnesia, 2.6 silica, 5.9 sulphate of calcium, 16.7 phosphate of calcium, 3.5 ferric phosphate, and 16.6 chloride of sodium.

CONJUGATED COMPOUNDS. *Copulated compounds. Corps conjugués ou copulés. Gepaarte Verbindungen.*—These terms, the meaning of which has never been very clearly defined, were first introduced into organic chemistry by Gerhardt, in 1839. He had observed that certain acids, especially sulphuric acid, produce, by their action on organic bodies, peculiar compounds in which the characteristic properties of the original substances are no longer perceptible; benzoic acid, for example, is converted by sulphuric acid into sulpho-benzoic acid, a compound in which the presence of sulphuric acid cannot be detected by barium-salts. This kind of union was called by Gerhardt copulation (*accouplement*); the product, a copulated compound (*sel copulé*), and the organic body which united with the sulphuric acid, was called the *copula* (*copule, Paarling*).

To explain the formation and properties of these substances, Gerhardt supposed that the action of sulphuric acid and similar acids on organic bodies may take place in two ways. Either the acting acid loses its saturating power, in which case the product is formed by substitution, *e.g.* *sulphobenzide*, $\frac{C^{12}H_5}{SO^2}$ from *benzole*, $C^{12}H_6$, by the substitution of SO^2 for 1 at. H; or the acting acid retains its saturating capacity, in which combination takes place by copulation. In many cases both these actions were supposed to take place together; thus the formation and composition of sulpho-benzoic acid (anhydrous) were represented by the formula $\frac{C^{14}H^4}{SO^2}O^3 + SO^3$.

Similar views regarding the constitution of such acids were put forth about the same time by Dumas and Piria, who designated them as "conjugated acids." Berzelius also adopted the terms copulated and conjugated, but applied them in a different sense, namely, to designate compounds which he could not regard as formed by the union of elements or compound radicles in opposite electrical states; thus water, metallic oxides, and the corresponding oxides of organic radicles, were supposed to be capable of uniting with acids, or electro-negative bodies, in the ordinary way; but the union of all other

bodies was called copulation. Thus acetic acid, $C^4H^3O^3$, was regarded as oxalic acid, C^2O^3 , copulated with methyl, C^2H^3 ; trichloroacetic acid, $C^4Cl^3O^3$, as oxalic acid, C^2O^3 copulated with sesquichloride of carbon, C^2Cl^3 . A copulated compound was defined as a compound of an active substance (*e. g.* the oxalic acid in the compounds just mentioned) with a passive substance or copula. Substitution (of Cl for H for example) was supposed to take place only in the latter. These views of Berzelius have clearly no connection with those previously mentioned. Gerhardt in fact protested against this use of terms which he had introduced in a different sense, and, at the same time, defined conjugated compounds as bodies produced by the substitution of "residues" (or compound radicles) for elementary bodies,—this definition including the amides, compound ethers, nitro-substitution compounds, as well as the compounds formed by the action of sulphuric, phosphoric, and other polybasic acids on hydro-carbons and organic acids.

In a memoir on the anilides published by Laurent and Gerhardt in 1848, the following definition is given:—"We designate as conjugate compounds, all such as are formed by the direct union of two bodies, with elimination of water, and are capable of reproducing the original bodies by again taking up the elements of water."

The following are examples:

Ethyl-sulphuric acid, formed from alcohol and sulphuric acid:

Acetic ether from alcohol and acetic acid:

Nitro-benzoic acid, from benzoic and nitric acids:

Sulpho-benzoic acid, from benzoic and sulphuric acid:

Benzamide, from benzoic acid and ammonia:

It is easy to see, however, that on this definition nearly all chemical compounds might be regarded as conjugated: for the mode of action just illustrated is precisely that which takes place in the formation of the simplest salts, *e. g.*:

More recently (in his *Traité de Chimie Organique*, 1853-56) Gerhardt, while he admits that in a certain sense all organic compounds may be regarded as conjugated, nevertheless restricts the actual use of the term to certain groups of bodies, without, however, distinctly stating what they are. He no longer applies it to the ethers, either acid or neutral, or to the amides; but includes among conjugated compounds the amic acids, and compounds formed by the substitution of bromine, chlorine, or nitril, for hydrogen. The idea of a conjugated compound he explains as follows:—

"To connect together two or more systems of double decomposition of one and the same body, it is often advantageous to represent its composition by a conjugated radicle, that is to say, a radicle made up of several radicles, each of which represents one such system of decomposition. We must regard as conjugated the radicle of every body capable of being transformed, by certain very simple reactions, into compounds belonging to other radicles (*radicaux constituants*), or in other words, the radicle of every body resulting from the metamorphosis of such combinations. Thus acetyl, C^2H^3O , may be regarded as a conjugated radicle composed of carbonyl, CO, and methyl, CH^3 , because acetic acid and its derivatives are capable of splitting up into compounds containing carbonyl, and others containing methyl (*i. 17*); and conversely, acetic acid may be produced by the action of carbonic anhydride on potassium-methyl. Similarly with the radicles of the other fatty acids; thus, formyl = CO.H; propionyl = CO.C²H³; butyryl = CO.C³H⁷; amyl = CO.C⁴H⁹, &c. The same acid radicles may also be regarded as alcohol-radicles in which H² is replaced by O; thus acetyl, C^2H^3O , may be regarded as formed from ethyl, C^2H^5 ; propionyl, C^3H^5O , from trityl, C^3H^7 ; butyryl, C^4H^7O , from tetryl, C^4H^9 : this mode of representation corresponding to the fact that the alcohols are converted into fatty acids by oxidation."

In general, complex radicles may be regarded as conjugated either by addition or by substitution; *e. g.* tetrethylammonium, $N(C^2H^5)^4$, is either a compound of N with 4 at. ethyl; or it is ammonium, NH^4 , in which 4 at. H are replaced by ethyl. The mode of representation by substitution is especially applicable to bodies formed by the action

of chlorine, bromine, nitric acid, or sulphuric acid on organic bodies, and to the amides, amines, and ammonium-bases.

From these considerations—for the full development of which we must refer to *Gerhardt's Traité* (iv. 602)—it will be seen that Gerhardt ultimately gave up the idea of conjugated compounds as distinct from others, and retained the term merely for the sake of comprehending certain substances in groups, and exhibiting certain analogies in a clearer light. His formulæ, in fact, represent decompositions, the most important transformations being indicated by the radicles which appear in the typical formula: thus, when acetic acid is written, $\begin{matrix} \text{C}^2\text{H}^3\text{O} \\ \text{H} \end{matrix} \bigg\} \text{O}$, we are reminded that 1 at. of hydrogen may be exchanged for a metal or other basylous radicle, and that 1 at. O (outside the radicle) may be replaced by S, yielding thiactic acid, or by 2 at. Cl, yielding chloride of acetyl and chloride of hydrogen. In these transformations the radicle acetyl remains unaltered, and may be regarded as a simple substance; but any other transformations must affect the radicle itself, and to indicate these, the formula of acetyl must be resolved into others, in the manner above mentioned, the acetyl then appearing as a conjugate instead of as a simple radicle. (See CLASSIFICATION, i. 1017.)

Considered in this light, conjugate radicles are merely modes of expression adopted for convenience; and it is easy to show that by the extensions of the typical mode of representation of chemical compounds which have come into use since the publication of Gerhardt's work, the use of conjugate radicles may be dispensed with altogether (see TYPES). For example, Gerhardt represents the amic acids as containing radicles of this class, and refers them to the type H^2O ; thus—

but they may also be referred to the mixed type $\begin{matrix} \text{NH}^3 \\ \text{OH}^2 \end{matrix} \bigg\}$, and then the conjugate radicles may be broken up: thus—

In like manner, many sulpho-acids, supposed by Gerhardt to contain conjugate radicles, because they were referred to the type H^2O , may be regarded as derived from the mixed type $\begin{matrix} \text{H}^4\text{O} \\ \text{H}^2 \end{matrix} \bigg\}$ and as containing simple radicles, e.g.:

The same mode of representation may be applied to the acid ethers of dibasic acids. If they are referred to the type H^2O , they must be supposed to contain conjugate radicles:

but by referring them to the type H^4O^2 , they appear as acid salts exactly analogous to acid sulphate of potassium:

These examples are sufficient to show that the transformations of any compound, so far as they are known, may be represented by typical formulæ without the assumption

of conjugate radicles. Still the use of these radicles is often convenient, inasmuch as it affords typical formulæ of comparatively simple structure, and such as bring prominently into view a certain set of reactions, which may be the especial object of consideration. But it applies equally well to all classes of compounds, excepting of course the very simplest; and the compounds to which the term conjugate has been and still is by some chemists most frequently applied, are not distinguished by any essential characters from those which are commonly assumed to be of simple constitution.

We must not, however, omit to notice that there are a few compounds, produced by the action of sulphuric acid on organic bodies,—the very class, indeed, to which the term conjugate was originally applied,—which are still supposed, by some chemists, to possess peculiar properties entitling them to the name.

One characteristic of a true conjugated acid, is said to be the comparatively greater permanence of the compound radicle which it contains, and the power possessed by that radicle of passing from one type to another without decomposition. Thus, sulphophenylic acid is transformed by pentachloride of phosphorus into chloride of sulphophenyl, and this, by the action of ammonia, into sulphophenylamide:

Here the radicle $\text{C}^6\text{H}^5(\text{SO}^2)$, which is found in all the three compounds, is said to be conjugated. The formation of the chloride from the acid may, however, be shown to take place quite in the usual way, without assuming any peculiar fixity in this radicle. The action of chloride of phosphorus on acids and other oxides is known to consist in the replacement of O, in the type H^2O , by Cl^2 , the result being the formation of two separate chlorides, because the bond which held together the two atoms of hydrogen, or their equivalents in the type H^2O , is broken up: thus,

In like manner, if we represent sulphophenylic acid by a formula modelled on the mixed type $\text{H}^2\text{O}\left\{\begin{smallmatrix} \text{H}^2\text{O} \\ \text{H}^2 \end{smallmatrix}\right\}$, we find that

The chloride belongs to the mixed type $\text{H}^2\text{HCl}\left\{\begin{smallmatrix} \text{H}^2 \\ \text{HCl} \end{smallmatrix}\right\}$, the two molecules H^2 and HCl being held together by the radicle SO^2 , just as the two molecules H^2 and H^2O were in the original acid.

In fact, chloride of sulphophenyl is related to sulphophenylic acid in exactly the same manner as chlorhydrosulphuric acid (SO^2HCl), the compound formed by the action of pentachloride of phosphorus on sulphuric acid, is related to that acid:

If sulphophenylic acid is to be regarded as conjugated, on account of the formation of chloride of sulphophenyl, sulphuric acid ought likewise to be regarded as a conjugated acid, on account of the formation of chlorhydrosulphuric acid:

Chlorhydrosulphuric acid would then be regarded as the chloride of the same radicle, namely, $\text{H}(\text{SO}^2)\text{O}.\text{Cl}$; in fact, when treated with water, it reproduces sulphuric acid, just as chloride of sulphophenyl reproduces sulphophenylic acid. (Kekulé.)

Another class of acids to which the term conjugate is still sometimes applied, includes those which result from a peculiar action of sulphuric acid, especially of the fuming acid, on certain organic bodies,—the change consisting in the abstraction of an atom of hydrogen from the radicle of the compound, which radicle accordingly undergoes an alteration of atomicity, becoming, for example, diatomic instead of monatomic.

This change may, however, be easily represented by means of mixed types, as in the following formulæ of sulphacetic and sulphobenzoic acids :

These sulpho-acids are formed from acetic and benzoic acid in the same manner as isethionic acid, $\begin{array}{c} (\text{C}^2\text{H}^4)' \\ (\text{SO}^2)'' \\ \text{H}^2 \end{array} \left\{ \begin{array}{c} \text{O} \\ \text{O} \\ \text{H}^2 \end{array} \right\}$, from alcohol, $\begin{array}{c} \text{C}^2\text{H}^3 \\ \text{H} \end{array} \left\{ \begin{array}{c} \text{O} \\ \text{H} \end{array} \right\}$. Now this last acid may be formed

by the action of boiling water on sulphate of carbyl, $\text{C}^2\text{H}^4\text{S}^2\text{O}^6$, or $\begin{array}{c} (\text{C}^2\text{H}^4)' \\ (\text{SO}^2)'' \\ (\text{SO}^2)'' \end{array} \left\{ \begin{array}{c} \text{O} \\ \text{O} \\ \text{O} \end{array} \right\}$, which is itself a product of the action of sulphuric anhydride upon ethylene C^2H^4 . In this last mode of formation there is no alteration of the radicle; consequently, if such alteration were supposed to necessitate the representation of the resulting compound by a formula containing a conjugate radicle, *e. g.* sulphacetic acid, by $\begin{array}{c} \text{C}^2\text{H}^4\text{O}(\text{SO}^2)' \\ \text{H} \end{array} \left\{ \begin{array}{c} \text{O} \\ \text{H} \end{array} \right\}$, and isethionic acid, by $\begin{array}{c} \text{C}^2\text{H}^3(\text{SO}^2)' \\ \text{H} \end{array} \left\{ \begin{array}{c} \text{O} \\ \text{H} \end{array} \right\}$, it would follow that the last-mentioned acid might be regarded as conjugated or non-conjugated, according as it was formed from alcohol or from olefiant gas.

From all these considerations it follows that there is no case in which the use of conjugate radicles is a matter of necessity, the use of a radicle or of a type of greater or less complexity being in all cases a matter of convenience, and determined by the particular kind of chemical transformation which the formula is intended to represent. It would be well, therefore, if the idea of conjugation, as denoting any peculiar mode of chemical combination, were altogether banished from the science (Kekulé, *Lehrbuch der Organischen Chemie*, 1859, i. 192).—On the history of conjugate compounds, see also Limpricht and v. Uslar, *Ann. Ch. Pharm.* cii. 139; Mendius, *ibid.* ciii. 39; Kekulé, *ibid.* civ. 129; cvi. 129; Limpricht, *ibid.* civ. 177); also the articles CLASSIFICATION, RADICLES, SUBSTITUTION, and TYPES, in this Dictionary.

CONNECTIVE TISSUE. *Bindgewebe*.—This term is applied to a tissue chemically allied to cartilage, though of a simpler character, and comprises, not merely the porous soft cellular substance, characterised by the readiness with which it may be filled with air, which connects together the various organs and tissues of the animal organism, and was formerly called *cellular tissue*, but also those morphological elements which constitute the solid basis of many of the animal membranes and ligaments. The tissue which connects the organs one with another, forming a network of variously sized meshes composed of long slender fibres (of 0.0003–0.0005" diameter), for the most part united in bundles, is called *amorphous* (Henle), or *loose*, or *areolar connective tissue* (Kölliker). This tissue gradually passes into a more solid variety distinguished by the epithet *formed* (Henle), or *compact* (Kölliker), which forms the basis of the tendons and ligaments, the fibrous membranes and muscular fasciæ, the envelopes of many soft organs (the *dura mater*, *neurolemma*, &c.), the serous and synovial membranes, the coats of the veins, the so-called vascular membranes, (*pia mater*, *choroidæ*, &c.), the interarticular cartilages, &c.

The true connective tissue is, however, constantly mixed with vessels, nerves, fat-cells, elastic fibres, and frequently also with unstriped muscular fibres, which cannot be mechanically separated from it, so that its chemical examination is a matter of some difficulty; but from the analysis of those organs, such as the tendons, in which it is mixed with the smallest amount of these morphological elements, it appears to be identical in composition with gelatin.

Connective tissue immersed in boiling water contracts somewhat at first, but soon swells up like a jelly, and dissolves on prolonged boiling, yielding a solution of gelatin. If the water contains an *acid* or *alkali* in solution, the transformation is effected much more quickly.

The change which here takes place is rather physical than chemical: for the connective, and indeed all the gelatinising tissues, appear to have essentially the same composition as gelatin itself, as may be seen from the following analyses by Scherer

(Ann. Ch. Pharm. lx. 46–49) and Mulder (*Vers. einer allgem. physiol. Chem.* Braunschweig, 1844—51, p. 333.)

	Scherer.				Mulder.	
	Isinglass.	Tendons.	Sclerótica.		Gelatin from: Stag's horn. Isinglass.	
Carbon . . .	50·557	50·774	49·563	50·995	50·05	50·76
Hydrogen . .	6·903	7·152	7·148	7·075	6·64	6·64
Nitrogen . .	18·790	18·230	18·470	18·723	18·39	18·31
Oxygen . . .	23·670	23·754	24·819	23·207	24·92	24·29

In concentrated *acetic acid* connective tissue swells up and becomes transparent, but does not dissolve till water is added and heat applied. The acetic solution is not precipitated either by red or by yellow prussiate. In dilute acetic acid, the fibres of connective tissue likewise swell up, becoming transparent and invisible, but do not dissolve, even after several hours' boiling; for on washing with pure water, or neutralising the acid with ammonia, they reappear in their original form. As most of the other textural elements which are intermixed with the connective tissue are not rendered invisible by acetic acid, they are brought more distinctly into view by its application: hence this acid affords valuable aid in the histological study of the tissues. In *alkalis* the fibres also swell up in the gelatinous form, but if the action of the alkali has been continued for some time, they do not reappear on addition of water, but are thereby dissolved.

Embryonic connective tissue (Virchow's *mucous tissue*) does not yield gelatin when boiled with water, (Scherer); it consists, in addition to fusiform cells, of a peculiar intercellular substance, which, when digested with water, yields albumin together with a gelatinous or mucous substance. (*Lehmann's Physiological Chemistry*, iii. 46; *Gmelin's Handbuch*, viii. [2] 457).

CONNELLITE. A Cornish mineral, consisting of cupric chloride, sulphate, and water, forming small fibrous crystals, belonging to the hexagonal system, translucent, of blue colour and glassy lustre, insoluble in water, easily soluble in hydrochloric and nitric acids. (Connell, J. pr. Chem. xlii. 453.)

CONTACT ACTION. *Catalytic action, Catalysis.* These terms are applied to a numerous class of chemical actions, in which the combination of two bodies, or the decomposition of a compound, is brought about by the intervention of a substance which shows no tendency to unite with either of the bodies concerned, and remains unaffected by the changes which take place. Berzelius, who first drew attention to this class of actions, supposed that substances acting in this manner possessed a peculiar power which he called "catalytic force" (from *καταλυνειν*, to resolve); he regarded this power as a manifestation of electric force, different, however, from the ordinary action of electricity. Mitscherlich designates substances thus acting "contact substances," and the mode of action, as chemical action or combination by contact.

Examples of these contact actions are found both in inorganic and in organic chemistry; *e. g.* the action of platinum and other metals in inducing the combination of oxygen and hydrogen; the rapid decomposition of peroxide of hydrogen by the presence of platinum, silver, fibrin, &c.; the conversion of starch into dextrin and sugar by boiling with acidulated water; the conversion of cane-sugar into grape-sugar by contact with acids; and the numerous and varied phenomena of fermentation and putrefaction.

The connection between these somewhat obscure phenomena and those of ordinary chemical action, is perhaps to be found in the idea suggested by Berzelius, that they are due to some modification of the electric state of the bodies, or, to speak more generally, to a polarisation of the combining or separating atoms induced by the presence of the apparently inactive body. Take, for example, the action of platinum in inducing the combination of oxygen and hydrogen. We know from the effects of Grove's gas-battery (see **ELECTRICITY**), that when two glass tubes containing oxygen and hydrogen respectively are inverted over water, and platinum plates immersed in them, partly in the gas and partly in the water, the plates being also connected by a wire outside the tubes, the gases gradually disappear, and a voltaic circuit is formed, in which the platinum immersed in the hydrogen corresponds to the positive or zinc plate of the ordinary battery. This effect indicates a polarisation of the molecules of hydrogen, oxygen, and platinum, such as is represented in the following diagram:

Now it is highly probable that a similar polarisation and consequent combination of the oxygen and hydrogen takes place when a clean platinum plate or wire, or finely divided platinum, is introduced into a mixture of those gases, the effect of the metal

being due to the facility with which its contiguous particles place themselves in opposite electrical or polar states. The peculiar efficacy of platinum in bringing about such combinations, appears to be related to its medium position in the electrical or chemical series: we know, indeed, from the purely chemical relations of platinum, that it is almost equally disposed to play the part either of a chlorous or acid, or of a positive or basylous element. The more energetic action of the finely-divided metal is of course due to its larger surface, and to the power which such bodies possess of condensing gases within their pores. The decomposition of peroxide of hydrogen, by contact with platinum and other metals, may be supposed to take place in a similar manner.

The polarised state to which we have attributed the action of platinum in these cases is by no means an isolated condition, but one which pervades the whole range of chemical phenomena. That the whole of the molecules composing a voltaic circuit may be regarded as polarised, was pointed out many years ago by Graham (*Elements of Chemistry*, 1st ed., 1841); and that a similar polarised state comes into play in ordinary cases of chemical action, and may serve to account for many phenomena usually regarded as somewhat obscure,—such as the peculiar energy of bodies in the so-called nascent state,—the decomposition of peroxide of hydrogen by certain metallic oxides, which are themselves at the same time reduced to a lower state of oxidation—the

reaction between hydrochloric acid and hydride of copper ($\overset{+}{\text{Cu}}\overset{-}{\text{H}} + \overset{+}{\text{H}}\overset{-}{\text{Cl}} = \overset{+}{\text{Cu}}\overset{-}{\text{Cl}} + \overset{+}{\text{H}}\overset{-}{\text{H}}$)—the mutual decomposition of hydriodic and iodic acids—and many similar phenomena,—was shown by Brodie in his paper “On the condition of certain elements at the moment of chemical charge” (Phil. Trans. 1850, p. 759); see also CHEMICAL AFFINITY (i. 858). When, therefore, we refer the action of platinum and other metals to chemical or electrical polarity, we merely point out that these phenomena may be regarded as particular cases of a recognised mode of action. Whether the so-called contact actions which are so frequently observed in organic chemistry, such as the action of ferments, and the conversion of starch into sugar by the action of acids, can be explained in a similar manner, is a question which does not at present admit of a decided answer. (See a paper by Dr. T. L. Phipson: *La Force catalytique ou études sur les Phénomènes de Contact.* Haarlem, 1858.)

It not unfrequently happens that reactions are effected with ease by using a considerable excess of one of the reagents, which can be brought about only with difficulty, or not at all, by using only as much of the reagent in question as actually takes part in the chemical change. These reactions may reasonably be regarded as a special class of contact actions, the excess of the reagent facilitating the action of that portion which takes part in the reaction, in much the same way as in other cases, the “*contact-substance*” promotes the action of a body chemically different from itself. The most probable explanation that has hitherto been suggested of this *action of the mass* of a reagent, and of catalytic actions in general, is that the contact-substance assists the reaction, by exerting its affinity in the same direction as the bodies striving to react upon another, but under such conditions that it cannot itself undergo alteration. This supposed mode of action will be made more easily intelligible by an example: if oxalic acid is heated with nitric acid until it begins to be oxidised, and water is then added to the mixture until the action ceases, the oxidation immediately begins again on the addition of a small quantity of a protosalt of manganese (Mercer). In this instance, the tendency of the manganous salt to become a manganic salt, acts in the same direction as the attraction of the elements of the oxalic acid for the oxygen of the nitric acid, which is thus decomposed under the influence of both substances acting together, under circumstances in which it would not have been decomposed by either alone; a sesquisalt of manganese being, however, incapable of existing in an acid solution containing oxalic acid, the protosalt of manganese remains unchanged, although aiding by its presence to bring about the reaction. This mode of explaining many cases of so-called action of contact, was first suggested by Mercer (Brit. Assoc. Rep. 1842, vol. ix. Notices and Abstracts, p. 32); it was further developed by Playfair (Mem. and Proc. Chem. Soc. (1847) iii. 348), and is applied by Kekulé (Lehrb. d. Org. Chem. i. 142, note) to the explanation not only of such phenomena, but, in the way indicated above, to those commonly referred to the *action of mass*.

CONVALLAMARETIN. A substance produced by the action of acids and alkalis on convallamarin. It separates from the liquid in crystalline spangles, cakes together into a resinous mass on boiling, melts when heated alone, and decomposes by dry distillation. (Walz.)

CONVALLAMARIN. A bitter substance contained, together with convallarin, in *Convallaria majalis* (Solomon's seal). It is obtained by diluting and filtering the mother-liquor from which the convallarin has separated, then digesting with animal charcoal, precipitating with tannic acid, and separating the tannic acid with oxide of lead.

Convallamarin is a white powder, having a bitter taste, with peculiar sweetish after-taste, easily soluble in water and alcohol, nearly insoluble in ether. By heating the aqueous solution with dilute sulphuric acid, the convallamarin is resolved into sugar, water, and convallamaretin. Nitric acid colours convallamarin yellow; strong sulphuric acid colours it violet, but the colour disappears on dilution. Alkalis decomposes it, with separation of convallamaretin. (Walz.)

CONVALLARETIN. See CONVALLARIN.

CONVALLARIA. The flowers of *Convallaria majalis* (Solomon's seal) yield, by distillation with water, a small quantity of a volatile, crystalline, strong-smelling camphoroidal substance, and a bitter principle (Herberger). Walz (N. Jahrb. Pharm. 1858, x. 145) has obtained from this plant two compounds, named convallarin and convallamarin.

In the herb and stalks of lily of the valley, *Convallaria multiflora*, Walz finds asparagin, starch, sugar, citric acid, malic acid, and a crystallisable substance which produces a scratching sensation in the throat.

CONVALLARIN. A substance contained in *Convallaria majalis*. The plant, collected during or after the flowering time, is dried, pulverised, and exhausted with alcohol of 0.84; the tincture is precipitated with subacetate of lead; the lead removed from the filtrate by sulphuretted hydrogen; and the crystals of convallarin, which separate on evaporation, are purified by washing with ether.

Convallarin is composed, according to Walz, of $C^{34}H^{31}O^{11}$; it crystallises in right rectangular prisms, is sparingly soluble in water, to which it imparts an irritating taste, and the property of frothing when agitated. By prolonged boiling with acids, it is said to yield sugar and convallaretin, $C^{28}H^{26}O^6$, a yellowish-white crystalline mass, soluble in ether, and having a slight resinous taste.

CONVOLVULIC ACID. An acid formed from convolvulin, under the influence of bases, by addition of the elements of water. It was first obtained by Kaiser (Ann. Ch. Pharm. li. 30), who called it hydro-rhodeoretin, and assigned to it the formula $C^{12}H^{36}O^{21}$, afterwards more fully examined by Mayer (*ibid.* lxxxiii. 126: xcv. 162), who gave it the name rhodeoretic acid, and regarded it as a dibasic acid, $C^{36}H^{60}O^{19}.H^2$, or $C^{72}H^{60}.O^{36}.2HO$; subsequently, however, he has considered it as a tribasic acid, with the formula $C^{62}H^{50}.O^{32}.3HO$ (or sexbasic, according to the formula $C^{62}H^{100}.O^{35}.H^6$).

Convolvulic acid is prepared by boiling 100 grammes of convolvulin in 500 grms. of baryta-water with frequent agitation; precipitating the baryta, after cooling, with a slight excess of sulphuric acid; then removing the excess of sulphuric acid by agitation with carbonate of lead; precipitating the dissolved lead by sulphuretted hydrogen, and evaporating the filtrate on the water-bath.

Convolvulic acid is a white, very hygrometric substance, resembling convolvulin in appearance, soluble in all proportions in water and in alcohol, insoluble in ether. The aqueous solution has a strong acid reaction, and a very faint odour like that of quinces. It softens at a few degrees above $100^{\circ}C.$, melts between 100° and 120° , and decomposes at higher temperatures.

It contains, according to the mean of Mayer's analyses, 52.60 per cent. carbon and 7.81 hydrogen, whence Mayer deduces the formula $C^{62}H^{53}O^{35}$ (52.8 per cent. C, and 7.5 O), representing the acid as convolvulin, *plus* 3 at. water. This formula is, however, improbable, on account of the uneven numbers of atoms of hydrogen and oxygen.

Convolvulic acid reacts like convolvulin with acetic, nitric, and strong sulphuric acid. By boiling with dilute sulphuric or hydrochloric acid, it is resolved into convolvulinic acid and glucose; the same effect is produced by emulsin:

Convolvulic acid expels carbonic acid from alkaline and earthy carbonates, especially with the aid of heat. The aqueous solution of the acid, either free or after neutralisation with ammonia, does not precipitate the solution of any neutral metallic salt; but with basic acetate of lead, it yields white bulky flakes.

The acid, boiled with excess of *baryta-water*, yields a so-called neutral salt, $C^{62}H^{51}Ba^2O^{35}(?)$, while if the acid is in excess, an acid salt, $C^{62}H^{52}BaO^{35}(?)$, is obtained. Both salts are amorphous, diaphanous, brittle, bitter, with an odour of quinces, very soluble in water and alcohol, melt between 100° and $110^{\circ}C.$ A *calcium-salt*, $C^{62}H^{51}Ca^2O^{35}(?)$, obtained by boiling the acid with milk of lime, is amorphous; slightly yellowish: its aqueous solution has a faint odour of quinces.

An *acid potassium-salt*, containing 5.65 per cent. potash, is obtained by saturating the acid with potash, evaporating to dryness and redissolving in alcohol. It is amorphous, very soluble in water, sparingly in alcohol. The aqueous solution is bitter, and has the odour of quinces. This salt melts between 100° and $110^{\circ}C.$ (Mayer.)

CONVOLVULIN. A resin contained in the tuberose or officinal jalap-root (the rhizome of *Convolvulus Schiedanus*, Zucc). According to Mayer's last investigations (Ann. Ch. Pharm. xcv. 161), it contains $C^{31}H^{50}O^{16}$ or $C^{62}H^{50}O^{32}$, and is homologous with jalapin, the resin of fusiform jalap (*Convolvulus orizabensis*, Pell). [It may be inferred from Mayer's experiments, though the fact is not distinctly stated, that convolvulin and jalapin exist together in both kinds of jalap-root, the convolvulin being more abundant in the tuberose, the latter in the fusiform species.] Mayer formerly regarded it as $C^{52}H^{60}O^{36} + HO$; Kayser (*loc. cit.*) as $C^{52}H^{50}O^{30}$; Laurent as $C^{18}H^{10}O^{24}$, or $C^{34}H^{10}O^{12}$.

Convolvulin is prepared from the root of *Convolvulus Schiedanus* by exhausting the root with boiling water; drying, and coarsely pulverising it; then treating it three times with twice its weight of alcohol of 90 per cent.; mixing the alcoholic extract with water till it begins to show turbidity; then treating the liquid twice with animal charcoal; distilling the alcohol from the filtrate; repeatedly treating the residual pulverised resin (amounting to between 10 and 15 per cent. of the root) with ether; dissolving the residue in the smallest possible quantity of absolute alcohol; precipitating with ether; and repeating the solution and precipitation till the precipitate is quite free from the portion of the crude resin which is soluble in ether. The residue ultimately obtained is pure convolvulin.

Convolvulin is a colourless transparent resin, which, when pulverised, yields a white powder like gum arabic. It is tasteless and inodorous, nearly insoluble in water, easily soluble in alcohol, but insoluble in ether, whereby it is distinguished from jalapin; the alcoholic solution has a slight acid reaction. The resin melts below $100^{\circ}C.$ when moist; but in the dry state it softens only at 141° , and melts at 150° to a light yellow transparent liquid; above 155° it begins to decompose. When heated in the air on platinum foil, it burns with a smoky flame, diffusing an odour like that of caramel.

Convolvulin, dried at $150^{\circ}C.$, contains, according to Mayer's analysis, from 54.21 to 55.01 per cent. carbon, and 7.89 to 8.07 hydrogen; the formula, $C^{31}H^{50}O^{16}$, requires 54.97 C and 7.37 H.

Finely divided convolvulin dissolves in aqueous alkalis even in the cold, more easily when heated, and is converted into convolvulic acid. It dissolves also in acetic acid. Very dilute nitric acid dissolves it slowly in the cold, more readily when heated, but with decomposition. Stronger nitric acid decomposes it immediately, with evolution of nitrous acid and formation of oxalic acid and ipomæic acid, an isomer of sebacic acid ($C^{10}H^{18}O^4$).

Convolvulin dissolved in alcohol is resolved by hydrochloric acid into convolvulinolic acid and glucose:

Convolvulin is not affected by cold dilute sulphuric acid; but, when triturated with strong sulphuric acid, it dissolves with fine carmine-red colour, changing after a while to brown; the solution after standing for a longer time deposits a brown-black substance. In this reaction also, convolvulin is resolved into convolvulinol and glucose. It is therefore a glucoside.

Convolvulin is the active principle of jalap-resin; it exerts a very strong purgative action, even in doses of a few grains.

CONVOLVULINOLIC ACID. *Convolvulinol, Rhodocortinol.* (Kaiser, *loc. cit.*—Mayer, *loc. cit.*)—This compound is produced, together with glucose, by the action of dilute acids, or of emulsin, on convolvulic acid. To prepare it, 30 grms. of convolvulic acid are dissolved in 300 grms. of water, the solution is heated to the boiling point, and 20 grms. of strong sulphuric acid diluted with 200 grms. of water are added to it, the boiling being continued for some time. Convolvulinolic acid then partly separates as an oil, partly remains dissolved in the water, and separates in colourless microscopic needles on cooling. It is inodorous, but has a harsh, slightly bitter taste. It dissolves but very sparingly in pure water, more freely in acidulated water, very easily in alcohol, less easily in ether; it does not crystallise either from alcohol or from ether. It feels greasy and softens between the fingers, melts at 38.5° or $39^{\circ}C.$ to a yellow oily liquid, and solidifies again at 36° . The melted acid, diffused in water, imparts to it a peculiar odour like that of the carob bean.

Heated on platinum foil in contact with the air, it appears to volatilise for the most part without decomposition, the vapours having a strong cough-exciting odour like that of sebacic acid. Strong sulphuric acid colours convolvulinol, first yellowish, then amaranth-red, like convolvulin. Strong nitric acid oxidises it to oxalic and ipomæic acids.

Convolvulinolic acid, prepared as above, contains, according to the mean of Mayer's

analyses, 65·47 per cent. carbon and 10·71 hydrogen, whence he deduces the improbable formula $C^{26}H^{25}O^7$ (65·8 per cent. C, and 10·5 H). When separated from its salts, however, it has, according to Mayer, the composition $C^{26}H^{24}O^6$. A product having this composition is likewise obtained by heating convolvulin or convolvulic acid with hydrate of sodium and a little water, as long as hydrogen continues to escape, decomposing the aqueous solution of the product with sulphuric acid, and purifying by solution in alcohol, and treatment with animal charcoal. It resembles the preceding in all its properties, excepting that it melts at a somewhat higher temperature (40° — 45° C.), and has a stronger acid reaction.

Mayer applies the term convolvulinol to the product of the action of acids on convolvulic acid, and designates as convolvulinolic acid the compound separated from the convolvulinolates, or obtained by the process last described; but it is most probable that the two substances are merely the same acid in different states of hydration. All these products require re-examination.

The convolvulinolates are composed, according to Mayer, of $C^{26}H^{24}MO^7$, or $MO.C^{26}H^{24}O^6$. Those of the alkali-metals are easily soluble in water and in alcohol, and are obtained by treating the alcoholic solution of the acid with caustic alkalis. Those of the alkaline-earth metals are sparingly soluble, and are obtained in like manner. Those of most of the heavy metals are insoluble and are obtained by precipitation. The lead-salt is said to contain $C^{26}H^{23}PbO^6$. (Mayer.)

CONVOLVULACEÆ. An order of plants yielding many useful products. The roots of several species of *Convolvulus* and *Ipomœa* yield purgative resins, or gum-resins. *Convolvulus scammonium*, L., yields scammony (q. v.). *C. Schiedanus* and *C. orizabensis*, or *Ipomœa orizabensis*, yield jalap. *C. turpethum*, or *I. turpethum*, also yields a purgative resin. *C. batatas*, or *Batatas edulis*, the Spanish potato, yields edible tubers, resembling the common potato, but of sweeter taste (i. 520). *C. scoparius*, L., and *C. floridus*, L., yield one of the woods called rose-wood.

CONYLENE. See ADDENDA (p. 964).

COPAHENE or COPAIVENE.

COPAHILENE.

} See COPAIBA OIL.

COPAHUVIC or COPAIVIC ACID. See COPAIBA RESINS.

COPAIBA BALSAM. See BALSAMS (i. 492).

COPAIBA OIL. *Essence de Copahu.* (Bonastre [1825], J. Pharm. xi. 529.—Ader, J. Pharm. xv. 95.—Gerber, Br. Arch. xxx. 157.—Blanchet, Ann. Ch. Pharm. vii. 156.—Soubeiran and Capitaine, J. Pharm. xxvi. 70.—Gm. xiv. 286.)—The volatile oil contained in balsam of copaiba. It belongs to the camphenes, $C^{10}H^{18}$, or $C^{20}H^{16}$. Copaiba balsam is a mixture of this oil with resins, the proportion of the oil varying from 30 to 60 per cent. in balsams from different localities.

The oil is obtained by distilling the balsam with water, and may be purified by drying over chloride of calcium and rectifying. To obtain the whole of the oil, the distillation with water must be repeated six or eight times (Soubeiran and Capitaine). According to Ader, the oil may be separated by agitating 100 pts. of the balsam with an equal quantity of alcohol of specific gravity 0·836, then adding $37\frac{1}{2}$ pts. of soda-ley of specific gravity 1·33, and diluting the whole with 150 pts. of water. The oil then gradually rises to the surface.

Pure oil of copaiba is transparent, colourless, or yellowish-green, mobile, and has an aromatic odour like that of the balsam; that obtained by Ader's method is said to have a more disagreeable odour; the taste is sharp and persistently bitter. Specific gravity 0·881—0·91, increasing to 0·96 on exposure to the air. Boiling-point 245° — 260° C. Optical rotatory power = $34^{\circ}18'$ to the left. Expansion from 0° to 100° C. = 0·083132; from 100° to 200° = 0·104034 (Aubergier, J. Pharm. xvii. 278). The oil is neutral. It solidifies, partly crystalline, at -26° C. Oil of copaiba dissolves in $2\frac{1}{2}$ pts. of absolute alcohol, and in 25—30 pts. of alcohol of specific gravity 0·85. (According to Stoltze, it dissolves in all proportions in alcohol of this strength.) With sulphide of carbon and anhydrous ether, it mixes in all proportions, but not with more than half its weight of common ether. It dissolves sulphur and phosphorus with aid of heat. It likewise dissolves glacial acetic acid and hydrocyanic acid, and mixes with alcoholic succinic and benzoic acids; also with solution of oxalic acid, but not with citric acid. It absorbs ammonia, becoming milk-white and viscid. (Gerber.)

Copaiba oil becomes brown and viscid by continued boiling. Chlorine in sunshine makes it hot, colours it yellowish blue, and then green, and separates white crystalline masses (Blanchet). Iodine, slowly added to the oil, dissolves without detonation (Blanchet), forming a reddish-yellow, or brown-black liquid: if it be added more quickly, heating and frothing take place, and a brown mass is formed (Gerber). It detonates with fuming nitric acid, leaving a brown resin. With nitric acid of specific gravity

1.32, it resinises only when heated (Blanchet). According to Bonastre, it assumes a violet tint at the beginning of the action. Weaker nitric acid forms with the oil a small quantity of yellow resin, precipitable by water (Gerber). *Oil of vitriol* makes it hot and turns it red-brown (Stoltze). With a few drops of oil of vitriol it becomes hot and blacker; but when dropped into a larger quantity of oil of vitriol, it forms a red-brown solution of sulphoterebic acid. (Gerhardt, *Compt. rend.* xvii. 314.)

With *hydrochloric acid*, copaiba oil forms a solid and a liquid compound. The oil, shaken up with *aqueous potash* or *soda*, becomes heated, acquires a brown colour, and yields to water a small quantity of resin, which does not pre-exist in the oil, but is produced from it by the action of the alkali (Gerber). Distilled with 24 pts. water and 8 pts. chloride of lime, it gives off carbonic acid and forms chloroform. Distilled with *hypobromite of potassium*, it forms bromoform. (Chautard, *Compt. rend.* xxxiv. 485.)

a. Hydrochlorate of Copahene or Copaivene. Hydrochlorate of Copaiba oil. Camphre de Copahu. $C^{10}H^{16}.2HCl$.—This is the solid hydrochlorate; it is prepared by passing dry hydrochloric acid gas through dehydrated oil of copaiba, separating the crystalline mass, which is deposited therefrom on cooling, from the brown oil, pressing it between filtering paper, mixing its solution in ether with alcohol of specific gravity 0.85, and washing with alcohol the crystalline mass which separates. (Blanchet.)

Hydrochlorate of copahene forms short, transparent, right rectangular prisms (resembling chlorate of potassium, according to Blanchet), which melt at $77^{\circ}C$. (Soubeiran and Capitaine). They are inodorous (Blanchet, Soubeiran and Capitaine); have a faint camphorous odour, and an aromatic bitter taste. (Gerber.)

The hydrochlorate, heated to 140° — $150^{\circ}C$, gives off a large quantity of hydrochloric acid gas (Soubeiran and Capitaine). When set on fire, it burns with a bright flame (Gerber). *Nitric acid*, heated with it, is said to give off nitrogen gas (Blanchet). *Oil of vitriol*, with aid of heat, dissolves it, and deposits it again in the crystalline form on cooling; at a stronger heat, the solution gives off hydrochloric acid gas. Heated with *sulphide of lead*, it yields an oil having an alliaceous odour. Its alcoholic solution is precipitated by *nitrate of silver* or *mercurous nitrate*. (Blanchet.)

It is insoluble in water and in cold alcohol, sparingly soluble in hot alcohol, easily soluble in ether (Blanchet). The alcoholic solution leaves when evaporated a thick oil, which smells like balsam of copaiba, and appears to hold in solution undecomposed dihydrochlorate of copaiba oil. (Soubeiran and Capitaine.)

Hydrochlorate of Copahilene.—This is the liquid portion of the product obtained by treating copaiba oil with hydrochloric acid. It always contains in solution a portion of the solid compound, which cannot be separated from it (Soubeiran and Capitaine). It is a black, viscid oil, smelling like castoreum, and without action on polarised light (Soubeiran and Capitaine). When distilled, it gives off hydrochloric acid gas, and yields a colourless oil, which is a solution of hydrochlorate of copahene (Soubeiran and Capitaine). It burns with a faint odour of hydrochloric acid. It gives up a portion of its hydrochloric acid when shaken up with water. It is soluble in alcohol and ether. (Gerber.)

Para-copaiba Oil. (Soubeiran and Capitaine [1840]. *J. Pharm.* xxvi. 70.—Posselt, *Ann. Pharm.* lxi. 67.)—This oil occurs in a variety of copaiba balsam from Brazil. It is separated by distilling with water, and the oil is dehydrated with chloride of calcium (Posselt). It is a transparent, colourless, viscid oil, of specific gravity 0.91 (0.898 according to Soubeiran and Capitaine), boiling at $250^{\circ}C$. It smells like the balsam, and has a sharp burning taste (Posselt). Rotatory power 28.553° to the left (Soubeiran and Capitaine). It dissolves in all proportions in *ether*, less easily in *absolute alcohol*, still less in *common alcohol*.

The oil becomes yellowish when boiled, afterwards brown, thick, tenacious, and charred (Posselt). *Chlorine* converts it, with evolution of hydrochloric acid, into a yellow sticky mass. The oil dissolves *iodine* without detonation. With *fuming nitric acid*, it detonates even in the cold; but nitric acid of specific gravity 1.32 resinises it only with aid of heat. Dilute nitric acid, heated with the oil, dissolves it completely after a few days, giving off nitrous acid, carbonic acid, and other volatile acids. From the solution of the oil in nitric acid, water throws down, after evaporation, a reddish-yellow acid resin, sparingly soluble in hot water, easily soluble in alcohol and ether, whilst a peculiar acid remains dissolved, which, when the solution is concentrated by evaporation, crystallises in slender, colourless, transparent laminae, easily soluble in water, alcohol, ether, and rock-oil, inodorous, having a bitter taste, and a slight acid reaction (Posselt). The oil absorbs *hydrochloric acid gas* with avidity, turning brown-red and fuming in the air, but not depositing any crystals on cooling.

COPAIBA-RESINS. (Schweizer, Pogg. Ann. xvii. 784; xxi. 172.—Rose, *ibid.* xxxiii. 83.—Hess, Ann. Ch. Pharm. xxix. 140.—Fehling, *ibid.* xl. 110.—Posselt, *ibid.* lxix. 67.)—Copaiba balsam contains several resins which remain behind after the distillation of the volatile oil; certain samples of this balsam have been found to contain peculiar resins.

The resins obtained from ordinary copaiba balsam may be separated into a crystallisable resin called copaivic acid (the α -resin of Berzelius), and an uncrystallisable β -resin. The latter, which forms but a small proportion of the whole, remains behind, when the entire mass of resin is treated with cold rock-oil, as a brown unctuous mass, easily soluble in alcohol or ether.

COPAIVIC ACID. *Copahuic acid. α -resin of Berzelius.* $C^{20}H^{30}O^2$, or $C^{10}H^{20}O^1$.—This crystallisable resin exists in copaiba balsam to an amount varying from 20 to 66 per cent. It is the constituent which determines the hardening of the balsam by magnesia, an effect which, however, does not take place if the proportion of copaivic acid is below 50 per cent. (Procter). According to Schweizer, the acid may be prepared by dissolving the entire mass of resins obtained from copaiba balsam in aqueous ammonia, and leaving the solution to evaporate in a cool place. Crystals then separate which may be obtained pure by washing with ether and recrystallisation from alcohol. Or the resinous mass is heated with cold rock-oil, the solution left to evaporate, the residue dissolved in alcohol, and the copaivic acid left to crystallise by spontaneous evaporation. Or the entire mass is dissolved in alcohol, and the solution left to evaporate.

Copaivic acid forms colourless rhombic crystals, soluble in strong alcohol; the solution reddens litmus. It dissolves easily in ether, in oils both fixed and volatile, and in sulphide of carbon. It is decomposed by heating.

The acid dissolves in aqueous fixed alkalis and in ammonia. The alcoholic solution mixes without decomposition with alcoholic potash or with strong aqueous potash; but, on adding a larger quantity of water, a precipitate is formed.

Copaivic acid appears to be monobasic. The *calcium-salt*, $C^{20}H^{29}CaO^2$, is a white precipitate, which separates on mixing an alcoholic solution of the resin containing a little ammonia with alcoholic chloride of calcium, and then adding water. *Copaivate of lead*, $C^{20}H^{29}PbO^2$, is obtained by mixing the alcoholic solutions of the resin and acetate of lead, as a white, fusible, slightly crystalline precipitate. *Copaivate of silver*, $C^{20}H^{29}AgO^2$, separates, on mixing the solution of the resin with an alcoholic solution of nitrate of silver mixed with a little ammonia, as a white crystalline precipitate, sparingly soluble in alcohol, easily soluble in ammonia, easily fusible, and turning brown on exposure to light.

OXYCOPAIVIC ACID. $C^{20}H^{28}O^3$, or $HO.C^{10}H^{27}O^5$.—This acid resin was found by Fehling in a sediment deposited from a turbid copaiba balsam from Para. By solution in alcohol and slow evaporation, it is obtained in colourless regular crystals, whose primary form is a rhombic prism having the acute summits truncated. It becomes strongly electric by friction; dissolves readily in ether, less readily in alcohol; melts at about $120^\circ C$. When the solution of the resin in ether and alcohol is quickly evaporated in a flat dish, and stirred at the same time, a hydrated resin, $C^{20}H^{28}O^3.H^2O$, or $C^{10}H^{18}O^5.2HO$, sometimes separates as an amorphous powder; it has the same composition as the oxysilvic acid described by Hess, but differs from it in properties. This hydrated resin softens in boiling water; it forms with bases the same salts as the anhydrous resin.

Oxycopaivic acid, heated with *nitric acid*, gives off carbonic and nitrous acids, and yields two products, a resin and a new acid. The resin, said to be $C^{36}H^{20}O^{15}$, is light yellow, has a strong and disagreeably bitter taste, and unites with bases. The acid is free from nitrogen, of brownish colour, deliquescent, very soluble in water and in alcohol, easily decomposes carbonates, forms soluble salts with the alkalis, a sparingly soluble salt with baryta, insoluble salts with lead, mercury, and silver; the lead-salt has the composition $2Pb^2O.C^{18}H^{18}O^7$, or $4PbO.C^{30}H^{18}O^{14}$ (?).

When oxycopaivic acid is evaporated to dryness with nitric acid, there remains a pitchy mass, part of which dissolves in alcohol, leaving a humoidal substance having the composition $C^6H^6O^2$.

Oxycopaivates.—Oxycopaivic acid dissolved in alcohol exhibits an acid reaction. The oxycopaivates of the *alkali-metals* are soluble in water; the ammoniacal solution gives off all its ammonia by evaporation. The *lead-salt*, $C^{20}H^{27}PbO^3$, or $PbO.C^{10}H^{27}O^5$, is obtained as a white precipitate on mixing the alcoholic solution of the resin containing a little ammonia with an alcoholic solution of acetate of lead. The *silversalt*, $C^{20}H^{27}AgO^3$, or $AgO.C^{10}H^{27}O^5$, separates as a white amorphous precipitate on mixing a solution of the acid in aqueous ammonia with excess of nitrate of silver.

ACID COPAIBA-RESIN.—This resin was found by Martin and Vigne (J. Pharm.

1842, p. 52), in a crystalline deposit of copaiba balsam, which dissolved in hot alcohol, but separated out again for the most part as the solution cooled. As it has not been further investigated, its identity or non-identity with one of the resins previously described, must for the present remain undecided.

From clear copaiba balsam, Martin and Vigne prepared a resin different from the crystalline substance.

INDIFFERENT COPAIBA-RESINS.—Whether the β -resin (p. 18) belongs to this group is doubtful, inasmuch as it is said to dissolve in alkalis.

In a very fluid copaiba balsam of peculiar constitution, Posselt found, besides para-copaiba oil, two indifferent amorphous resins, the first of which (containing 60·3 per cent. carbon, 8·3 hydrogen, and 31·4 oxygen) was soluble in weak boiling alcohol; the second (containing 82·0 carbon, 10·5 hydrogen, and 7·5 oxygen) dissolved sparingly in boiling absolute alcohol, separated out for the most part on cooling, and was insoluble in dilute alcohol. Neither of these resins combines with alkalis. (Handw. d. Chem. ii. [3] 799.)

COPAIVENE. The camphene contained in the crystallised hydrochlorate of copaiba oil; it has not yet been isolated (p. 16).

COPAIVIC ACID. See COPAIBA RESINS.

COPAIVILENE or COPAIVYL. Syn. with COPAIVENE.

COPAL. A valuable resin of which the best coach-varnish is made. It exudes spontaneously from several trees, namely, the *Rhus copallina*, a terebinthaceous tree, native of North America, the *Elaeocarpus copalifer*, which grows in the East Indies, and the *Hymenaea verrucosa*, which grows chiefly in Madagascar. French writers likewise give the name copal to the resin of the *Hymenaea Courbaril*, growing in Brazil and the West Indies; but in England and Germany this resin is called *animé* (see vol. i. p. 296). There is altogether a considerable amount of discrepancy in the statements respecting the trees which furnish copal.

Copal generally occurs in flat pieces, rough on the outside, and of various shapes and sizes. Its physical properties vary to a certain extent according to its origin; but the lumps are, for the most part, opaque on the outside, transparent internally, of yellowish to yellowish-brown colour, sometimes nearly colourless; turbid and translucent lumps also occur; insects and parts of plants are not unfrequently enclosed within the resin. Copal is hard; it has a very lustrous conchoidal fracture, is easily pulverised, does not cake together even when chewed, but becomes rather soft at 50° C. The specific gravity of copal varies from 1·045 to 1·139 according to its origin, and perhaps also according to its age.

The solubility of copal in different liquids varies also with its origin, American copal being much less soluble in *alcohol*, *oil of turpentine*, and *oil of rosemary*, than East Indian or African copal. By exposure to the air, especially when pulverised and placed in a hot air-chamber, it absorbs oxygen, and then becomes more soluble in alcohol and in oil of turpentine. The solubility is also increased by melting the copal at the lowest possible temperature; but American copal is more difficult to fuse than the other varieties, and sometimes remains so insoluble as to be quite useless for making varnishes. Anhydrous copal in the natural state is but very sparingly soluble, but swells up to a tough elastic substance when boiled. In pure *ether*, copal swells up to a transparent jelly, and afterwards changes to a syrupy mass. If this mass be heated to commencing ebullition, and alcohol of specific gravity 0·82 be added in successive small quantities, a clear solution is obtained; but if the alcohol be added cold or all at once, the mass coagulates and does not dissolve. Copal is but partially soluble in *sulphide of carbon*, but *oil of caoutchouc* dissolves it easily, even in the cold.

Copal dissolves in *strong sulphuric* and *nitric acids*, but is decomposed by those acids if only slightly heated.

The statements respecting the solubility of copal in *caustic alkalis* vary considerably, doubtless because the experiments have been made upon different varieties. According to Filhol, neither ammonia nor potash dissolves it in the cold; but if the liquid is heated to the boiling point, the resin coagulates and floats on the surface in the form of a spongy mass, which does not dissolve, even after several hours' boiling,—because the compound of the resin with the alkali, though soluble in pure water, is quite insoluble in water containing excess of alkali.

The following analyses of various kinds of copal have been made by Filhol:

	Copal from Calcutta, in tears.	Copal from Calcutta, in very white, flat lumps.		Copal from Bombay.	Copal from Madagascar.
Carbon . . .	80·66	80·34	80·29	79·70	79·80
Hydrogen . .	8·77	10·32	10·52	10·40	9·42
Oxygen . . .	10·57	9·14	9·14	9·90	10·78
	100·00	100·00	100·00	100·00	100·00
		c 2			

Filhol has obtained from East Indian copal, five distinct resins, some of which however pass into others by oxidation, so that they may be regarded as different oxides of the same radicle; viz.:

α-resin: Soft, fusible at the heat of the water bath; soluble in alcohol of 72 per cent., also in ether, and in oil of turpentine; forms, with bases, resinates soluble in ether, but (excepting the potassium-salt) insoluble in alcohol.

β-resin: Soft, fusible below 100° C.; soluble in all proportions in alcohol, ether and oil of turpentine; forms resinates soluble in ether, insoluble in absolute alcohol.

γ-resin: White, soluble in absolute alcohol and in ether; less fusible than the preceding; forms resinates insoluble in alcohol and ether.

δ-resin: White, insoluble in alcohol and ether, soluble in alcoholic potash; very difficult to fuse.

ε-resin: Gelatinous; insoluble in all menstrua.

These resins yielded by analysis:

	Carbon.	Hydrogen.
<i>α-resin</i> . . .	77.76 to 76.94	10.12 to 10.24
<i>β-resin</i> . . .	76.04 — 76.85	10.03 — 10.86
<i>γ-resin</i> . . .	80.53 — 80.70	10.43 — 10.66
<i>ε-resin</i> . . .	81.16 — 81.68	10.54 — 10.43

The lead-salts formed from the first two yielded:

Oxide of lead . . .	^α 26.17 to 26.32	^β 25 to 28
---------------------	-----------------------------	-----------------------

These analyses were perhaps not made with definite substances. The quantities of lead-oxide found in the resinates are nearly the same as in the lead-salts obtained from the turpentine-resins (see TURPENTINE); hence it is probable that the resinous constituents of copal are similar in composition to the resins of turpentine. (Gerh. iii. 669; Handw. d. Chem. ii. [3] 202.)

COPAL VARNISH. Copal may be dissolved by digestion in linseed oil, rendered drying by quicklime, with a heat very little less than sufficient to boil or decompose the oil. This solution, diluted with oil of turpentine, forms a beautiful transparent varnish, which, when properly applied, and slowly dried, is very hard and durable. This varnish is applied to snuff-boxes, tea-boards, and other utensils. It preserves and gives lustre to paintings, and greatly restores the decayed colours of old pictures, by filling up the cracks, and rendering the surfaces capable of reflecting light more uniformly.

Mr. Sheldrake has found, that camphor has a powerful action on copal; for if powdered copal be triturated with a little camphor, it softens, and becomes a coherent mass; and camphor, added either to alcohol or oil of turpentine, renders it a solvent of copal. Half an ounce of camphor is sufficient for a quart of oil of turpentine, which should be of the best quality; and the copal, about the quantity of a large walnut, should be broken into very small pieces, but not reduced to a fine powder. The mixture should be set on a fire so brisk as to make the mixture boil almost immediately; and the vessel should be of tin or other metal, strong, shaped like a wine-bottle with a long neck, and capable of holding two quarts. The mouth is stopped with a cork, in which a notch is cut to prevent the vessel from bursting. It is probably owing to the quantity of camphor it contains, that oil of lavender is a solvent of copal. Camphor and alcohol dissolve copal still more readily than camphor and oil of turpentine.

In the 51st volume of Tilloch's Magazine, Mr. Cornelius Varley states, that a good varnish may be made by pouring upon the purest lumps of copal, reduced to a fine mass in a mortar, colourless spirits of turpentine, to about one-third higher than the copal, and triturating the mixture occasionally in the course of the day. Next morning it may be poured off into a bottle for use. Successive portions of oil of turpentine may thus be worked with the same copal mass. Camphorated oil of turpentine, and oil of spike-lavender, are also recommended as separate solvents, without trituration. The latter, however, though very good for drawings or prints, will not do for varnishing pictures, as it dissolves the paint underneath, and runs down while drying.

Fat varnish.—Take copal 16 parts, linseed or poppy oil made drying with litharge 8, oil of turpentine 16. Melt the copal in a matrass, by exposing it to a moderate heat; pour then upon it the boiling-hot oil; stir the mixture, and when the temperature has fallen to about 200° F. add the oil of turpentine heated. Strain the whole immediately through linen cloth, and keep the varnish in a wide-mouthed bottle. It becomes very clear in a little while, and is almost colourless when well made. This varnish is applied on coaches, also generally on polished iron, brass, copper, and wood.—U.

COPALIN. *Fossil copal, Highgate resin.*—A fossil resin found in roundish lumps in the blue clay of Highgate Hill. It resembles copal resin in hardness, colour, lustre, and transparency, and is likewise but sparingly soluble in alcohol. Sp. gr. 1·010 (Johnston), 1·05 (Bastick). It emits a resinous odour when broken, volatilises in the air at a gentle heat, and burns easily with yellow flame and much smoke. *Sulphuric acid* dissolves it with purple-brown colour. *Nitric acid* converts it into an acid resin, which is precipitated by water as a yellow powder, forms soluble salts with the alkali-metals, insoluble with all the rest. According to Johnston's analysis (Phil. Mag. [3] xiv. 87), it contains 85·4 per cent. carbon, and 11·8 hydrogen, 2·7 oxygen, and 0·13 ash, whence may be deduced the formula $C^{30}H^{18}O$ or $C^{60}H^{36}O_2$. (Johnston, from the old atomic weight of carbon, $C = 6·12$, calculated the formula $C^{10}H^{12}O$.)

Kemgott obtained from India a resin which agreed with the Highgate resin in properties, and had a specific gravity of 1·053; it contained fragments of Alpine plants and insects. An analysis by Duflos showed it to contain 85·73 per cent. carbon, 11·50 hydrogen, and 2·77 oxygen.

Another resin, resembling the preceding in external appearance, occurs in the form of flattened drops or coatings on calespar, on the walls of a dyke of trap at the old lead mine in Northumberland called *Settling Stones*. It has a pale yellow to deep red colour, with pale green opalescence. Sp. gr. 1·16—1·54; hard, but brittle; does not melt at 400° F., but burns in the flame of a candle with empyreumatic odour. It is insoluble in water, and nearly insoluble in alcohol. It contains 85·13 per cent. carbon, 10·85 hydrogen, and 3·26 ash = 99·24, numbers agreeing nearly with the formula C^2H^2 . (Dana, ii. 267.)

COPIAPITE. *Yellow Copperas.*—A hydrated basic ferric sulphate, $2Fe^{2+}O_3 \cdot 5SO_3 + 3HO$, occurring in the district of Copiapo in the province of Coquimbo, in northern Chili, in six-sided tables and grains, which cleave readily parallel to the base. Also fibrous and inerusting. It is translucent, with yellow colour and vitreous lustre. Several other basic ferric sulphates are also found native, viz. *Stypticite* and *Fibroferrite* from Chili, *Pitticite* from Fahlun in Sweden, and *Misy* found near Gesler in the Harz; they are formed by the weathering of iron pyrites, and are probably not definite compounds. (See SULPHATES.)

COPPER. Synonymes: *Kupfer, Cuivre, Cuprum, Venus*. Symbols and Atomic weights: Cu = 31·6 (*cupricum*); Ccu = 73·2 (*cuprosium*.)

Copper has been known from the earliest times, and appears to have been used for weapons, tools, and agricultural implements much earlier than iron. It was indeed much more likely to attract the attention of primitive nations than iron, as it is found naturally in the metallic state, is malleable and ductile immediately after fusion, and acquires considerable hardness when mixed with other metals. Isidorus, who wrote at the beginning of the seventh century, says: "Apud antiquos priore æris quam ferri cognitus usus, ære quippe primi proindebant terram, ære certamina belli gerebant." The Romans, who obtained it from the island of Cyprus, called it *æs cyprum*, a term afterwards shortened into *cuprium*, which ultimately became *cuprum*. The Greeks called it χαλκός, from Chalcis in Eubœa, another locality whence it was obtained. Both the Greek χαλκός and the Roman *æs* appear, however, to have been used indifferently for copper, bronze, and brass. Pliny uses the word *æs* in both senses, as appears from the following passages: "*Æs fit a lapide æroso quem vocant cadmiam,*" which probably refers to brass; and again, "*Fit et ex alio lapide quem chalcitem vocant in Cypro, ubi prima fuit æris inventio,*" where *æs* appears to signify copper.

Occurrence.—Copper occurs very abundantly and in a great variety of forms. It is found in the metallic state; also as oxide, chloride, carbonate, phosphate, sulphate, silicate, arsenate, and vanadate; as sulphide, sometimes alone, but more frequently in combination with the sulphides of other metals, as in copper-pyrites, purple copper, and the several varieties of fahl-ore. It is found to the amount of 0·1 to 0·2 per cent. in many specimens of meteoric iron. According to Walchner (Compt. rend. xxiii. 12), copper is as widely distributed in nature as iron, though less abundantly, small quantities of it being invariably found in iron-ores, in soils, and in ferruginous mineral waters. It has also been found in sea-weed (Malaguti, Durocher, and Sarzeau, Ann. Ch. Phys. [3] xxviii. 129), a fact which proves its existence in sea-water,—in the blood of various *Ascidia* and *Cephalopoda* (Harless, Chem. Gaz. 1848, p. 214), in the blue blood of *Limulus Cyclops* (Genth, Pogg. Ann. xcv. 60), and in very minute quantity in the bodies of animals of higher organisation (Jahresb. d. Chem. 1847–8, pp. 871, 874; 1849, p. 530). According to Odling and Dupré (Guy's Hospital Reports, Oct. 1858), small quantities of copper are constantly found in flour, straw, hay, meat, eggs, cheese, and other articles of food; in the animal organism, it exists in

proportionally large quantity in the liver and the kidneys, while the blood contains only traces of it.

Of the various copper minerals above enumerated, a few only can be regarded as ores of copper, that is to say, as minerals from which the metal can be profitably extracted.

1. *Native copper*.—Metallic copper is not unfrequently found in copper ores, occurring in isolated particles, thin laminae, dendritic pieces, and sometimes in solid blocks. Pieces of ore are sometimes found consisting of a nucleus of metallic copper coated successively with red oxide and with carbonate of copper. Large masses of native copper have been found on the coast of Lake Superior near Kewenaw Point, in veins that intersect the trap and sandstone. Dr. Percy states, on the authority of Professor Brush of Yale College (U. S.), that in 1858, 6000 tons of copper were procured from these deposits; one mass found at Minnesota, weighed 500 tons. Another mass thrown down in 1853 at the North American mine, was 40 feet long, and weighed 200 tons. Native copper is found also in Siberia; in the island of Nalsole, one of the Faroe group; in many of the Cornish mines; near Harlech, North Wales; and in Brazil, Chili, and Peru. The North American native copper contains about $\frac{3}{10}$ per cent. of silver, for the most part intimately mixed with it, but sometimes in visible grains, lumps, or threads. The Chili copper also contains silver, sometimes to the amount of 7 or 8 per cent.

2. *Oxides*.—The *red oxide*, Cu^4O , or Cu^2O , is found in Cornish, South American, and especially in Australian ores. A large vein of it was worked at Chessy in France, but it is now nearly exhausted. When pure it contains 88·78 per cent. of copper.

The *black oxide*, Cu^2O , or CuO , occurs at Kewenaw Point, Lake Superior, forming a vein in conglomerate, from which about 40,000 lbs. of ore have been extracted; but it is now exhausted. The pure oxide contains 79·82 per cent. copper.

3. *Carbonates*.—The *green carbonate* or *malachite*, $\text{Cu}^2\text{CO}^4 + \text{H}^2\text{O}$, or $\text{CuO.CO}^2 + \text{CuO.HO}$, occurs abundantly in many localities, especially in Siberia and in South Australia: the pure mineral contains 57·33 per cent. of copper. The *blue carbonate* or *Azurite*, Cu^3HCO^4 , or $2(\text{CuO.CO}^2) + \text{CuO.HO}$, is found in considerable quantity at Chessy, near Lyons, and has been imported from South Australia in admixture with the green carbonate. When pure it contains 55·16 per cent. of copper.

4. *Sulphides*.—*Vitreous or grey Sulphide of Copper*, Cu^4S , or Cu^2S , occurs frequently in Cornwall. It contains 79·79 per cent. copper, but is generally associated with iron to the amount of 0·5 to 3·33 per cent.

Purple copper.—This term is applied to several minerals consisting of cuprous and ferric sulphides, combined or mixed in various proportions. Rammelsberg divides them into three classes, the first comprising ores containing 56 to 58 per cent. of copper, the second 60 to 64 per cent., and the third 70 per cent. They form valuable ores, and are abundant in Cornwall, Sweden, and many parts of North America. The mineral $3\text{Cu}^4\text{S.Fe}^4\text{S}^3$, or $3\text{Cu}^2\text{S.Fe}^2\text{S}^3$, occurs disseminated in the cupriferous shale of the Mansfeld district of Prussian Saxony, and in Pennsylvania.

Copper pyrites or *Yellow copper ore*, CuFeS , or $\text{Cu}^2\text{S.Fe}^2\text{S}^3$.—Copper 34·8 per cent. This is the most abundant ore of copper, and is found in large quantities in Cornwall and Devonshire, at Fahlun and Åtvidaberg in Sweden, in Cuba, South America, and many parts of the United States. The Cornish mines yield annually from 150,000 to 160,000 tons of this ore, from which 10,000 to 12,000 tons of pure copper are smelted: the Cornish ore is imbedded in quartz; that of Sweden in gneiss.

Fahl-ore, or *True Grey copper ore*.—This term includes a considerable number of minerals consisting of protosulphide of copper combined with the sulphides of antimony and arsenic, the copper being more or less replaced by iron, zinc, silver, and mercury. The copper varies from 30 to 48 per cent., according to the foreign metals present; the mercury varies from 2 to 15 per cent. Fahl-ores not containing silver are the richest in copper, containing 48 per cent.; in the most highly argentiferous ores, on the other hand, some of which contain 31 per cent. silver, the proportion of copper may be as low as 15 per cent.—*Bourbonite* is a sulphantimonite of copper and lead, containing 41·7 per cent. Pb, and 12·7 per cent. Cu, sometimes with a small quantity of iron. These ores occur in numerous localities, and often very abundantly.

Atacamite, the native oxychloride of copper from Peru and Chili, and *chrysocolla*, the native silicate found associated with other copper ores in various localities, are likewise used for the extraction of the metal.

The sulphuretted ores of copper are found in veins traversing the ancient rocks. Near these primitive veins are often found beds of copper ores, evidently arising from decomposition of the mineral in the vein by the action of water. The first change consists in the conversion of the sulphide of copper into sulphate by the oxidating action of the air contained in the water; the sulphate then dissolves, and is carried away by

the water; and when this cupreous solution filters through beds of carbonate of calcium, or remains in the cavities of such calcareous beds, double decomposition takes place, resulting in the formation of sulphate of calcium, which is carried away by the water, and carbonate of copper, which is deposited. If this reaction takes place at a high temperature, oxide of copper is deposited, instead of carbonate; and, if organic substances are present, the copper may be reduced to sulphide or red oxide, or even to the metallic state. This reaction may explain the occurrence of beds of carbonate and oxide of copper so frequently found in the neighbourhood of veins of copper pyrites, and of the small crystals of sulphide of copper, which are found disseminated through certain bituminous schists, as in the Mansfeld district of Prussian Saxony.

Preparation of Metallic Copper.

The processes of copper-smelting vary greatly according to the nature of the ore. The treatment of the oxides and carbonates of copper is comparatively simple, the reduction being effected by melting the ore in contact with charcoal, or other carbonaceous matter, and a siliceous flux. The oxide of copper has, however, a strong tendency to unite with the silica, forming a highly cupriferous slag. To prevent the loss thence arising, it is necessary either to add a strong base, with which the silica may unite in preference to the oxide of copper, or else a quantity of copper pyrites, iron pyrites, or other sulphuretted ore, the sulphur in which may combine with the oxygen, and reduce the copper to the metallic state, thereby preventing it from forming a silicate. The first method is adopted at Chessy, where copper ores, consisting of malachite, azurite, and red oxide, mixed with clay, hydrated oxide of iron, and calamine, are smelted with coke and lime. The second method is practised at the copper works in the Ural, where a mixture of copper ores, consisting of native copper imbedded in quartz and magnetic iron ore, malachite, red and black oxide of copper, &c., and copper pyrites, is smelted in blast furnaces fed with wood. The metal obtained by these operations is an impure copper, called *black copper* (*Schwarzkupfer*, *cuivre noir*), which is purified or refined by processes to be hereafter described.

Sulphuretted copper ores require a much more complicated treatment, depending mainly on the fact that copper has a greater affinity for sulphur, and a less affinity for oxygen, than iron and the other metals with which it is associated. They are first *roasted*, to convert a considerable portion of the sulphides into oxides; then the roasted ore is melted, either in reverberatory or in blast furnaces, with addition of slag and other fluxes, if the ore does not already contain a sufficient proportion of silicates. During this operation, the oxide of copper formed in the roasting is reconverted into sulphide, while the iron which remained in the roasted ore as sulphide, passes to the state of oxide. A slag is then formed, containing the greater part of the iron in the ore, and a sulphide of iron and copper (*coarse metal*, *Rohstein*, *matte cuivreuse*), containing the greater part of the sulphide of copper in the ore, and a much smaller proportion of sulphide of iron. The coarse metal, which may be described as a concentrated copper ore, is now again roasted or calcined, and the roasted product is again fused with the slags of other operations, frequently also with addition of oxidised copper ores, when such are available. This operation yields a second slag, containing a larger proportion of iron, and a second regulus containing a still larger proportion of sulphide of copper than the first: and by repeating these calcining and melting operations, a certain number of times, varying according to the nature of the ore and the construction of the furnaces, a regulus is at length obtained, consisting almost wholly of sulphide of copper. Now when this compound is roasted, with free access of air, the first result is to oxidise both the sulphur and the copper, the sulphur mainly going off as sulphurous acid, so that after a while there remains a mixture of sulphide and oxide of copper, which compounds, at a certain temperature, decompose each other in such a manner as to yield sulphurous acid and metallic copper (*e.g.* $2\text{Cu}^2\text{S} + \text{Cu}^2\text{O} = \text{SO}^2 + \text{Cu}^0$). The product of the operation is a regulus of metallic copper, varying considerably in purity according to the particular series of operations to which it has been subjected, and known as *coarse copper*, *blister copper*, *Schwarzkupfer*, *cuivre noir*, &c. This impure metal is lastly subjected to the *refining* process, which is more or less complicated, according to the degree of purity of the coarse copper.

The several operations of calcining and melting are performed either in reverberatory furnaces, or in blast furnaces similar to those used in the smelting of iron, only not so large. The choice of one or the other form of furnace, is determined by the circumstances of the locality. Where there is abundance of coal, and of good fire-clay for the construction of the furnace, as in the neighbourhood of Swansea in South Wales, reverberatory furnaces are used; but where these conditions are not fulfilled, as in most of the continental localities where copper is smelted, the preference is given to blast furnaces, partly because they are less quickly corroded by the action of the

melted slag, partly because they ensure a more economical consumption of the fuel, and less loss of copper in the slags.

Copper-smelting in Reverberatory Furnaces: Welsh Process.

Copper-smelting has been carried on in the British Isles from very early times. There are records of copper-works in Northumberland, Cumberland, and Yorkshire in the reign of Edward III.; and smelting works were subsequently established in Lancashire, Staffordshire, Gloucestershire, Cornwall, and the neighbourhood of Bristol, in most cases in the neighbourhood of copper mines. At all these old works, blast-furnaces appear to have been used. In the seventeenth century, copper-smelting was extensively carried on at Neath in South Wales; but at present the largest copper-works in Great Britain are at Swansea, a locality eminently adapted for the purpose, not only by the great abundance of coal in its vicinity, but also by its position on the coast, at a short distance from Cornwall and Devonshire, the counties from which the largest quantities of copper ore are obtained, and easily accessible to vessels conveying ore from Spain, South America, Australia, and other parts of the world.

The ores smelted at Swansea may be divided into five classes:

1. Sulphides of copper, mixed with a large proportion of sulphide of iron, and only a very small quantity of oxidised copper-compounds. The gangue is formed of quartz and earthy matters. Proportion of copper from 3 to 15 per cent.

2. Cuprififerous pyrites, similar in composition to the preceding, but containing a larger proportion of copper, viz. 15 to 25 per cent.

3. Cuprififerous pyrites containing very little iron pyrites, or any other substance hurtful to the quality of the copper, but a larger proportion of oxidised copper-compounds.

4. Ores consisting chiefly of oxidised copper-compounds, mixed with copper pyrites and purple copper. Gangue quartzose. Proportion of copper 25 to 45 per cent.

5. Very rich oxidised copper ores, free from sulphides and injurious substances; they contain from 60 to 80 per cent. of copper, in the metallic state, and as oxide and carbonate. These choice ores come principally from Chili.

The facility with which the reduction is effected, as well as the quality of the metal produced, depends in great measure on the judicious admixture of these several varieties of ore. When a plentiful supply of oxides or carbonates can be obtained to mix with the sulphides at a certain stage, the number of operations from the first calcination to the refining may be reduced to six; but when only sulphurous ores are at hand, eight, or even ten or twelve operations may be required. The following is an outline of the process, as carried on under the most favourable circumstances.

1. *Calcination.*—The process is commenced with ores of the first-class, consisting essentially of the sulphides of copper and iron. They are calcined in a large reverberatory furnace, called the calciner, of which *fig. 132* represents a horizontal section, and *fig. 131* a vertical section through the line X Y of the plan. The hearth of the furnace is formed of fire-brick, and is either square, as represented in the figure, or more frequently oblong, about 20 feet by 12 feet being usual dimensions. The vault descends rapidly from the end above the fire-place F, to the opposite end R, where the gases enter the tall chimney. The furnace is charged with from 3 to 3½ tons of ore, by the east-iron hoppers T, the charge being uniformly spread over the hearth by means of long iron tools called *stirring rabbles*, introduced by the side doors *p*, which are four or six in number, according to the length of the furnace. The projections between these doors serve to prevent the charge from getting heaped up in the intervening space, a position from which it could only be removed by stirring from the opposite side. The fuel used is anthracite mixed with ¼ of its weight of bituminous coal, to make it cake together and form a mass of a due degree of porosity. The air passing upwards through this heated mass of carbon, its oxygen is completely converted into carbonic oxide, which, together with the nitrogen, passes on through the body of the furnace, and burns at the expense of the air, which enters by the aperture *o* (*fig. 132*), situated near the fire-bridge, and by smaller apertures in the side doors; the vault of the furnace thus becomes filled with a long flame of carbonic oxide, burning in contact with the stratum of air containing excess of oxygen, which enters by the apertures above-mentioned, and spreads itself over the hearth. The ore on the hearth is thus constantly immersed in a stratum of oxidising gas, kept at a high temperature by the combustion of the carbonic oxide just above it. A considerable portion of the sulphur in the ore is thus converted into sulphurous acid, which escapes by the chimney, the copper and the iron being at the same time partially converted into oxides. The calcination lasts from 12 to 24 hours, the charge being stirred from time to time to expose a fresh surface to the oxidising atmosphere, and the heat regulated so as not to permit the particles to clot or sinter together, the tendency to which diminishes, how-

ever, as the calcination proceeds. When the calcination is completed, the ore is raked into the holes, *r r*, on the sides of the hearth, through which it falls into the vault *U* below, where water is thrown upon it.

Fig. 131.

Fig. 132.

An idea of the change which takes place in the calcining process, may be gathered from the following analyses of samples of raw and calcined ore, by Le Play. (*Description des procédés métallurgiques employés dans le Pays de Galles pour la fabrication du Cuivre*. Paris, 1848.)

Raw ore.		Calcined ore.	
Cuprous oxide, Cu_2O	0.4		5.4
Copper pyrites	22.7		11.2
Iron pyrites, FeS	22.4	Sesquisulphide of iron (Fe^3S_3)	11.2
Various sulphides	1.0		0.6
Sesquioxide of iron	0.6		11.7
Various oxides	0.3		0.6
Silica	34.3		34.3
Earthy ashes	2.0		2.0
Water and carbonic acid in combination	0.5	Sulphuric acid combined	1.1
	84.2		78.1
Atmospheric oxygen consumed by this amount of ore in the calcination	15.8	Evolved as gas. {	Water and carbonic acid 0.5 Sulphurous acid. 21.4
	100.0		100.0

The loss of weight which occurred during calcination, was found to be 7.2 per cent. and the loss of sulphur 51.9 per cent. of the total in the ore.

2. *Melting of the calcined ore.*—This process is performed in a reverberatory furnace, called the ore-furnace, represented in figures 133, 134.

The fuel is a mixture of 2 pts. anthracite and 1 pt. bituminous coal. The temperature

is raised higher than in the calcining furnace, by increasing the draught. The hearth is formed of slag, and has a depressed basin at B, into which the melted metal sinks. The charge consists of the calcined product of the preceding operation mixed with *metal slag*, a product obtained in operation No. 4, and sometimes with unroasted ore of the third class (p. 24), and a certain quantity of fluor spar to render the slag more fluid. The oxides and sulphides decompose one another, the products being chiefly sulphide of copper, oxide of iron, which passes into the slag as silicate, and sulphurous acid, which escapes, the oxidation of the sulphur being also partly due, as in the preceding operation, to the action of the air in the furnace. The process is completed in four or five hours. The products consist of a regulus, called *coarse metal*, containing the greater part of the copper as sulphide and a certain quantity of sulphide of iron, and a slag rich in iron and containing numerous siliceous fragments disseminated through it, which give it a muddy consistence. This slag is raked out of the furnace by a rabble introduced through the door *p*, and falls into a series of

Fig. 133.

Fig. 134.

rectangular cavities *U*, formed in a bed of sand. At the same time, the melted coarse metal collected in the basin *B*, is run out by a tap-hole at the bottom into a reservoir *R*, containing water, whereby it is granulated.

The *coarse metal* contains about 33 per cent. of copper. It is brittle, and easily pulverised: its fractured surface is non-crystalline, uneven, more or less granular, generally vesicular, and of a bronze colour. The following analyses have been made of it by Leplay and by Napier,

Composition of Coarse Metal.

	Lepay (mean).		Napier.
Copper	33·7	Copper	21·1—39·5
Iron	33·6	Iron	33·2—36·4
Nickel, cobalt, manganese	1·0		
Tin	0·7		
Arsenic	0·3		
Sulphur	29·2	Sulphur	45·5—25·0
Slag mechanically mixed	1·1		
	<hr/> 99·6		

The slag, called *ore-furnace slag*, generally consists of a hard, brittle, black matrix, in which are imbedded sharp angular pieces of white quartz. It frequently contains small shots of coarse metal. If these are numerous, the slag must be remelted in subsequent operations. Its average composition, as determined by Lepay, is as follows:—

Composition of Ore-furnace Slag.

Quartz in admixture	30·5
Silica in combination	30·0
Alumina	2·9
Protoxide of iron	28·5
Lime	2·0
Magnesia	0·6
Various oxides (of tin, manganese, nickel, and cobalt)	1·4
Fluorine	1·0
Calcium	1·1
Copper	0·5
Iron	0·9
Sulphur	0·6
	<hr/> 100·0

This slag has nearly the composition of a ferrous metasilicate, Fe^2SiO_3 or $2\text{FeO} \cdot \text{SiO}_2$.

It appears, then, that in the melting process in the ore-furnace, a considerable portion of the iron of the calcined ore is removed in the slag, and the whole of the copper, excepting the small portion which passes into the slag, is concentrated in a regulus containing, on the average, as much copper as pure copper pyrites (p. 22). The reduction of the sesquioxide of iron in the calcined ore to protoxide is due to the action of the sulphur, which is oxidised to sulphurous acid at the expense of the ferric oxide. Any copper that may exist in the state of silicate in the *metal slag*, forming part of the charge of the ore-furnace, is converted into cuprous sulphide by mutual decomposition with the sulphide of iron, which is always present in this furnace, and passes into the coarse metal.

3. *Calcination of the granulated coarse metal.*—This operation is performed in a calciner, with free access of air, the charge being frequently stirred and turned over. The calcination is complete in about 24 hours, the heat being gradually raised towards the end of the process. No satisfactory analysis of the calcined product has yet been made. Lepay, however, found that, in a sample of coarse metal containing 33·7 per cent. copper, 34·2 iron, 1·5 of various other metals, 29·5 sulphur, and 1·1 slag, the proportion of sulphur was reduced by calcination to 16·4 per cent. The sulphur is evolved as sulphurous and sulphuric acids.

4. *Melting of the calcined coarse metal.*—The calcined product No. 3 is melted with addition of matters rich in oxide of copper, namely, *roaster* and *refinery slags*, and a quantity of ores of the fourth class (p. 24), consisting of oxides and carbonates of copper. The furnace is similar to the ore-furnace (*fig. 133*), excepting that the hearth has no basin. The process is conducted in a similar manner, excepting that it is continued two hours longer, and the heat is raised higher. The reaction consists mainly in a double decomposition between the sulphide of iron and oxide of copper, whereby oxide of iron is formed, which passes into the slag as silicate, and sulphide of copper, which forms the regulus; very little sulphurous acid is evolved. The slag is skimmed off, and drawn out of the furnace through the end opening below, where sand-beds are placed to receive it. The regulus is tapped off into sand-moulds immediately in front of and below the tap-hole of the furnace.

The composition of the regulus produced in this operation, varies with the proportion

of oxide of copper mixed with the calcined coarse metal. When a sufficient quantity of oxide and carbonate can be added to decompose the whole of the sulphide of iron present, the regulus has very nearly the composition of cuprous sulphide, Cu_2S , the decomposition taking place as represented by the equation —

The regulus formed under these circumstances is called *white metal*. It has a dark bluish grey colour, and faint metallic lustre, is compact and brittle, with uneven, granular, and more or less crystalline fracture. It contains on the average 73.2 per cent. copper. A sample analysed by Leplay, of specific gravity 5.70, contained 77.4 per cent. copper, 0.7 iron, with traces of nickel and cobalt, 0.1 tin and arsenic, 21.0 sulphur, and 0.3 slag and sand. Pure cuprous sulphide contains 80 per cent. copper. (See SULPHIDES OF COPPER AND IRON, ii. 77).

The slag, called *metal-slag*, is brittle, compact, and occasionally very crystalline, of blue-grey to bronze yellow colour, and inclining to metallic lustre. An analysis by Leplay gave:

Silica	33.8	Magnesia	0.3
Alumina	1.5	Slag mechan- { Copper	2.9
Protoxide of iron	56.0	ically mixed. { Iron	0.3
Cuprous oxide	0.9	{ Sulphur	0.8
Various oxides	2.1		
Lime	1.4		100.0

If the proportion of oxidised copper-compounds in the charge is less than what is required for producing white-metal of the composition above given, the regulus will contain a considerable quantity of iron, constituting, from its colour, what is called *blue metal*; white-metal indeed passes insensibly into blue metal as the proportion of iron increases.

Blue metal always contains metallic copper diffused through it in very minute particles, and protruding into the interior of cavities in the mass, in delicate hair-like filaments. The manner in which this metallic copper is formed is not very clearly understood; but the reduction appears to take place during cooling, and to depend upon a reaction between the sulphide of copper in the regulus and the oxides in the slag. When the oxidised copper-compounds in the charge are in excess, some of the copper is likewise reduced, and a regulus is formed similar for the most part, in composition, colour, and properties, to white metal, but exhibiting on its upper surface numerous pimple-like excrescences, whence it is called *pimple-metal*.

5. *Roasting of the White or Blue metal*.—In this operation, the sulphur, which had hitherto been retained in union with the copper as an agent of concentration, is finally expelled in the form of sulphurous acid, and at the same time certain foreign metals, namely, arsenic, antimony, iron, cobalt, nickel, tin, &c., are removed, by conversion either into volatile oxides, or into silicates, which pass into the slag. The process consists of two successive reactions, which take place in the same furnace: 1. The direct action of the air on the metal kept at a temperature near its melting point; 2. The reaction of the oxide of copper thus formed on the sulphides not decomposed by the roasting, whereby sulphurous acid is evolved, and copper reduced to the metallic state. The metallic copper thus obtained is called *blister copper*, from the appearance of its surface. There is also formed a slag very rich in copper, called *roaster-slag*, which is added to the furnace-charge in the smelting of the calcined granulated coarse metal (No. 4).

The operation is performed in a reverberatory furnace similar to the melting furnace (*fig.* 133), but having a side door by which the pigs of regulus are introduced: and lateral openings near the fire-bridge for the admission of air. The rich oxidised ores of class 5 (ii. 24) are added to the charge. In half an hour, the pigs begin to melt, and the temperature is so regulated that the fusion may be complete in six or eight hours. The surface of the melted mass appears to boil, owing to the escape of sulphurous acid, produced by the mutual decomposition of the oxides and sulphides. The slag which forms on the surface of the melted regulus, is skimmed off twice during the operation, once immediately after fusion, and a second time just before tapping. After a while, the temperature of the furnace is lowered sufficiently to allow the regulus to solidify. When it has become pasty, its surface is thrown up into craters, in consequence of the continued evolution of gas, whereby the extent of surface exposed to the air is greatly increased and the oxidation assisted. Finally, the regulus is again melted into sand-moulds, where it solidifies in the form of *blister copper*.

The following are analyses of blister copper and roaster slag.

<i>Blister copper.</i>	<i>Leplay.</i>	<i>Napier.</i>		
Copper	98.4	97.5	98.0	98.5
Iron	0.7	0.7	0.5	0.8
Nickel, cobalt, manganese	0.3	1.0	0.7	0.0
Tin and arsenic	0.4	0.2	0.3	0.1
Sulphur	0.2	0.6	0.5	0.6
	100.0	100.0	100.0	100.0

<i>Roaster slag.</i>	<i>Leplay.</i>
Silica	47.5

Ferrous oxide	28.0
Oxides of nickel, cobalt, manganese	0.9
Stannous oxide	0.3
Lime and magnesia	traces
Metallic copper	2.0
	98.6

According to Leplay, roaster-slag contains on an average 20 per cent. of copper, inclusive of that present in the metallic state. It is vesicular, more or less scoriaceous, of dark reddish-brown colour, varied here and there with greyish black, and without metallic lustre.

6. *Refining.*—This is the last operation, and its object is to remove the foreign metals and the remainder of the sulphur. The reagents by which this change is effected are, the oxygen of the air, and the siliceous matters of the hearth and walls of the furnace, together with those which are furnished by the sand adhering to the pigs of blistered copper. The refinery furnace is similar in construction to a melting furnace, excepting that the bottom inclines gradually from all sides towards the deepest part, which is near the end door, and there is a large door on one side, but neither a hole in the roof nor a side tap-hole. The furnace is charged with 6 or 8 tons of pigs of blistered copper, which are melted and exposed for about 15 hours, to the oxidising action of the air which enters the furnace. The oxide of copper formed, acts either immediately, or after combining with silica, on the sulphur and metals more oxidable than the copper, thereby oxidising and causing them to pass into the slag, together with the excess of oxide of copper. The slag is skimmed off through the end opening.

The copper, thus freed from foreign metals and sulphur, is, however, in a peculiar state, being intimately mixed with a considerable quantity of red oxide, which destroys its malleability; in this state it is called *dry copper*. To deoxidise and *toughen* it, a quantity of anthracite, or free-burning coal—charcoal was formerly used—is thrown on the surface, and after a short time, a large pole of oak or birch, the greener the better, is thrust into it, and kept down by fixing a prop under the end which protrudes from the furnace. Under the influence of the high temperature, the wood gives off a large quantity of reducing gases, which cause the metal to boil violently, carrying the particles of carbon below its surface, and greatly accelerating the reducing action. After twenty minutes of this treatment, which is called *poling*, the refiner takes out a sample of the melted metal in a small ingot-mould, and when the ingot is cold, places it on an anvil, and tests its quality by hammering. As soon as it is found to possess the characters of good metal (*tough pitch*), the surface is again skimmed as fast as possible, and the metal ladled out into moulds. Should the metal, during the process of lading, become more or less *dry* by oxidation, it is again poled for a short time. If, on the contrary, the poling has been continued too long, the copper again becomes brittle, probably because the oxides of certain other metals, lead, antimony, &c. present in small quantity, are reduced by the poling, and the copper consequently becomes alloyed with these metals; in this state it is said to be *overpoled*. To remedy this defect, the surface is uncovered, and exposed for a short time to oxidation. When the copper is intended for rolling, a certain quantity of lead may be advantageously added to it just before lading. The proportion used is very variable, sometimes as much as 80 lbs. of lead to 6 tons of copper, sometimes not more than 14 to 30 lbs.

The *refinery-slag* is very rich in copper. A specimen analysed by Leplay contained:

Silica	47.4	Stannous oxide	0.2
Alumina	2.0	Lime	1.0
Cuprous oxide	36.2	Magnesia	0.2
Ferrous oxide	3.1	Shots of metallic copper	9.0
Oxides of nickel, manganese, &c.	0.4		99.5

A specimen examined by Dr. Percy contained 57.9 per cent. copper existing as cuprous oxide, and 2.65 metallic copper; making a total of 60.55 per cent. copper.

It has already been observed, that when a plentiful supply of rich oxidised ores cannot be obtained, the calcinations and fusions have to be repeated a greater number of times: thus, instead of at once subjecting the white or blue metal resulting from the melting of the calcined coarse metal to the process of *roasting* (as above described), it is necessary, under such circumstances, to calcine it again, and subject the calcined product to an additional melting before commencing the roasting.

The *metal-slag* (No. 4), and likewise the *ore-furnace slag* when it contains numerous shots of regulus, are sometimes remelted in order to concentrate the regulus which they contain.

Lastly, we must notice the process of making what is called "best selected copper," which is merely a very pure metal used for fine purposes, especially for making the best brass. The process consists in melting one of the numerous varieties of *blue metal*, and tapping it into a series of moulds or sand-beds. The pigs nearest to the furnace then contain the greater portion of the metallic impurities, while those more remote contain a purer regulus, which is then roasted and refined. Another method is to roast the blue metal, or *pimple metal*, till about half the copper is reduced. The residual metal, called *regule*, *best regule*, or *spongy regule*, is afterwards roasted and refined by itself.

Copper Smelting in Blast Furnaces.

This is the method chiefly adopted on the continent of Europe, as in Sweden and in Germany.

Swedish process.—The Swedish copper ores, the principal mines of which are at Falun, in Dalecarlia, and Åtridaberg, in Ostrogothia, consist of copper pyrites mixed with a large amount of iron pyrites and siliceous minerals.

1. *Roasting or Calcination.*—The ore is first *roasted* either in kilns formed by walls

Fig. 135.

built in the manner shown in *fig. 135*, or in open pyramidal heaps, most frequently the latter. In either case, a bed of wood about 12 inches high is formed on the ground, and on this the ore is piled in alternate layers with small charcoal, to the height of 2 or 3 feet in the kilns, and 10 or 12 feet in the heaps. By this means, a large portion of the sulphur is burnt away, while the iron is chiefly oxidised, as in the Welsh

process of calcination. The roasted ore should retain sufficient sulphur to furnish, when smelted, a regulus yielding from 20 to 30 per cent. of copper.

2. *Fusion of the roasted ore.*—The roasted ore is next mixed with *black copper slag* a product obtained in the fourth operation, and containing a large amount of iron. The proportions should be so adjusted as to yield, when smelted, a regulus containing from 20 to 30 per cent. of copper, and a slag having nearly the composition Fe^2SiO^3 , or $3\text{FeO} \cdot 2\text{SiO}^3$, which is found to possess the proper degree of liquidity. The mixture of ore and black copper slag is smelted with coke, or a mixture of coke and charcoal in a cupola (*Schacht-ofen*), called the *ore-furnace*, about 18 feet high, the fire being urged by a blast. The regulus obtained is a mixture or compound of the subsulphides of copper and iron.

3. *Roasting of the regulus.*—The regulus is next roasted in a range of kilns constructed on each side of a medium wall in the manner represented in *fig. 135*. The roasting is repeated four, five, or even six times. When the first firing is finished, the regulus is transferred to the next kiln, then to the next, and so on till it is roasted "dead" or "sweet." No charcoal is added in the first firing, but in the second $1\frac{1}{2}$ measure of charcoal is spread upon the wood, and the quantity is increased in each successive firing, till, in the sixth, 12 measures of charcoal are added, forming three layers, including that on the wood. The entire roasting generally lasts from seven to eight weeks. During the roasting, oxide of zinc is formed from sulphide contained in the regulus.

Fusion for black copper.—The roasted regulus from the last operation is next smelted in the *black copper furnace*, which is also a cupola, but of smaller dimensions than the ore-furnace, in admixture with a roasted regulus (*thin regulus*) obtained in preceding operations, also with *refinery slags*, furnace-residues containing copper, and *ore-furnace slags*, sometimes also with addition of quartz. The products are *black copper* (*Schwartzkupfer*), an impure metallic copper, so-called from its superficial crust

of black oxide; *thin regulus*, containing from 55 to 72 per cent. of copper; and *black copper slag*, chiefly consisting of silicate of iron, but containing about 1 per cent. of copper. This slag is added to the charge of the ore-furnace in a subsequent operation, and the thin regulus is remelted in a subsequent fusion for black copper.

The black copper has lastly to be *refined*, to free it from sulphur and foreign metals. This is effected, as in the Welsh process, by melting it under a layer of charcoal, and subjecting it at the same time to the action of a current of air. The arrangements are similar to those used in Germany, which will be presently described.

The following are analyses of the *black* and *refined copper* of Ätvidaberg, made at the mining school of Fahlun:—

	Black copper.	Refined copper.
Copper	94.39	99.460
Iron	2.04	0.111
Zinc	1.55	—
Cobalt and nickel	0.63	0.110
Tin	0.07	scarcely a trace
Lead	0.19	ditto.
Silver	0.11	0.065
Gold	not looked for	0.0015
Sulphur	0.80	0.017
Arsenic	trace	
	99.78	99.7645

The greater part of the cobalt is separated in the refining, and becomes concentrated in the slag.

Mansfeld process.—The copper ore of the Mansfeld district in Prussian Saxony consists of argillaceous schists (*Kupfer-schiefer*), largely impregnated with bitumen, and containing copper pyrites disseminated in small crystals. The schist is first roasted in

Fig. 136.

Fig. 137.

pyramidal heaps on beds of wood. Very little fuel is required, the fire being kept up by the combustion of the bitumen contained in the schist. The roasted ore is then mixed with from 5 to 8 per cent. of fluor spar, cupriferous slag from subsequent stages of preceding operations, and often with small quantities of cupriferous schists containing carbonate of lime. This mixture is smelted in cupolas from 15 to 20 feet high, heated with coke. Fig. 136 is a vertical section of the furnace, passing through one of the *tuyeres*. Fig. 137 is a front view, with a section of the lower part of the shaft. This lower part of the crucible is formed of siliceous grit, the upper part of brick. The furnace (the ore-furnace) has two *tuyeres* *tt*,

placed either on the same side of the shaft (as in the figure), or on opposite sides. At the bottom of the crucible are two apertures, *o o'*, which are opened alternately to allow the fused products to run into the basins *C C'*. The furnace is filled with ore and fuel in alternate layers. The regulus and slag are constantly running from the furnace into one or other of the basins *C C'*. The slag is moulded into large bricks, which serve for building. The regulus (*Rohstein*), which does not amount to more than $\frac{1}{10}$ of the weight of the roasted ore, is composed of cuprous sulphide, Cu_2S , and ferrous sulphide, FeS , and contains from 20 to 60 per cent. of copper, according to the nature of the ore. The poorer kinds of regulus containing from 20 to 30 per cent. of copper are roasted three times on beds of wood, and again smelted with slags from preceding operations, those being selected which lay immediately above the regulus in the basins *C C'*. A new regulus (*Spurstein*) is thus obtained, containing as large a proportion of copper as the first regulus of the richer ores.

The richer reguli (*Spurstein* and *Dünnstein*) are roasted six times in succession on beds of wood in kilns,—brick-walled kilns like those represented in *fig. 135* (p. 30). During the roasting a considerable quantity of sulphate of copper is formed, which is removed by lixiviation and crystallised.

The roasted and lixivated regulus (*Gaarrost*) is now smelted with a due proportion of slag in a blast furnace, similar to that represented in *fig. 136*, but smaller. The products are *black copper*, a rich regulus (*Dünnstein*), which is added to the second regulus obtained in the preceding operation, and slag. The black copper is removed in the form of discs, by throwing water on the surface so as to form a solid crust. It contains about 95 per cent. of copper, 3 or 4 per cent. of iron, and small quantities of silver and antimony.

The quantity of silver in the black copper is generally sufficient to render its extraction profitable. This is effected by a process called *eliquation*, depending on the fact that lead forms with silver a more fusible alloy than with copper. The argentiferous copper is melted with lead (argentiferous lead, if it can be had), and the melted alloy is either suffered to cool very slowly, in which case the copper solidifies first in combination with a portion of the lead, while the rest of the lead, in combination with nearly the whole of the silver, remains liquid, or the whole of the fused mass is cast into discs, which are then subjected to a gradually increasing heat, the effect of which is to melt out the silver in combination with part of the lead, while an alloy of lead and copper remains in the solid state. The argentiferous lead is then cupelled to separate the silver. (See SILVER.)

The alloy of lead and copper thus obtained, still, however, retains a small portion of silver, which is sometimes separated from it by subjecting it to a higher temperature

in contact with a current of air, whereby a fresh portion of lead containing silver is separated, not, however, in the metallic state, but in the form of litharge.

Refining.—The black copper thus desilverised is refined in a reverberatory furnace constructed like a cupelling furnace.

The metal is fused on the hearth *a*, *fig. 138*, and subjected to the oxidising action of a blast of air from the tuyeres *n*, *fig. 139*. A red slag is then formed containing the foreign metals, iron, lead, &c., and a considerable quantity of cuprous oxide; it is removed from time to time by the door *p*. The refiner judges of the progress of the

operation by taking out from time to time, a small quantity of the melted metal, and examining it in the manner to be presently described. When the process is finished, the melted copper is run off into the basins *h h*, and a little water is poured

upon it to form a crust on the surface, which is then taken off in the form of a disc called a *rosette*.

When the black copper does not contain silver, it is not subjected to the eliquation pro-

Fig. 139.

cess, but is immediately refined, in a small furnace, called a *refining hearth*, of which *fig. 140* is a vertical section and *fig. 141* is a perspective view.

It consists of a hemispherical crucible C, about 2 or 2½ feet in diameter, and 15 to 18 inches deep, and made of English fire-clay mixed with sand, and well beaten down. It is surrounded by a raised platform, having an opening A, which can be closed by a door.

Fig. 140.

Fig. 141.

The crucible having been dried by filling it with lighted charcoal, fresh charcoal is added, the pigs or discs of black copper are placed on the charcoal opposite to the tuyere T, and the blast is turned on. As soon as this portion of copper is melted, more is added, care being also taken to keep the crucible full of charcoal. A channel *i i*, allows the slag produced during the refining process to run off. As the oxidation proceeds, sulphurous acid is given off, sometimes accompanied by white vapours of oxide of antimony. The first portions of slag which run off are of a greenish colour, and contain much oxide of iron; the subsequent portions are of a dark red colour, and are rich in copper. To judge of the progress of the operation, the refiner from time to time dips a cylindrical iron rod into the melted copper, then quickly withdraws it, cools it by immersion in cold water, knocks off the hollow cylinder of copper adhering to the end, and examines it. If it is thick, smooth on the outer surface, and yellowish-red inside, the copper is "too young," and must be further exposed to the action of the blast. When it becomes thin, brownish-red, and crinkled on the outer surface, of a pure copper-red in the interior, with metallic lustre, and may be bent several times without breaking, the copper may be regarded as refined, or nearly so. When it becomes so thin as no longer to form a continuous coating, but merely to surround the iron in some places like network, and in others to present the appearance of small pointed or

bearded excrescences, the blast should be immediately stopped, as the copper is over-refined or "übergaar."

When the refining is judged to be complete, the copper is taken out in *rosettes* in the manner above described.

Toughening (Hammergaarmachen).—Rosette copper, though tolerably pure, is not very malleable, because it contains a considerable quantity of red oxide; in fact, it is in the state called "dry" by English smelters. It is sold for the manufacture of brass, and other purposes in which it requires to be melted up again. To convert it into malleable copper, it is again melted on a refining hearth, under charcoal, but with the tuyere less inclined than in the preceding process, so that the oxidising action of the blast may not be so strong. There is nothing peculiar in the process, excepting that it must be done with great care, so as just to reduce the oxide by the action of the red-hot charcoal, without bringing it into the *over-refined* state, like the over-poled copper of the English works (p. 29). The refiner takes out a sample now and then, and tests its qualities by hammering. Altogether the refining and toughening of the black copper is a more tedious process than that of the English *blister copper* (p. 29.) because the black copper is less pure than the latter.

The following analytical data in elucidation of the Mansfeld process are taken from *Percy's Metallurgy*:—

Rivot and Phillips's Method of Copper Smelting.

This method consists in completing the extraction of the copper by means of metallic iron, after the greater part has been separated by the ordinary process of reduction with coal or charcoal. Napier (Dingl. pol. J. xxvii. 293) had shown that copper may be precipitated from fused silicates containing it, by the action of the electric current, the mineral being fused in a black-lead crucible connected with the positive pole of the battery, and the negative pole being formed of an iron plate dipping into the fused mass. It was afterwards found, by numerous experiments made at the *École des Mines* in Paris, that metallic iron alone, without the aid of the battery, is capable of precipitating copper from silicates in a state of fusion, just as it does from

* With other metals.

saline solutions at ordinary temperatures. In applying this method to practice, however, it was found that the expenditure of iron would be too heavy; hence the modification above noticed was adopted, of only using the iron to complete the reduction. The process is as follows: The ore is pounded, roasted in the calcining furnace, and then heated till all the sulphates are decomposed; by this means nearly all the sulphur is expelled. The roasted ore is then fused with lime and non-bituminous coal. The fusion, which must be quickly conducted, yields two products, viz. reduced copper at the bottom, and a fused mass of slag or silicate (called the *bath*) floating on the top; this contains the remainder of the copper, usually from 2 to 2½ pts. in a thousand (? in a hundred). This residual portion of copper is precipitated by the immersion of iron bars into the melted slag: the reduction occupies from three to four hours for a charge of 5 ctr. The slag, after this treatment, still retains from 0·005 to 0·0065 copper; the copper yielded by it is also contaminated with 0·004 iron and sulphur, and still requires refining. The estimated saving by this process, as compared with the ordinary method under given circumstances, is about 17 per cent. (Jahresb. d. Chem. i. 1921.)

Extraction of Copper in the Wet Way: CEMENTATION COPPER.

This method consists in precipitating copper from solution by metallic iron. It is not much practised, being economical only under peculiar circumstances. The drainage-water of mines in which the copper exists as sulphide, often contains sulphate of copper formed by oxidation of the pyrites. Solutions of copper are also prepared artificially by treating the poorer oxidised ores with sulphuric or hydrochloric acid, or by roasting pyritiferous ores, and extracting the sulphate by lixiviation (p. 32). Dr. Richardson, of Newcastle, exposes a mixture of pulverised copper pyrites and chloride of sodium or potassium, occasionally moistened with water (or salt-water may be directly used) to a temperature not lower than 80° F.; the copper is thereby converted into chloride, which is lixiviated with water. Ammonia has also been proposed as a solvent for extracting oxide of copper from the ores.

The precipitation is best effected by wrought iron; cast iron acts more slowly. The precipitation is accelerated by agitation, which has the effect of loosening a basic iron-salt which adheres to the surface of the metal, thereby exposing a fresh surface. The precipitated copper (*cementation copper*) is then melted and refined. This method is well adapted to the treatment of the poorer oxidised ores, like those of Twista in the Waldeck, especially where fuel is scarce.

According to Gaultier de Claubry and Dechaud, the process may be accelerated and the consumption of iron diminished [? at the expense of zinc] by the use of a voltaic battery, the copper being likewise obtained in more coherent form. Copper is sometimes precipitated from its solutions in the metallic state without the use of iron, probably because the solution contains a cuprous salt, which splits up into a cupric salt and metallic copper.

The precipitation of copper from the solutions of its pure salts by electrolysis, as in the electrolytic process, yields the metal in its state of greatest purity.

For further details on the metallurgy of copper, see *Percy's Metallurgy*, i. 289; *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 818; *Kerl's Hüttenkunde*, ii. 158; *Regnault's Cours de Chimie*, iii. 281.

Impurities in Commercial Copper.

A careful investigation of the nature and amount of the metallic impurities in numerous varieties of commercial copper, from various sources, has lately been made by Messrs. A bel and Field (Chem. Soc. J. xiv. 280), the general results of which are as follows:—

1. *Arsenic and silver* are almost invariable impurities in copper.
2. The occurrence of *bismuth* in copper is very general; this metal appears, indeed, to be always present, excepting when carbonates of copper have been used in the production of the metal, as in the Australian and Russian coppers. Field has shown (*ibid.* p. 304) that bismuth is of very common occurrence in copper minerals.
3. *Antimony* is not of so frequent occurrence in copper as is generally supposed; the bismuth existing in copper has doubtless often been mistaken for antimony, both these metals being precipitated by water from their acid solutions.
4. *Lead* is of very rare occurrence in cake-copper, but appears to be an almost invariable constituent of copper which has been manufactured into sheet or rod.
5. *Iron*, which, like sulphur, exists in considerable proportions in unrefined copper, is almost completely removed by the refining process.

The special results of the investigation are given in the following table:—

Metallic impurities in different varieties of Copper.

Copper rolled into thin ribbon	0·03

Physical Properties of Metallic Copper.

Native copper forms crystals belonging to the regular system, viz. cubes, octahedrons, rhombic dodecahedrons, and intermediate forms. Similar forms are exhibited by copper crystallised from fusion. When a dilute solution of copper is left for some time in contact with wood, the copper is sometimes deposited from the liquid in cubes, octahedrons, and long four-sided prisms (elongated cubes), acumined with four octahedral faces resting on the edges (Wagner, Schw. J. xlvii. 325). In other cases, wood precipitates copper in thin ductile plates, with warty surfaces.

Copper in the massive state is very hard and elastic, and strongly sonorous. It has considerable toughness, and may be beaten out into very thin leaves, and drawn out into very fine wire. It is hardened by hammering or wire-drawing, but may be softened or annealed by heating it to redness, and either leaving it to cool slowly, or plunging it into cold water. Its fracture is red, shining, indented, and slightly granular; after hammering, it exhibits a fibrous fracture, with a light-red, silky radiance. The greater the purity of the copper, the greater is its malleability, and generally speaking its softness, and the less heat is required to deprive it of the brittleness produced by heating. Copper contaminated with other metals exhibits, not an indented, but a scaly, granular fracture, with but little lustre, and after hammering, a scaly, dingy red fracture, also with feeble lustre. (For the *Tenacity* of copper, see COHESION, i. 1076.)

The *specific gravity* of copper free from internal cavities varies from about 8·91 to 8·95. According to Marchand and Scheerer (J. pr. Chem. xxvii. 193), that of crystallised native copper is 8·94; of electrotype copper, 8·914; of pure copper after fusion under a layer of common salt, 8·921; of unignited copper wire, from 8·939 to 8·949; of ignited wire, 8·930; of flattened wire, 8·951; of copper plate formed by rolling and afterwards hammered, 8·952. Copper when cooled from fusion in contact with the air is very apt to assume a vesicular structure, by which its density is greatly diminished. This *vesicular structure* was formerly attributed to a cause similar to that of the "spitting" of silver, the copper being supposed to absorb oxygen while in the melted state, and to give it up again in cooling; but it has been shown by Dick (Phil. Mag. [4] xi. 409), and recently more completely demonstrated by Matthiessen and Russell (*ibid.* Feb. 1862), that the vesicular structure is produced only when the copper is melted under charcoal, and air or oxygen gas likewise has access to it,—and that the effect is due to the

formation of cuprous oxide, and its subsequent reduction by the charcoal, whereby carbonic oxide is produced, and, endeavouring to escape as the melted metal is about to solidify, forms cavities within it, and sometimes throws up the surface in vegetations. Copper, fused with free access of air and then cast in an atmosphere of coal gas, exhibited the same cavernous structure, the specific gravity of two portions thus cast being only 6.926 and 6.438, whereas two portions of the same fused metal cast in air had the specific gravities 8.618 and 8.665. Again, copper fused and left to cool under charcoal had a specific gravity of 8.952; the same cast in coal-gas, 8.929, whereas another portion of the same cast in air had a specific gravity of only 6.193.

Sulphur acts in the same manner as charcoal. The density of vesicular copper is greatly increased by hammering, but that of copper not possessing the vesicular structure is but little increased even by very powerful pressure. Marchand and Scheerer found that the density of copper fused under common salt was increased by a pressure of 300,000 lbs. only from 8.921 to 8.930.

The *cubical expansion* of copper by heat for 1°C. is 0.000051 (the volume at 0°C. being taken as unity), hence the *linear expansion* is 0.000017 (H. Kopp, Ann. Ch. Pharm. lxxxi. 1); according to Troughton, it is 0.000019188.

Specific heat = 0.09515, between 0° and 100°C. (Regnault.)

Copper melts more easily than gold, less easily than silver. According to Pouillet, therefore, its melting point is between 1000° and 1200°C. ; according to Guyton-Morveau, it is 1207°C. (2204°F.); according to Daniell, 1398°C. (2538°F.). All these determinations of very high temperatures are liable to great uncertainty. It expands on solidifying. Copper containing red oxide melts at a lower temperature than pure copper, but does not form so thin a liquid; it likewise solidifies more slowly. If the proportion of oxide is larger, the mass does not expand in solidifying. The expansion is also prevented by an admixture of 0.1 per cent. of potassium, zinc, or lead. Copper containing carbon behaves in the fused state like pure copper.

Electric Conductivity.—Copper possesses great power of conducting heat and electricity, standing in this respect next to silver. Its electric conductivity has been studied with great care by Matthiessen and Holzmänn (Phil. Trans. 1860, pt. i.; see also Matthiessen, Proc. Roy. Soc. xi. 126), who have examined particularly the effect produced upon it by the presence of foreign substances, a subject of great importance with reference to the use of copper wires for electro-telegraphy. The results are given in the following table:

Electro-conductivity of Copper, that of a hard-drawn Silver wire being = 100.

Wires hard drawn.	How prepared.	Conducting power.	Temperature. C.
1. Pure copper	Protoxide reduced by hydrogen . . .	93.00	at 18.6°
2. " "	Electrotype copper not melted . . .	93.46	" 20.2
3. " "	commercial " . . .	93.02	" 18.4
4. " "	No. 3. After fusion in hydrogen . . .	92.76	" 19.3
5. " "	No. 3. Hydrogen passed through the metal while melted . . .	92.99	" 17.5
Mean of the twelve determinations from which the preceding numbers were deduced . . .		93.08	" 18.9
Extremes observed		92.22	" 19.3

3.	Tough-cake (make not specified), containing traces of lead, nickel, antimony, red oxide of copper, &c.	71.03	"	17.3
4.	Best selected (make not specified), containing traces of iron, nickel, antimony, red oxide of copper, &c.	81.35	"	14.2
5.	Australian, Burra Burra. Traces of iron and red oxide of copper only were found	88.86	"	14.0
6.	American, Lake Superior, containing traces of iron and red oxide of copper, and 0.03 per cent. silver.	92.57	"	15.0

Finely divided copper.—Copper may be obtained in this state: 1. By reducing the carbonate at a very gentle heat in an atmosphere of hydrogen (Osann, Pogg. Ann. lii. 406). 2. By boiling a concentrated solution of sulphate of copper not containing free acid, with distilled zinc. As soon as the liquid loses its colour, which it does in a short time, the zinc is removed, and the copper powder well boiled with dilute sulphuric acid, then washed uninterruptedly with water, pressed between bibulous paper, and dried at 75° C., or in a warm retort through the tubulure of which a stream of hydrogen is passed (Böttger, Ann. Ch. Pharm. xxxix. 172). 3. By igniting a mixture of 5 pts. cuprous chloride and 6 dry carbonate of sodium with sal-ammoniac, and afterwards exhausting with water. (Wöhler and Liebig, Pogg. Ann. xxi. 583). Copper thus prepared is a soft, dark-red, dull looking powder, which easily acquires the ordinary lustre of the metal by pressure, and if pressed together while red-hot welds together into a compact mass.

Chemical properties of Copper.

Copper has much less affinity for oxygen than iron, and decomposes water only at a bright red heat and to a small extent. In dry air it remains unaltered at ordinary temperatures, but oxidises rapidly at a red heat. In damp air it acquires a green coating of basic carbonate, and its oxidation is remarkably promoted by the presence of acids. The weaker acids, such as acetic acid, have no effect on copper, unless assisted by the oxygen of the air, when the copper rapidly combines with the oxygen and a salt of the acid is formed (see ACETATES OF COPPER, i. 14). Copper does not dissolve in cold *hydrochloric acid*; but when boiled with that acid, especially in the finely divided state, it displaces hydrogen, and slowly dissolves as hemichloride Cu^2Cl . (Vogel, Schw. J. xxxii. 301; Odling, Chem. Soc. Qu. J. ix. 291.)

Nitric acid of ordinary strength acts violently on copper, with copious evolution of nitric oxide and formation of cupric nitrate:

But the strongest nitric acid (specific gravity 1.52) does not act on copper, the metal when immersed in it remaining bright and quiescent; probably the action begins in the manner just described, and an extremely thin film of nitrate is formed on the surface of the metal, which being insoluble in the strong acid, stops the further action. The same passive state is exhibited by other metals when immersed in strong nitric acid, especially by iron (*q. v.*) On diluting the acid with water, a violent action is instantly set up.

Nitro-muriatic acid dissolves copper with facility, forming cupric chloride. Copper is not attacked by dilute sulphuric acid, or even by strong sulphuric acid at common temperatures, but on applying heat, sulphurous anhydride is evolved and sulphate of copper is produced :

This at least is the principal reaction which takes place; but a portion of the sulphuric acid suffers more complete decomposition, sulphur being deposited, part of which remains in the free state, while the rest unites with the copper as sulphide.

Copper likewise oxidises in alkaline and in saline solutions exposed to the air. In a dilute solution of ammonia exposed to the air, it is converted into cuprous oxide and dissolves.

Copper in the state of foil or filings takes fire in chlorine gas at ordinary temperatures. At a red heat, it unites directly with bromine, iodine, sulphur, selenium, silicon, and all the metals; with mercury at ordinary temperatures. With carbon and with nitrogen it does not appear to unite directly, even at a red heat.

Compounds of Copper.

Copper forms two classes of compounds, the *Proto-compounds*, or *Cupric compounds*, containing 1 at. of the metal united with 1 at. of a monatomic radicle, or 2 at. metal with 1 at. of a diatomic radicle; *e. g.* CuCl , $\text{Cu}(\text{NO}^3)$, Cu^2O , Cu^2SO^4 ; and *Hemi-compounds*, or *Cuprous compounds* (commonly called *di-compounds*), containing 2 at. copper with 1 at. of a monatomic radicle, or 4 at. copper with 1 at. of a diatomic radicle, *e. g.* Cu^2Cl , Cu^2O , &c. The cupric compounds may be supposed to contain the radicle *Cupricum*, $\text{Cu} = 31.6$; and the cuprous compounds, the radicle *Cuprosium*, $\text{Ccu} = 73.2$, their formulæ then becoming CcuCl , Ccu^2O , &c. There are also a few compounds containing copper united with electro-negative radicles in other proportions, *e. g.* a nitride, Cu^6N , or perhaps Ccu^3N .

COPPER, ALLOYS OF. Copper unites easily with most other metals. Many of the alloys were formerly stated to be chemical compounds formed in atomic proportions, but it is most probable that all of them (excepting those of copper and arsenic, which element occupies an intermediate place between metals and metalloids) are merely homogeneous mixtures.

The presence of small quantities of foreign metals, as arsenic, bismuth, zinc, iron, &c., in copper, produces considerable modification of its physical properties, for the most part impairing its malleability, tenacity, power of conducting heat and electricity, &c.

1. With **Aluminium**. (See i. 155).

2. With **Antimony**. An alloy obtained by fusing the metals together in equal quantities is of a pale violet colour, very brittle, and of laminar structure. According to Karsten, copper alloyed with 0.15 per cent. antimony is brittle when cold, and very brittle at a red heat.

3. With **Arsenic**. An arsenide of copper, Cu^6As , occurs native, as *Domeykite*, in the copper mines of Coquimbo and Copiapo in Chili, and in some Cornish mines, in reniform and botryoidal shapes, also massive and disseminated. Hardness, 3 to 3.5; lustre, metallic; colour, tin-white, with slightly yellowish or iridescent tarnish; fracture, uneven. Specimens from Chile, analysed by Domeyko, gave: 1. From Calabazo, 28.36 per cent. As, and 71.64 Cu. 2. From Copiapo, 23.29 As, 70.70 Cu, 0.52 Fe, and 3.87 S = 98.28. The formula Cu^6As requires 28.3 As, and 71.7 Cu. The Cornish mineral *Conduerite* (*q. v.*) appears to be a mixture of Domeykite with red copper ore, arsenious acid, and arsenate of copper.

Alloys of copper and arsenic may be formed by melting the two metals together, in which case, however, there is considerable loss of arsenic by volatilisation;—or by heating copper with arsenious acid and charcoal, or other carbonaceous matter; or by heating an arsenite or arsenate of copper with charcoal. The alloy called white copper, or white tombac, which has nearly the composition Cu^4As , is obtained in this manner. Percy (*Metallurgy*, i. 281) describes an experiment in which an intimate mixture of 500 grs. of copper, 1000 grs. of arsenious acid, 1000 grs. of carbonate of sodium, and 500 grs. starch, exposed to a strong red heat, yielded a hard, brittle alloy, having a crystalline and dark bluish-grey fracture, melting before the blow-pipe below a red heat, and evolving copious arsenical fumes. It was

found to contain 34·2 per cent. arsenic, which is rather more than the amount indicated by the formula Cu^4As (66·2 Cu + 33·8 As). Berthier (*Traité des Essais par la voie sèche*, ii. 410) describes an alloy obtained by melting 1 pt. of the tetra-cupric arsenide, Cu^4As , with 4 pts. of copper, as semi-ductile, reddish-grey, with a slightly fibrous fracture, and susceptible of a fine polish.

Tricupric arsenide, or *Tricuprarsine*, Cu^3As (analogous to NH^3 , PH^3 , AsH^3 , &c.), is produced by passing arsenetted hydrogen gas over dry chloride of copper, or into a solution of cupric sulphate:

It is a black substance. (Kane, Pogg. Ann. xliv. 471.)

Copper alloyed with 0·15 per cent. arsenic, becomes somewhat brittle when cold, and very brittle at a red heat.

The arsenides of copper, fused with nitre in proper proportion, yield arsenate of potassium and metallic copper free from arsenic. Heated with oxide or arsenate of copper, they give off arsenious oxide, and yield metallic copper. A mixture of 10 pts. Cu^4As and 6 pts. Cu^2O yields, when heated, 10·9 pts. copper; and a mixture of 10 pts. Cu^4As with 6 pts. tetra-cupric arsenate $\text{Cu}^4\text{As}_2\text{O}_7$ yields about 9·2 pts. copper, supposing the operation to be performed in perfectly closed vessels. When the fusion is effected in an open crucible, part of the arsenic is roasted by atmospheric oxidation, and less oxide or arsenate of copper is required to render the metal pure. (Berthier.)

4. With **Bismuth**. The two metals unite at a temperature below the melting point of copper. An alloy of 1 pt. copper and 2 pts. bismuth begins to expand a considerable time after solidification (Marx, Schw. J. lviii. 470). Copper alloyed with small quantities of bismuth remains ductile at mean temperatures, but when hammered becomes so hard and brittle as to require a second ignition, and if the quantity of bismuth exceeds 0·6 per cent., the alloy cracks on the edges when hammered at a red heat (Karsten). Bismuth is a frequent impurity in metallic copper (p. 36).

5. With **Cadmium**. An alloy containing 54·29 pts. copper and 45·71 cadmium has a light yellowish white colour, a fine-grained scaly structure, and is very brittle. The cadmium volatilises completely when the alloy is heated to the melting point of copper. Even a small quantity of cadmium renders copper brittle. (Stromeyer.)

6. With **Gold**. (See GOLD.)

7. With **Iridium**. (See IRIDIUM.)

8. With **Iron**. Combination between copper and iron takes place with difficulty.—100 pts. of copper may be made to unite by fusion with any quantity of bar-iron from 1 pt. to 100 and upwards. The intensity of the copper colour increases till the quantities of the two metals become equal; but the more the quantity of the iron exceeds that of the copper, the paler does the alloy become on the fractured surface. The alloy of 2 pts. copper to 1 pt. iron has the greatest tenacity; if the proportion of iron be increased, the hardness increases but the tenacity diminishes, and the fracture then becomes laminar. From ores containing the sulphides of iron and copper, the following alloys containing different proportions of the two metals may be prepared. One alloy of this kind was copper-red on the outer surface, had a pale uniform fracture, and was magnetic. Another exhibited externally a copper-red colour inclining to grey, had a deep copper-coloured and laminated fracture, was magnetic, and interspersed with isolated granules of copper and a few granules of iron. A third was iron-coloured, hard, had a laminar fracture, was strongly magnetic, and exhibited isolated granules of copper and numerous granules of iron. (Mushet, Phil. Mag. [3] vi. 81.)—According to former statements, the alloy of copper and iron is grey, slightly extensible, more difficult to fuse than copper, and magnetic even when it contains only $\frac{1}{10}$ pt. of iron. The brittleness of iron at a red heat appears sometimes to proceed from admixture of copper.

Carbon interferes with the combination of iron and copper. Copper impairs the quality of steel; and in the proportion of 2 per cent. renders it brittle. (See IRON, CARBURET OF.)

9. With **Lead**. The two metals fuse together at a strong red heat, but the mixture, unless cooled very rapidly, separates into two alloys, the lower consisting of cupriferous lead, the upper of plumbiferous copper. By rapid cooling, an apparently homogeneous mixture may be obtained, but on heating it again, the compound containing the larger proportion of lead fuses out, while that which contains the larger proportion of copper remains; this is the principle of the eliquation process (p. 32).

Small quantities of lead diminish the ductility of copper, both at common temperatures and at a red heat. Copper containing 0·1 per cent. lead may be used for ordinary purposes, but cannot be formed into thin leaves or wires; that which contains 0·3 per cent. lead works better cold than hot, as in the latter case it cracks immediately at the edges. (Karsten.)

Lead enters into the composition of many ancient bronzes, sometimes in large proportion; see Tables B and D, pp. 45, 50.

10. With **Manganese**. Reddish white, very malleable, acquires a green tarnish by exposure to the air.

11. With **Mercury**. See MERCURY.

12. With **Molybdenum**. Pale, copper-coloured alloy; malleable if the molybdenum is not in excess.

13. With **Nickel**. The alloys are very extensible, and incline to white in proportion to the quantity of nickel: 10 pts. copper with 1 pt. nickel form a pale copper-red alloy, perfectly ductile; 10 pts. copper to 2 nickel, reddish white; 10 copper to 3 nickel, almost white; 10 copper to 4 nickel perfectly white, exhibiting on the touchstone the whiteness of silver. (Frick, Schw. xlvi. 114.)

Old slags from disused mines at Suhl contain white granules of metal, which are extracted and sold as Suhlman nickel silver (*Suhler Weiss-Kupfer*). According to Brandes, Schw. J. xxxix. 17), this alloy contains 88 per cent. copper, 8.75 nickel, 0.75 sulphur and antimony, and 1.75 iron, silicon, and aluminium.

For the alloys of copper, nickel, and zinc, see p. 51.

14. With **Platinum** and the allied metals. (See those metals.)

15. With **Potassium**. According to Serullas, copper heated to redness with cream of tartar does not become alloyed with potassium. According to Karsten, copper thus treated takes up a quantity of potassium not exceeding 0.13 per cent., and is thereby rendered somewhat less ductile when hot.

16. With **Silver**. See SILVER.

17. With **Tin**. The alloys of tin and copper are of great importance, constituting bronze, gun-metal, and bell-metal. The following details are taken from *Gmelin's Handbook* (v. 481).

The arms of the ancients were sometimes made of bronze, an alloy formed of a large quantity of copper with a little tin. It is obtained by fusing the two metals together, generally in a reverberatory furnace; if the mixture is not stirred, two distinct strata are apt to form, containing very different proportions of the constituent metals. The combination of the metals in equal parts takes place without evolution of light and heat. (Gehlen.)

TABLE A.—*Properties of Alloys of Copper and Tin*, according to Mallet (Dingl. polyt. J. lxxxv. 378).

1 at. copper = 31.6, and 1 at. tin = 58.9.

At.* Cu. Sn.	Per cent. Cu.	Spec. Grav.	Colour.	Fracture.	Tenacity	Order of Mal- leability.	Order of Hard- ness.	Order of Fusi- bility.

In this table, *r.* under *Colour*, denotes red, *y.* yellow, *gr.* grey. Under *Fracture*, *f. gr.* denotes fine-grained, *c.* conchoidal, *v.* vitreous, *lam.* laminar. The numbers under *Tenacity*, denote the weight in tons required to break a rod whose transverse section measures a square inch. The malleability was determined at 60° F. (15.6 C.) Under *Hardness* and *Fusibility*, the number 1 denotes the minimum. *a*, *b*, and *c* are gun-metal; *d*, is hard brass for pin-makers; *e* to *i* are bell-metal; *k* and *l*, bell-metal for small bells; *m*, *n*, and *o*, speculum-metal. (Mallet.)

* The "atoms" in this column and in the corresponding column of Table C (p. 47) must be understood as merely indicating proportions; the alloys are not definite compounds.

a. Copper, alloyed with a very small quantity of tin, becomes so hard and brittle when hammered cold, that it requires to be again heated to full redness. (Karsten.)

b. 32 pts. copper to 1 tin: resists the solvent action of hydrochloric acid much more completely than pure copper, and is therefore adapted for the sheathing of ships. (Mushet, Phil. Mag. [3] vi. 444.)

c. 19 pts. copper to 1 tin: golden yellow, hard, malleable.

d. From 8 to 11 pts. copper to 1 tin: yellow and slightly malleable: *Gun-metal*. The best proportion appears to be 9 pts. copper to 1 tin. The alloy of 11 pts. copper to 1 tin appears uniform after sudden cooling, to the unassisted sight; but when examined with a lens, it appears to be composed of striated faces of a reddish alloy mixed with a white one. If it be still more rapidly solidified by pouring it into thick iron moulds, an alloy is obtained which appears perfectly uniform, even under the lens. When quickly cooled in water after continued strong ignition, it remains uniform; but if suffered to cool slowly after continued ignition, it becomes variable in composition, like that which has been slowly cooled after fusion. Hence the alloy which is uniform at the melting heat, and likewise at a strong red heat, separates into two different alloys when slowly cooled. The large mass of a cannon cannot be cooled, even by moulds which conduct heat well, suddenly enough to prevent the formation of two distinct alloys, the one that is richer in copper solidifying first, while that which is richer in tin, containing 82·3 per cent. copper to 17·7 tin, partly rises to the top, and partly sinks into the mould. (Karsten, Schw. J. lxx. 387.)

e. 6·25 pts. copper to 1 tin: the densest of all the alloys; its specific gravity is 8·87. (Briche.)

f. From 4 to 5 pts. copper to 1 tin: *Bell-metal*. Yellowish-grey, and, when very slowly cooled from a red heat, very hard, difficult to file, sonorous, brittle, exhibiting a fine-grained fracture. When heated to redness, and then suddenly cooled by immersion in water, it becomes soft, and easy to file and turn, but may be hardened again by ignition and slow cooling. The Chinese cymbals called *Gong-gongs* are made of this alloy (D'Arcet, Gilb. Ann. lvi. 104; further Ann. Ch. Phys. liv. 331). Bell-metal becomes malleable at a temperature not far below redness (Wollaston, Gilb. Ann. lvi. 106).—An alloy of 4 pts. copper and 1 tin fused, and then very slowly cooled, exhibits a striated surface, a dingy white close fracture, and is very brittle. When poured out into cold iron moulds, it exhibits the same properties; but if immersed in cold water, after being kept for some time at a low red heat, it becomes yellowish-white and extensible. During the ignition, if somewhat too strong, white globules of an alloy richer in tin are seen to ooze out, but at a higher temperature, when the whole mass becomes liquid, they disappear. Hence the alloy appears to be resolved at a temperature below its melting point, into two other compounds, which, on slow cooling, reunite and form a brittle alloy, but remain separated if the cooling be more sudden.

g. 3 pts. copper to 1 tin: reddish-white; very brittle; specific gravity 8·879 (Chaudet). With a small quantity of arsenic it forms a *speculum-metal*. (Little.)

h. 2 pts. copper to 1 tin: steel-grey, very hard. Remains uniform, even after slow cooling from a state of fusion (Karsten).—2 pts. copper, 1 tin, and $\frac{1}{10}$ arsenic, form a *speculum-metal*; so likewise do 62 pts. copper, 33 tin, 2·5 arsenic, and 8 brass. (Little.)

i. 1 pt. copper to 1 tin: bluish-white, like zinc; slightly malleable, not very hard; specific gravity 8·468 (Chaudet), 8·79 (Briche). Remains uniform after slow as well as after sudden cooling. (Karsten.)

k. 1 pt. copper to 2 tin: white; brittle. Uniform, even after slow cooling. (Karsten.)

l. 1 pt. copper to 3 tin: bluish white, exhibits a crystalline aspect and fibrous texture; cracks under the hammer. Specific gravity 7·813. (Chaudet.)

m. 1 pt. copper to 3·6 tin. In a tinned copper boiler, regular six-sided prisms were found to be formed, with indistinct cleavage parallel to *p* (Miller, Phil. Mag. [3] vi. 107). Yellow-greenish-white; shining; ductile; of specific gravity 7·53; fusing at a red heat; slowly attacked by dilute, easily by strong nitric acid; dissolves rapidly in boiling hydrochloric acid. (Gives by analysis 21·38 per cent. copper, and 77·63 tin, which agrees nearly with the formula CuSn^2 (31·33 Cu and 78·67 Sn). (Roth, Pogg. Ann. xxxvi. 478.)

n. 1 pt. copper to 10 tin: malleable to a certain extent, but cracks under the hammer; specific gravity 7·472. (Chaudet.)

Boiling hydrochloric acid extracts tin from these alloys, and leaves a compound containing a large quantity of copper with a small quantity of tin. (Chaudet, Ann. Ch. Phys. vii. 275.)

The following table exhibits the composition of numerous bronzes, ancient and modern. Some of them contain larger quantities of zinc and lead than of tin, but they are placed here for the sake of comparison with the rest. See also Table D (p. 50).

19. With **Zinc** (Gm. v. 477).—The most important alloy of these metals is *brass*, which contains about 2 pts. by weight of copper to 1 pt. of zinc. Other proportions form *Tombac*, *Pinchbeck*, *Prince's metal*, *Similor*, *Mannheim gold*, *Mosaic gold*, &c.

The alloys are prepared: 1. By adding zinc to melted copper, or by fusing the metals together in a covered crucible, the zinc being placed below, and the copper in small pieces at top. For brass, the proportion is 7 pts. copper to 3 pts. zinc. Part of the zinc always burns away. The fusion is performed in crucibles, seven of which are usually placed in a circular air-furnace.—2. By igniting copper in small pieces with zinc-oxide and charcoal or coal powder. In this older method of making brass, roasted native calamine or furnace-calamine is ignited in covered crucibles with charcoal powder and copper, the latter being cut into small pieces or granulated.—3. Copper exposed at a red heat to vapours of zinc is completely penetrated by them, but does not lose its form.—*Lyons Gold-lace* is prepared by exposing rods of copper to the vapour of zinc till they are converted into brass on the surface, and then drawing them out into wire. A copper coin placed in a crucible above a mixture of zinc-oxide and charcoal, and moderately ignited, is converted into brass without obliteration of the device.—4. By precipitation. *Spirious gold-wire* is prepared by boiling copper-wire (previously cleaned with nitric acid) with hydrochloric acid, cream of tartar, and a mixture of 1 pt. zinc and 12 pts. mercury. When sulphate of copper dissolved in 20 pts. water, is precipitated by zinc, the black flakes at first thrown down are an alloy of copper and zinc.

Copper alloyed with a small quantity of zinc exhibits a paler red and yellowish-red colour; a larger quantity renders it yellow, the colour being brightest when the two metals are united in equal parts; a still greater quantity of zinc makes it white (Lewis). In certain proportions, the alloy of copper and zinc is more ductile at ordinary temperatures than pure copper, but generally brittle at a red heat. Very small quantities of zinc do not impair the ductility of copper at ordinary temperatures, excepting that, when thus alloyed, it sooner becomes hard and brittle by hammering, and therefore requires to be oftener heated to redness; but even 0.6 per cent. of zinc is sufficient to cause copper to crack when hammered at a red heat (Karsten). The most ductile of all the alloys of copper and zinc are those which contain 84.5 per cent. of copper to 15.5 of zinc (tombac), and 71.5 copper to 28.5 zinc (brass). The alloy formed of equal weights of the two metals cracks in rolling. An excess of zinc renders the alloy brittle, the most brittle of all being that which contains 1 at. copper to $1\frac{1}{2}$ to 2 at. zinc (Karsten.) Small quantities of lead diminish the ductility of the alloy; tin increases its hardness. (Karsten.)

All alloys in which the amount of zinc does not exceed 50 per cent. exhibit the reaction of copper towards acids and in the voltaic circuit, and they do not precipitate the salts of copper. But alloys containing excess of zinc decompose copper-salts, being thereby converted into perfectly pure copper; they likewise dissolve completely in acids which have no action on copper alone, the solution taking place the more quickly as the excess of zinc is greater. If the quantity of acid is insufficient to dissolve the whole, the copper first dissolved is reprecipitated, the liquid at length retaining nothing but zinc (Karsten). Brass turns red when rubbed with hydrochloric acid, because the acid dissolves the zinc in preference to the copper; but when rubbed with ammonia, it turns white, because the ammonia dissolves out the copper. (Berzelius.)

TABLE C.—*Properties of Alloys of Copper and Zinc*, according to Mallet (Dingl. polyt. J. lxxxv. 378).

In this table, *r* under *Colour*, denotes red, *y.* yellow, *gr.* grey, *silv. w.* silver-white. Under *Fracture*, *c. gr.* denotes coarse-grained, *f. gr.* fine-grained, *f. f.* fine-fibred, *c.* conchoidal, *v.* vitreous, *lam.* laminar. The numbers under *Tenacity* denote the weight in tons required to break a rod whose transverse section measures a square inch. Under *Malleability*, *br.* signifies brittle, *v. br.* very brittle, *s. d.* slightly ductile: the malleability was determined at 60° F. (15.6 C.). Under *Hardness* and *Fusibility*, the number 1 denotes the minimum.

The compound corresponding in percentage composition to ZnCu^5 is *Prince's metal*, or *Bath metal*; ZnCu^4 is German and Dutch brass; ZnCu^3 is rolled brass; ZnCu^2 is English brass; ZnCu is German brass; Zn^2Cu is German brass for watchmakers. (Mallet.)

From experiments by F. H. Storer (*Memoirs of the American Academy*, New Series, viii. 97), it appears that alloys of copper and zinc, formed by melting the two metals together in the most varied proportions, then leaving the mass to cool partially, and pouring out the still fluid portion (as for the crystallisation of bismuth, i. 590), yield crystals of similar aspect, sometimes exhibiting distinct octahedral faces, sometimes in confused aggregates of crystals, but all of octahedral character, and bearing a striking resemblance to the crystals of pure copper obtained by fusion. From this resemblance, and from the observations of Nicklès (*Jahresber. d. Chem.* 1847—8, p. 434), that zinc crystallises in forms belonging to the regular system, Storer concludes that all the alloys of copper and zinc also crystallise in that system, and are not definite atomic compounds, but merely isomorphous mixtures of the two metals,—a conclusion further supported by the fact that none of the crystals were found to contain a larger proportion of either metal than the remainder of the molten liquid from which they had separated. The alloy containing from 5 to 6 per cent. of zinc was found to crystallise particularly well; the white alloys are difficult to crystallise, having a great tendency to assume the pasty condition on cooling. Alloys containing from 58 to 43 per cent. copper are much inclined, especially when quickly cooled, to form fibrous aggregates of crystals. The colours of the different alloys (on recently filed surfaces) exhibit a perfectly regular transition, without any sudden leaps, from the pure red of copper to yellow, and ultimately to white. The purest yellow is exhibited by those containing from 75 to 80 per cent. copper. The hardness increases with the proportion of zinc. Sudden cooling in water renders the alloys, for the most part, softer and less tenacious.

Brass—This alloy is harder than copper, and therefore resists wear better. It is very malleable and ductile, and may be raised by stamping into various objects, such as curtain-bands. At a red heat, however, it is very brittle. It is well adapted for casting, being easily fusible, and capable of receiving very delicate impressions from the mould. It is said to resist atmospheric influences better than copper; but when its surface is unprotected by lacquer, it rapidly tarnishes and becomes black.

During the process of stamping brass, that is, of subjecting it to heavy blows in dies, as for the manufacture of curtain-bands, &c., the metal requires to be annealed from time to time, and at the completion of the process the article remains discoloured by adhering oxide. This is removed by “dipping” the metal in aqua fortis of suitable strength, and then washing it with water. A bright metallic surface is thus produced, ready to receive the lacquer (a solution of shellac in alcohol). The colour may be varied by using acid of different strengths.

The pale yellow dead surface often seen on ornamental articles is produced by

"pickling" the metal, after stamping, in weak aqua fortis (say 1 pt. strong nitric acid to 7 or 8 pts. water); then, after washing with water, immersing it in much stronger acid, till a white "curd," due to a stratum of small gas bubbles, forms on the surface; again washing with water; roughly drying the object by moving it about in cold sawdust; then dipping it again in strong nitric acid for a few seconds; washing first in water, then in a cold solution of argol or impure cream of tartar; and lastly drying in hot sawdust.

The surface of brass is often coloured or bronzed after "dipping" and before lacquering. This is done by immersing the article in a solution of arsenious acid in hydrochloric acid, by applying a dilute aqueous solution of chloride of platinum, or an aqueous solution of corrosive sublimate mixed with vinegar, or by rubbing plumbago over the surface. Either of these applications produces a dark grey coating, which assumes a bronze-tint when lacquered. The corrosive sublimate solution is used for common work; the platinum-process for theodolites, levels, and other instruments. (*Percy's Metallurgy*.)

Muntz's metal.—This alloy and its application "for sheathing the bottoms of ships, and other such vessels," was the subject of a patent granted to the late G. F. Muntz of Birmingham, in 1832. The proportions specially recommended in the specification are 60 per cent. copper and 40 zinc; but these proportions may be varied from 50 up to 63 per cent., and from 50 down to 37 per cent. zinc. The metal is cast into ingots, and rolled *while hot* into sheets, which, when finished, are "pickled" in dilute sulphuric acid, and afterwards washed in water. In the same year Mr. Muntz obtained a second patent for "an improved manufacture of bolts, and other the like for ships' fastenings," the same proportions of copper and zinc being used; and in 1846, a third patent for the use of an alloy consisting of 56 per cent. copper, 43 $\frac{1}{4}$ zinc, and 3 $\frac{3}{4}$ lead. This last alloy does not appear to have been manufactured on a large scale, but Dr. Percy states that he has succeeded in rolling brass well, which contained not less than 8 per cent. of lead.

Muntz's metal, or yellow-metal sheathing, has entirely superseded copper sheathing in the merchant service, though the latter is still retained in the navy. Its special advantages are said to be that it keeps the bottoms of ships cleaner and costs much less than copper sheathing. It is now generally made in reverberatory furnaces, the zinc being cautiously added to the melted copper, and the melted metal tapped into a vessel lined with clay, out of which it is ladled into suitable cast iron ingot-moulds.

Mosaic gold.—Prepared by fusing equal weights of copper and zinc in a crucible at the lowest possible temperature, stirring constantly, and then adding a further quantity of zinc in small portions, till the colour of the fused mixture, after passing through the various shades of brass-yellow, purple-red, and violet, has become perfectly white. The alloy, after casting in the mould and cooling, exhibits the colour of gold, and does not tarnish by exposure to the air, even in the neighbourhood of the sea. (Hamilton and Parker, *Edinb. J. of Sc.* 1826.)

Brass solder.—2 pts. brass to 1 zinc, or if it is to be more ductile, 6 pts. brass, 5 silver, and 2 zinc.

Imitation bronze, Tombac, Pinchbeck, Prince's metal, Similor, Mannheim gold.—These terms are applied to alloys of zinc and copper, containing 80 per cent. or more of copper; also to alloys of copper with zinc, tin, and lead. The cheapness of zinc compared with tin, has caused these alloys to be extensively used of late years as substitutes for true bronze, which is an alloy of copper and tin, especially for ornamental articles, which are gilt or artificially bronzed on the surface. Alloys whose composition ranges from 85.5 per cent. copper, 11.5 zinc, and 4 tin, to 66 copper, 32 zinc, and 2 tin, may likewise be used for the casting of statues, as they run well into the mould, and are easily filed and chiselled. Those which approach to the latter composition, 66 per cent. copper, &c., are too yellow to be used, excepting for objects which are to be gilt or artificially bronzed; but the first-mentioned alloy yields a cast of a fine deep red colour, which, by exposure to the air, slowly acquires a very beautiful tarnish.

The alloy called *tombac*, containing 84.5 per cent. copper and 15.5 zinc, is very ductile and malleable. *Dutch-metal* is tombac beaten out into leaves $\frac{1}{52960}$ of an inch thick.

Bronze-colours or Bronze-powders, used for colouring objects cast in brass, imitation bronze, or plaster of Paris, and for various other ornamental purposes, are prepared by triturating Dutch-metal or other alloys of copper and zinc, &c., between rollers with water and resin, oil or fat, separating the finer particles from the grosser by levigation, sifting, &c., and lastly drying and heating them. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 463.)

The following Table exhibits the composition of various kinds of brass and imitation-bronze. See also Nos. 72, 73, 75, 76, 78, 79, and 82 of Table B, p. 46.

Alloys of Copper, Zinc, and Iron.—80 pts. zinc, 1 pt. copper, and 1 pt. cast iron form Sorel's *white brass*. It has the aspect and fracture of ordinary zinc, is said to be as hard as copper, and tougher than cast iron, to admit of turning, filing, and boring, and not to rust even in damp situations. (Berthier, Pogg. Ann lxx. 344.)

Alloys of Copper, Zinc and Nickel.—*Nickel-silver, German-silver, White copper, Packtong or Packfong, Weisskupfer, Neu-silber, Argentan, Maillechort.*—To prepare this alloy, which is much used as a substitute for silver, the copper and nickel are first melted in a crucible, and the zinc is then added in pieces previously heated. Or, the three metals, in a state of fine division, are mixed together in a crucible, copper being placed at top and bottom, the whole covered with charcoal powder and heated in an air-furnace with a strong draught, the mixture being stirred all the while, to ensure the complete solution of the difficultly fusible nickel. The longer and the more completely the mixture is fused, the more ductile does it become; part of the zinc burns away. (Gersdorff, Pogg. Ann. viii. 103.)

Proportions of the materials.—*a.* 2 pts. copper, 1 nickel, 1 zinc: serves for spoons and forks. *b.* 5 pts. copper, 2 nickel, 2 zinc: has the colour of silver alloyed with $\frac{1}{4}$ pt. copper; serves for knife and fork handles, snuffers, &c. *c.* 3 pts. copper, 1 nickel, 1 zinc: this proportion gives the best alloy for rolling. The addition of 3 pts. of lead to 100 pts. of the mixture *a*, or of 2 pts. lead to 100 pts. of the mixture *b*, yields an alloy adapted for cast articles, such as candlesticks, spurs, and bells. The addition of 2.5 pts. of iron or steel to 100 pts. of alloy, renders it much whiter, but likewise harder and more brittle; the iron must be previously fused with a portion of the copper, under a layer of charcoal-powder in the blast-furnace, and then melted together with the zinc and nickel and the rest of the copper (Gersdorff). *d.* 8 pts. copper, 3 nickel, and 5 zinc yield very good nickel-silver (Frick). An alloy of 10 pts. copper, 1 nickel, and 5 zinc, has still a pale yellow colour; that which contains 10 copper, 1 nickel and 7 zinc, is yellowish-white and less ductile than *d* (Frick). Larger quantities of iron do not enter into combination with the nickel-silver as a whole, but unite with part of the copper, nickel, and carbon, forming an alloy which floats like drops of oil on the surface of the nickel-silver. (Erdmann.)

Nickel-silver has a crystalline structure when solidified from fusion. It must, therefore, be heated to dull redness and cooled again completely before it is rolled or hammered; when once the crystalline structure has been destroyed, the alloy may be worked like brass (Gersdorff). Chinese nickel-silver may be worked even at a dull red heat, but at a stronger heat it flies to pieces on the slightest stroke of the hammer (Fyfe, Edinb. Phil. J. vii. 69). Nickel-silver is harder than silver, and susceptible of a high polish. Its colour approaches that of silver, but is greyer. A mixture of 1 pt. oil of vitriol and 7 pts. water turns it white when boiled with it (Gersdorff). It is not magnetic, or but slightly so; when it contains a certain amount of iron. It fuses at a bright red heat, the zinc burning away if the air has access to it. When exposed to the air, it acquires a slight yellow tarnish. When immersed in vinegar, it becomes coated with verdigris, only at those parts where the air can likewise act upon it (Frick). In vinegar it becomes greenish black; in wine, dark brown; in solution of common salt, red brown; in solution of sal-ammoniac or tartaric acid, black with green spots; and in oxalic acid, black (D'Arcet, J. Pharm. xxiii. 223). In water containing $\frac{1}{300}$ of potash-hydrate, it remains bright. (A. Vogel.)

a. Chinese packfong, of specific gravity 8.432. *b.* English nickel-silver, somewhat yellower than the German. *c.* Parisian Maillechort; contains also a trace of arsenic, which remains behind when the alloy is dissolved in nitric acid. *d* and *e.* From unknown sources. *f, g, and h.* English nickel-silver, used in Birmingham for articles that are to be plated. *i.* From Sheffield, distinguished by extraordinary elasticity, used for the friskets of printing-presses.

American nickel-silver.—1 pt. iron, 1 cobalt, 2 silver, 2 tin, 4 manganese, 24 nickel, 36 zinc, and 96 copper. (Gm. v. 498.)

COPPER, BROMIDES OF. Copper does not unite with bromine at ordinary temperatures, but on the application of heat, combination takes place, the chief product being the hemibromide, Cu^2Br .

Protobromide of Copper, or *Cupric Bromide*, CuBr_2 , is formed by evaporating the solution of cupric oxide in aqueous hydrobromic acid, and fusing the residue at a gentle heat. The residue is iron-black like plumbago. If the solution be left to evaporate in vacuo over oil of vitriol, anhydrous shining crystals are obtained, resembling iodine in appearance (Rammelsberg, Pogg. Ann. lv. 246). According to Berthelot, protobromide of copper gives off half its bromine even below a red heat; according to Rammelsberg, it gives off 36.8 per cent. and leaves cuprous bromide.

Hydrated Protobromide of copper, or *Hydrobromate of cupric oxide*.—The emerald-green solution of cupric bromide in water, or of cupric oxide in aqueous hydrobromic acid, or of copper in a mixture of hydrobromic and nitric acids, becomes brown on evaporation, and yields right rectangular prisms (greenish-yellow needles, according to Berthelot), which fuse at a gentle heat, giving off their water and leaving a residue of anhydrous protobromide of copper.

Protobromide of copper and the hydrated crystals deliquesce in the air, and dissolve readily in water; the green solution turns brown on evaporation, and likewise when mixed with oil of vitriol or with salts, these substances depriving it of its water (Löwig). Ammonia added to the solution in quantity not sufficient for complete precipitation, forms a pale green precipitate of hydrated oxybromide.

Ammonio-cupric bromides.—The compound $2\text{CuBr} \cdot 5\text{NH}_3$, is obtained by the action of dry ammonia gas on cupric bromide. It is a bluish powder, which, when heated, gives off water and bromide of ammonium. It dissolves in a small quantity of water, forming a deep blue solution, which becomes turbid when diluted, depositing hydrated cupric oxide, which turns black when heated in the liquid (Rammelsberg, *loc. cit.*). Another ammonio-bromide, containing $2\text{CuBr} \cdot 3\text{NH}_3$, is obtained by mixing a strong solution of cupric bromide with a sufficient quantity of strong ammonia to form a clear solution, and then adding alcohol. It forms small dark-green crystals, but in other respects resembles the preceding. Rammelsberg found in the former of these compounds 28.98 per cent., in the latter 19.98 per cent. ammonia.

Hemibromide of Copper, or *Cuprous Bromide*, Cu^2Br , or CuBr . *Dibromide of copper*.—When bromine is poured into the sealed end of a glass tube, the upper part of the tube filled with fine copper wire, and the copper heated to dull redness, combination takes place, attended with vivid incandescence. The protobromide which mixes with the mass is dissolved out by water. On dissolving the product in aqueous hydrobromic acid, any copper that may remain uncombined is left behind, and the cuprous bromide may be precipitated from the solution by water (Löwig). Another mode of preparation is to heat thin rolled-up copper-foil in a flask, at the bottom of which some bromine is placed, and when combination attended with ignition is set up, to drop more bromine in, till the whole of the copper disappears. Cuprous bromide is likewise obtained by heating cupric bromide to redness. It is a dark-greenish brown mass, which is decomposed by ignition, in contact with the air, is insoluble in water, but dissolves without colour in hydrobromic or hydrochloric acid. Nitric acid decomposes it, with evolution of nitric oxide. It is not acted on by sulphuric or acetic acid, even at the boiling heat. It is said to dissolve in aqueous ammonia, and to yield by evaporation crystals of an ammonio-bromide. (Berthelot.)

COPPER, CARBIDE OR CARBURET OF. Copper does not appear to form any definite compound with carbon. Pure (electrotype) copper may be fused under charcoal powder without undergoing any change of physical properties. Ordinary copper thus treated becomes brittle at a red heat; but the change is probably due to the presence of small quantities of foreign metals, as in overpoled copper (p. 29). Whether any small quantity of carbon is taken up by the copper has not been exactly ascertained. (*Percy's Metallurgy*, i. 269.)

COPPER, CHLORIDES OF. *a. Protochloride of Copper*, *Cupric Chloride*, *Chloride of Cupricum*. CuCl_2 .—This compound is obtained in the anhydrous state: 1. By the combustion of copper in chlorine-gas. Copper filings or copper foil introduced into dry chlorine, takes fire spontaneously, and burns with a greenish light, producing a mixture of cupric and cuprous chlorides, and if the chlorine is in excess, the latter is slowly converted into cupric chloride.—2. By heating the hydrated chloride to 200°C .

Anhydrous cupric chloride prepared by (1) forms a brown sublimate; by (2), a brownish-yellow powder. It has a caustic metallic taste, is fusible, and at a red heat gives off half its chlorine, and is converted into the hemichloride. Heated in a current of *phosphoretted hydrogen*, it yields hydrochloric acid gas and triphosphide of copper. Fused with *phosphorus*, it forms chloride of phosphorus and phosphide of copper (H. Rose, Pogg. Ann. xxvii. 117). It is not decomposed by *sulphuric anhydride* at ordinary temperatures (H. Rose, *ibid.* xxxviii. 121). *Sulphuric acid* does not decompose it at ordinary temperatures, but completely when heated, hydrochloric

acid being evolved (A. Vogel). Heated in a current of *ethylene gas*, protochloride of copper yields a mixture of copper and cuprous chloride (Wöhler). When exposed to the air, it turns green and deliquesces.

Hydrated protochloride of copper is produced: 1. By the deliquescence of the anhydrous chloride.—2. When copper immersed in hydrochloric acid is exposed to the air for a considerable time.—3. By dissolving copper in aqua regia.—4. By dissolving cupric oxide or carbonate in hydrochloric acid. The solution of cupric oxide in concentrated hydrochloric acid is attended with great development of heat.—5. By pouring a small quantity of water at 50° — 60° C. on a mixture of equal weights of pulverised sulphate of copper and common salt. The dark green liquid thus formed deposits, on cooling, crystals of sulphate of sodium, and by further evaporation the remainder of this salt, together with the excess of chloride of sodium: the decanted solution finally yields crystals of cupric chloride (Rieckher.) The emerald-green solution evaporated and cooled, yields green right-angled four-sided prisms, which at 100° C. turn brown, giving off the greater part of their water, but do not part with the whole, which amounts to 21.53 per cent., till they are heated to 200° (Graham, Ann. Ch. Pharm. xxix. 31). Cold sulphuric acid likewise abstracts water from them, and converts them into the brown anhydrous protochloride, which it does not dissolve or decompose (A. Vogel). The crystals deliquesce in the air.

From the aqueous solution, *phosphorus* throws down hemichloride of copper, and forms phosphoric acid (Boeck); the same precipitate is likewise produced by *mercury*, with formation of mercurous chloride; by *silver*, with formation of chloride of silver, black at first, but afterwards white (Wetzlar, Schw. J. lii. 475); and by *dichloride of tin*, with formation of tetrachloride of tin. Cuprous chloride is also precipitated on boiling the aqueous solution with *sugar*, and partly remains dissolved in the hydrochloric acid produced by the reaction (A. Vogel); a solution of protochloride of copper mixed with *ether*, and exposed to the sun's rays, loses its colour, and on the addition of water yields a precipitate of cuprous chloride. (Gehlen.)

The solution of protochloride of copper in a small quantity of water is emerald-green, but a larger quantity turns it pale blue. The concentrated solution assumes a yellow colour on the addition of strong hydrochloric acid. With strong sulphuric acid, it solidifies to a brown mass. Characters traced on paper with the solution turn yellow when heated, the writing disappearing as the paper cools.

Protochloride of copper is soluble in *alcohol* and in *ether*.

For the so-called *basic chlorides of copper*, see COPPER, OXYCHLORIDES OF.

Ammonio-cupric Chlorides.—100 pts. of dry cupric chloride quickly absorb 73.7 pts. ammonia, crumbling at the same time to a blue powder. The resulting compound,

which has the composition $3\text{NH}^3.\text{CuCl}$, or possibly $\text{NH}\text{Cu}(\text{NH}^3)_2.\text{Cl}$, gives off part of its ammonia on exposure to the air, and turns green. At 140° C. it gives off 2 at. ammonia, leaving an apple-green powder consisting of *chloride of cuprammonium*, NH^3CuCl . At a higher temperature, it gives off sal-ammoniac and a small quantity nitrogen, and leaves cuprous chloride. (H. Rose.)

The compound $3\text{NH}^3.\text{CuCl}$ is obtained as a hydrate, $2(3\text{NH}^3.\text{CuCl}).\text{H}^2\text{O}$, by passing *ammonia-gas* into a solution of cupric chloride, till the precipitate which first forms is redissolved. The liquid becomes heated nearly to the boiling point, and on cooling deposits the compound in dark blue prisms and octahedrons. (Kane.)

The *di-ammonio compound* is obtained, by passing ammonia-gas in excess through a hot saturated solution of cupric chloride, in dark blue hydrated octahedrons, which at 149° C. are reduced to $\text{NH}^3.\text{CuCl}$.

The *oxychloride*, Cu^3ClO , likewise absorbs ammonia-gas, forming the compound $\text{NH}^3.\text{Cu}^3\text{ClO}$.

Protochloride of copper forms double salts with the chlorides of the alkali-metals.

Chloride of Cupricum and Ammonium (*Kupfer-salmiak*), $\text{NH}^4\text{Cl.CuCl} + \text{H}^2\text{O}$, is obtained by dissolving 53.4 pts. sal-ammoniac and 67.4 pts. anhydrous or 85.4 pts. crystallised protochloride of copper in a small quantity of water, and leaving the solution to cool. This salt forms bluish-green quadratic octahedrons perfectly soluble in water and alcohol, and easily decomposed by heat (Mitscherlich, Graham); Henmann, by the same mode of preparation, obtained a salt with 2 at. water; so likewise did Hantz, by saturating hydrochloric acid with cupric carbonate, and mixing the solution with half the quantity of hydrochloric acid neutralised with ammonia.

Becquerel obtained several compounds of chloride of ammonium with basic cupric chloride (oxychloride) by filling the bend of a U-tube with clay, placing solution of sal-ammoniac in the one arm, cupric chloride in the other, and immersing the end of a bent strip of copper in each arm in such a manner as not to touch the clay. The end dipping into the sal-ammoniac became covered in the course of a few months with crystals exhibiting remarkable truncations of the angles and edges; they were resolved

by water into chloride of ammonium and oxychloride of copper. A similar compound was obtained with chloride of potassium.

Chloride of Cupricum and Potassium, $\text{KCl.CuCl} + \text{H}_2\text{O}$, is obtained in the same manner as the corresponding ammonium-salt, according to Mitscherlich, in quadratic octahedrons, according to Jacquelin, in double six-sided pyramids, soluble in water and in alcohol.

HEMICHLORIDE OF COPPER. *Cuprous Chloride. Chloride of Cuprosum.* Cu^2Cl or CuCl , also called *Dichloride of Copper*, *Boyle's Resina cupri*.—Produced: 1. Together with the protochloride, by the combustion of copper in chlorine gas.—2. Copper heated with protochloride of mercury, yields vapour of mercury and hemichloride of copper (Boyle). The decomposition takes place most readily with 1 pt. copper to 2 pts. corrosive sublimate (J. Davy). More exactly, 64 pts. (2 at.) copper and 136 pts. (1 at.) corrosive sublimate.—3. A plate of copper immersed in hydrochloric acid in a flask containing air, becomes covered with white tetrahedrons of hemichloride of copper (Proust).—4. The compound may also be formed by agitating copper-filings with a solution of the protochloride in a close vessel (Proust).—5. By precipitating cupric sulphate, hydrochlorate, nitrate, or acetate with aqueous dichloride of tin, or by treating cupric hydrate or carbonate with dichloride of tin dissolved in hydrochloric acid (Proust):

6. By treating aqueous protochloride of copper with phosphorus, ether, sugar, &c.—7. By heating the protochloride in a retort for a considerable time; digesting the residue with water for several days with the retort closed, to dissolve out the undecomposed protochloride, and pouring off the resulting solution; the residue consists of hemichloride (Proust).—8. By agitating pulverised cuprous oxide with hydrochloric acid in a close vessel (Proust, Chenevix).

Cuprous chloride, obtained by precipitation, is a white crystalline powder, which acquires a dingy violet and blackish-blue tint by exposure to sunlight. It crystallises from its solution in hot concentrated hydrochloric acid in white tetrahedrons (Proust), which turn bluish when exposed to light. According to J. Davy, it separates in olive-green prisms. It melts somewhat below a red heat, and when slowly cooled, solidifies in a translucent, light yellow mass (greyish-white; Proust); the residue obtained by rapid cooling is of a dark brown colour, and confused texture (J. Davy). Specific gravity of the melted mass = 3.677 (Karsten). In close vessels, it does not volatilise, even when strongly heated; but if heated in the air, it goes off in white vapours.

Heated to redness in a stream of *hydrogen*, it is converted into metal and hydrochloric acid gas; in an atmosphere of *phosphoretted hydrogen*, it yields hexcupric phosphide and hydrochloric acid gas (H. Rose, Pogg. Ann. iv. 110, 205). With *iron-filings* under water, it yields metallic copper and soluble protoxide of iron (Proust). *Ferrous sulphate* added to the solution of the hemichloride in hydrochloric acid, throws down metallic copper (Proust). Hemichloride of copper turns yellow when boiled with water; but the decomposition is not complete (Proust). With fused *hydrate of potassium* or the aqueous solution of potash, it yields cuprous oxide and chloride of potassium (Proust). When exposed to the air in the dry state, it slowly attracts moisture and turns green; in the moist state it is quickly converted into a green mass. (Proust). With *nitric acid* it forms first a violet and then a blue solution, the action being attended with great rise of temperature and violent evolution of nitric oxide (Proust). A mixture of hemichloride of copper and *sulphuric acid* assumes a faint violet colour when covered with a thin layer of fuming nitric acid. (Gmelin.)

Hemichloride of copper does not dissolve in water, or in dilute sulphuric acid; but it dissolves without colour in strong hydrochloric acid, in aqueous ammonia, and in solution of common salt. A similar solution is formed by agitating the acid in a close vessel with cuprous oxide, or with a mixture of the protoxide and excess of metallic copper; or by agitating copper-filings with a solution of the protochloride strongly supersaturated with hydrochloric acid; or by mixing the same solution with ether and exposing it to the sun's rays. The colourless liquid prepared hot, deposits crystals of hemichloride of copper on cooling. The solution, when mixed with a considerable quantity of water, deposits the greater part of the hemichloride in the form of a white powder. Small quantities of ammonia added to the solution, produce transparent cubes of hemichloride of copper and ammonium, which dissolve in a larger quantity of ammonia, forming a colourless liquid which turns blue on exposure to the air. Fuming nitric acid imparts to the solution a dark greenish-brown colour, which afterwards changes to yellow with evolution of nitrous gas. (Gmelin.)

The hydrochloric acid solution of hemichloride of copper imparts a blue colour to *molymbdic acid*, decolorises recently precipitated *Prussian blue*, throws down calomel from a solution of *corrosive sublimate*, and metallic gold from a solution of gold. (Proust.)

Aqueous cuproso-cupric Chloride is formed in solution by exposing the solution of cuprous oxide in excess of hydrochloric acid to the air; by mixing the same solution with a solution of protochloride of copper; or by agitating the latter with a small quantity of copper- filings. It is a dark brown liquid. (Proust.)

Ammonio-cuprous Chloride.—Hemichloride of copper forms a colourless solution with aqueous ammonia, from which potash throws down cuprous hydrate, provided the ammonia is not in too great excess.

Chloride of Cuprous and Ammonium.—The solution of cuprous chloride in strong hydrochloric acid mixed with small quantities of ammonia, deposits transparent crystals which appear to be cubes (Gmelin). A similar compound is likewise formed when a solution of sal-ammoniac in which copper is immersed is exposed to the air. (Becquerel.)

Chloride of Cuprous and Potassium, $2\text{KCl}.\text{CuCl}$, is produced when cuprous chloride, as obtained by mixing its hydrochloric acid solution with water, or by precipitating a cuprous salt with stannous chloride, is boiled with a small quantity of water, and mixed with chloride of potassium as long as the latter continues to dissolve. The solution on cooling deposits cubic crystals. Becquerel, by the electrolytic method described at page 53, obtained tetrahedral crystals of the same or similar constitution; also the corresponding *barium-salt*.

Chloride of Cuprous and Sodium.—Cuprous chloride dissolves very readily in solution of common salt, and on evaporating the liquid in vacuo, the double salt crystallises out; with difficulty, however, on account of its great solubility. Potash throws down cuprous oxide; ferrocyanide of potassium yields a white precipitate.

COPPER, DETECTION AND ESTIMATION OF. 1. *Reactions in the Dry Way*.—Copper and its compounds impart a green colour to flame.—The black oxide of copper dissolves by fusion in a vitreous flux, and produces a green glass. Any compound of copper fused with borax in the oxidising flame of the blowpipe forms a transparent glass, which is green while hot, but assumes a beautiful blue colour when cold. In the reducing flame, the glass becomes opaque, and covered on the surface with liver-coloured streaks of cuprous oxide, or metallic copper. This last reaction is somewhat difficult to obtain, especially when the quantity of copper is small, but it may always be ensured by fusing a small piece of metallic tin in the bead. Copper salts mixed with carbonate of sodium or cyanide of potassium, and heated on charcoal before the blowpipe, yield metallic copper. The oxides, carbonates, nitrates, and organic salts of copper are reduced on charcoal without the aid of an alkaline flux.

2. *Reactions in Solution.*

a. *Of Cupric salts*.—These salts in solution have generally a sky-blue colour; a strong solution of the chloride is green, but becomes blue on dilution with water. Copper is separated in the metallic state from its salts by *zinc, iron, lead*, and the more oxidable metals, which are dissolved and take the place of the former metal. Also by *phosphorus* from a solution of the sulphate or nitrate, and from a dilute solution of cupric chloride; but in a strong solution of the latter, phosphorus first produces a white precipitate of cuprous chloride, and then becomes blackened from formation of phosphide of copper. *Wood* precipitates metallic copper from its solutions after long contact. Copper is likewise easily precipitated from its solution by electrolysis, as in the electrolytic process.

Sulphydric acid and *alkaline sulphides* throw down a brownish-black precipitate of protosulphide of copper, insoluble in sulphide of potassium or sodium, slightly soluble in sulphide of ammonium.

Potash or *soda*, added to the solution of a cupric salt, throws down at first a light blue precipitate of hydrated cupric oxide, which, however, on agitation, takes up a portion of the undecomposed salt, and forms with it a green basic salt. An excess of the alkali throws down the hydrate in bulky blue flakes, which, on boiling the mixture, collect together in the form of a black powder, consisting of the anhydrous oxide. This reaction is greatly modified by the presence of *fixed organic substances*, such as sugar, tartaric acid, &c. In a solution of sulphate of copper, containing such substances in sufficient quantity, potash either produces no precipitate, or one which is quickly redissolved, forming a blue solution; and from this solution, when boiled, the copper is sometimes wholly precipitated as red or yellow cuprous oxide, as when grape-sugar is present, or partially, as with cane-sugar, or not at all, as with tartaric acid.

Ammonia, added by degrees, and with constant agitation, to the solution of a cupric salt, first throws down a green basic salt, and afterwards the blue hydrate: an excess of ammonia dissolves the precipitate, forming a deep blue solution. A copper solution diluted so far as to be colourless, becomes distinctly blue on the addition of ammonia.

The blue colour thus produced is still visible, according to Lassaigne, in a solution containing 1 pt. of copper in 100,000 pts. of liquid.

Carbonate of potassium or *sodium* throws down, with evolution of carbonic acid, a greenish-blue precipitate of a basic carbonate of copper, which, on boiling, is converted into the black oxide. *Carbonate of ammonium* produces the same precipitate, but when added in excess, dissolves it abundantly, forming a blue solution.

Cyanide of potassium causes a yellowish green precipitate of cupric cyanide, soluble in excess of the reagent: hydrochloric acid throws down white cuprous cyanide from this solution, soluble in excess of acid: sulphydric acid, or sulphide of ammonium, produces no precipitate.

Ferrocyanide of potassium forms with cupric salts a deep chocolate-coloured precipitate of ferrocyanide of copper. To very dilute solutions it imparts a reddish colour, which is even more delicate in its indications than the ammonia reaction, being still visible in a solution containing 1 pt. of copper in 400,000 pts. of liquid, according to Lassaigne, and in 1,000,000 pts. according to Sarzeau. Ferrocyanide of copper dissolves in aqueous ammonia, and reappears when the ammonia is evaporated. This reaction serves to detect extremely small quantities of copper, even when associated with other metals. Thus, if a solution containing copper and iron be treated with excess of ammonia, a few drops of ferrocyanide of potassium added, the liquid filtered, and the filtrate left to evaporate in a small white porcelain capsule, ferrocyanide of copper will be left behind, exhibiting its characteristic red colour (Warrington, Chem. Soc. Qu. J. v. 137). *Iodide of potassium* added to cupric salts forms a yellow precipitate of cuprous iodide, with separation of iodine. Cupric salts are completely reduced to cuprous salts by *alkaline sulphites*, partially by free sulphurous acid. *Hyposulphites*, at the boiling heat, throw down sulphide of copper.

B. Of Cuprous salts.—But few of these salts are capable of existing in solution. Cuprous oxide is decomposed by non-oxidising acids, such as sulphuric, phosphoric, oxalic, acetic, and even by dilute nitric acid, into metallic copper and a cupric salt, and is oxidised by strong nitric acid, yielding cupric nitrate. Hydrochloric acid added in small quantity to cuprous oxide converts it into white cuprous chloride, which dissolves in a larger quantity of the strong acid, forming a solution which is colourless if quite pure, but generally has a brown tint, due to the presence of a small quantity of anhydrous cupric chloride; on exposure to the air, it gradually turns green. The colourless or brownish solution exhibits the following reactions:—

Water added in sufficient quantity throws down a white precipitate of cuprous chloride, this compound being soluble only in strong hydrochloric acid.

Caustic potash, added in small quantity, neutralises the free acid, and precipitates the white cuprous chloride; in larger quantity it forms a brownish-yellow precipitate of cuprous hydrate, insoluble in excess of potash, soluble in a large quantity of ammonia; when exposed to the air, it gradually turns black.

Ammonia in excess forms a colourless solution, which gradually turns blue on exposure. Potash added to this ammoniacal solution throws down the brownish-yellow hydrate, provided the quantity of ammonia present is not very large in proportion to the potash. *Carbonate of ammonium* acts in like manner.

The *carbonates*, both neutral and acid, of *potassium* and *sodium* form a yellow precipitate of cuprous carbonate.

Iodide of potassium forms a white precipitate of cuprous iodide, without liberation of iodine.

Sulphydric acid produces a black precipitate of cuprous sulphide. *Alkaline sulphides* produce the same precipitate in solutions previously saturated with ammonia.

Zinc and *iron* precipitate metallic copper.

Cuprous solutions are formed by treating the solutions of cupric salts with alkaline sulphites. Free sulphurous acid produces but a partial deoxidation and decoloration, even after prolonged boiling, the product formed being a cuproso-cupric sulphate, which sometimes separates in red crystals; but if potash or ammonia be likewise added, the solution becomes quite colourless even in the cold, and contains a double sulphate of cuprosum and the alkali-metal. This colourless solution behaves with ammonia, and the other reagents above mentioned, in the same manner as the solution of cuprous chloride in hydrochloric acid (excepting that it is not decomposed by dilution), and yields with *cyanide of potassium* a white precipitate of cuprous cyanide, which dissolves in excess of the reagent, forming a solution which is not precipitated by sulphide of ammonium.

Cuprous salts, especially the solution of the chloride in hydrochloric acid, quickly absorb *carbonic oxide gas*. The solution of the chloride saturated with this gas is not precipitated by water, or even by alcohol. (Leblanc.)

Marsh-gas is likewise absorbed by the solution of cuprous chloride.

3. *Quantitative Estimation.*

When copper is dissolved in nitric acid, and the solution does not contain any other metal or non-volatile substance, it is sufficient to evaporate the solution to dryness in a platinum or porcelain crucible, adding a slight excess of nitric acid to prevent reduction of the copper by any deoxidising substance that may be present, and heat the residue to redness. The copper then remains as protoxide, which must be weighed immediately after cooling, with the cover on the crucible, because it is very hygroscopic: 100 pts. of the oxide correspond to 79.82 per cent. of copper.

In other cases the copper must be separated by precipitation. This may be done in several ways.

a. By *caustic potash*, which, when added to a boiling solution of a cupric salt, throws down the copper as protoxide, in the form of a heavy black powder. Care must be taken not to add the potash in too great excess, as a small quantity of the copper will then be retained in solution. The precipitate is to be washed with boiling water, then dried on the filter, ignited in a porcelain or platinum crucible, and weighed with the same precautions as before. As a small quantity of the protoxide may have been reduced by the organic matter of the filter, it is best, after weighing, to moisten it with a few drops of nitric acid, then ignite and weigh again.

b. *Hypochloride of sodium* may, in some cases, be advantageously used in place of caustic alkalis, to precipitate copper as protoxide. (Field, Chem. Soc. J. xiv. 159.)

c. When other metals are present, it is often necessary to precipitate the copper as sulphide, by *sulphydric acid*. In this case the precipitated sulphide must be washed as quickly as possible with water containing sulphydric acid, to prevent oxidation. The precipitate may then be dried, and the filter burnt with the precipitate on it, after which the precipitate is treated with strong nitric acid, which dissolves it, with separation of sulphur, and the copper is precipitated from the solution by potash as above. The chief precaution to be attended to in this process, is to wash the precipitated sulphide quickly, and to preserve it as completely as possible from contact with the air, otherwise the sulphide becomes partially oxidised and converted into sulphate, which, being soluble, runs through the filter; when this takes place, the filtrate becomes brown, because the copper thus carried through is again precipitated by the sulphydric acid in the filtered liquid.

From neutral or alkaline solutions, copper may also be precipitated by *sulphide of ammonium*, but this method is not quite so exact, because sulphide of copper is slightly soluble in that reagent, and the precipitate oxidises more quickly than that formed by sulphydric acid.

d. By *zinc or iron*. A very exact mode of estimating copper is to precipitate it from its solutions in the metallic state by means of pure zinc. The solution, which may contain sulphuric or hydrochloric acid, but should be free from nitric acid, is placed in a platinum capsule or crucible, previously weighed; a piece of zinc large enough to precipitate all the copper is immersed in it; and if the solution is neutral, hydrochloric acid is added in sufficient quantity to produce a moderately brisk disengagement of hydrogen, the vessel being covered with a watch-glass, to prevent splashing. The copper is immediately precipitated, partly on the platinum in a compact layer, partly in the spongy form. As soon as all the zinc appears to be dissolved, the precipitate must be pressed in different parts with a glass rod, to make sure that there are no little lumps of zinc remaining; the complete solution of the zinc may be insured by adding a few drops of hydrochloric acid, and observing whether any further evolution of hydrogen takes place. The clear solution is now to be decanted, and a drop of it tested for copper with ferrocyanide of potassium: if no coloration takes place, the precipitated copper may be washed with hot water by decantation, till the wash-water no longer gives a cloud with nitrate of silver; the greater part of the water in the crucible is then poured off, as much as possible of the remainder taken up by filter-paper, and the precipitated copper dried as rapidly as possible at 100° C., then left to cool and weighed. The precipitation may also be performed in a glass or porcelain vessel, but it is not so rapid as in platinum; it might, however, be accelerated by inserting a piece of platinum foil.

This process gives very exact results, provided the zinc used is perfectly pure; if, on the other hand, the zinc contains lead, or any other metal that will not dissolve in hydrochloric acid, that metal will mix with the precipitated copper and vitiate the result. It is necessary also to avoid using a piece of zinc much larger than is necessary, as in that case, after all the copper is precipitated, an electric circuit may be formed between this copper and the remaining zinc, which may cause a small portion of the dissolved zinc to be deposited on the copper in the metallic state, and to mix itself so intimately therewith, as to render its subsequent separation by hydrochloric acid very difficult. (H. Rose, *Chimie Analytique*, ii. 257.)

Iron is not so good a precipitant as zinc, because it always contains carbon, which remains undissolved and increases the weight of the precipitated copper (Rose). Moreover, unless a certain excess of hydrochloric acid is present, basic salts of iron are sure to be formed, which remain with the copper and increase its weight; and, on the other hand, if much free hydrochloric acid is present, a portion of the precipitated copper is likely to be dissolved in the form of cuprous chloride. (Field, *Chemical News*, i. 62.)

e. Other modes of precipitation.—The following methods have been recommended, but their results are, on the whole, not to be depended upon so much as those of the methods previously given. *α.* By *sulphocyanate of potassium*, in a neutral or slightly acidulated solution of copper, previously treated with an alkaline sulphite, to reduce the cupric salt to a cuprous salt. The precipitate, after being left to settle, is collected on a weighed filter, washed, dried at 100° C., and weighed, the copper being calculated from the weight of the cuprous sulphocyanate, CuCNS , which contains, 52.5 per cent. copper (Rivot). According to Rose, the method is not quite exact, because the sulphocyanate of copper is slightly soluble in water. *β.* By boiling the cupric solution with *hyposulphite of sodium*. The copper is then completely precipitated as sulphide, provided the quantity of the reagent added be only just what is required; but an excess retains a portion of the copper in solution as cuproso-potassic hyposulphite. The method is therefore very uncertain. *γ.* By *iodide of potassium*, which throws down cuprous iodide; but the precipitation is never complete. *δ.* By introducing a weighed piece of metallic copper into a solution of a cupric salt supersaturated with ammonia, and diluted with de-aerated water, so as to completely fill the containing vessel, which is then tightly closed. A quantity of copper is thereby dissolved just sufficient to convert the cupric oxide, Cu^2O , in the solution into cuprous oxide, Cu^+O ,—that is to say, a quantity equal to that which previously existed in the solution. Hence, if the copper plate be weighed after the reaction is complete, the loss of weight gives the quantity of copper in the original solution. This method, given by Levöl, is a modification of Fuchs's method of estimating sesquioxide of iron. (See IRON, ESTIMATION OF.) According to H. Rose (*Chimie Analytique*, ii. 259), the quantity of copper which it gives is always too large.

When copper exists in solution, in the form of a cuprous salt, it may be oxidised by nitric acid, and then precipitated by either of the methods above given.

If a solution of copper contains organic matter, but no fixed inorganic substance, it may be evaporated to dryness, then calcined in a current of air, to burn off the organic matter and oxidise the copper, which may then be moistened with a drop of nitric acid, ignited, and weighed; or the organic matter may be destroyed by either of the processes given in connection with arsenic (i. 366).

Volumetric Methods of estimating Copper.

Parke's method, by cyanide of potassium (*Mining Journal*, 1851).—When a solution of cyanide of potassium is slowly added to a blue ammoniacal solution of copper, the colour gradually becomes fainter and ultimately vanishes, in consequence of the formation of cupro-cyanide of ammonium. The reaction is complicated, several double cyanides of copper and ammonium being formed at first, but, according to Mohr, the ultimate result is the formation of the compound $\text{CuCy} \cdot \text{NH}_4\text{Cy}$, containing 2 at. cyanogen to 1 at. copper. On this supposition, each atom of copper (31.6 grs.) in the solution will require 2 at. cyanide of potassium ($2 \times 65 = 130$ grs.) to precipitate it.

To standardise the solution of cyanide of potassium, a known weight (5 to 10 grs.) of pure electrolyte copper is dissolved in nitric acid, the solution boiled to expel nitrous fumes, then diluted with water to about half a pint, and treated with ammonia in excess; and to the resulting blue liquid, the solution of cyanide of potassium is gradually added from the burette, till the deep blue colour is almost discharged and is replaced by a faint lilac tint. It is then left to stand for about twenty minutes, and if the colour does not completely disappear, a little more of the cyanide solution must be added from the burette, and the liquid again left to stand till the colour has disappeared. The number of burette divisions of the cyanide solution added will give the value in copper of a grain-measure (or of a cubic centimetre) of the solution. Thus, suppose that 200 divisions of the burette are equal to 1000 grain measures, and that 147.5 divisions of the solution are required to decolorise a solution containing 7.5 grains

of copper; then 200 such divisions would decolorise a solution of $\frac{200}{147.5} \cdot 7.5 = 10.17$ grains of copper. By repeating this determination two or three times with different quantities of copper, the mean value of 200 burette divisions may be found. It is convenient to dilute the solution, so that 200 burette divisions shall correspond exactly to 10 grains of copper.

The standard solution of cyanide thus obtained is to be applied in exactly the same manner, to estimate the amount of copper in any given solution. Thus, suppose 37 grs. of a copper-alloy to be dissolved in nitric acid, and that the solution treated with excess of ammonia is decolorised, as above, by 320 burette divisions of the standard cyanide solution; then the quantity of copper in the 37 grs. of alloy is $\frac{320}{200} \cdot 10 = 16$ grs., and the percentage of copper is $\frac{16}{37} \cdot 100 = 43.2$ per cent.

This method is very extensively used for the assaying of copper ores. When carefully performed, it will give the amount of copper correctly within 0.1 or 0.2 per cent. It has also the great advantage of not being vitiated by the presence of iron in the solution. When this metal is present, the cyanide-solution should be added to the ammoniacal liquid *without filtering off the suspended ferric oxide*; for this oxide holds an ammoniacal solution of copper with such tenacity, that it cannot be completely separated, even by several hours washing with boiling water. The method may also be applied to the estimation of copper alloys and minerals containing tin, antimony, or arsenic, but not to such as contain zinc, nickel, cobalt, manganese, or silver, because these metals likewise form double cyanides. (Field, Chemical News, i. 25.)

Pelouze's method, by sulphide of sodium.—The copper being dissolved in an acid, the solution is treated with excess of ammonia; and to the deep blue solution thus formed a solution of sulphide of sodium, of definite strength, is added. The copper is thereby precipitated in the form of an oxysulphide, $\text{Cu}_2\text{O} \cdot 5\text{Cu}_2\text{S}$. By adding the alkaline sulphide cautiously, it is easy to catch the precise moment when all the copper is precipitated, because the liquid at the same time becomes colourless. The quantity of the solution of the alkaline sulphide used indicates the quantity of copper present.

The exactness of this method is not diminished by the presence of iron, zinc, cadmium, tin, lead, or antimony, because the sulphide of sodium does not begin to act on these metals till the copper is completely precipitated; it is essential, however, that the iron be wholly in the state of sesquioxide. It is not necessary to separate the precipitate which some of these metals yield on the addition of ammonia, unless, indeed, it be very copious, in which case it might disguise the colour of the liquid. But the process is vitiated by the presence of cobalt, nickel, mercury, or silver; silver, however, and mercury, if in the state of mercurous oxide, may be easily separated by hydrochloric acid. According to some chemists, this process is liable to uncertainty from two causes: 1st. Because the oxysulphide of copper reduces a portion of the protoxide to hemioxide, thereby rendering the solution colourless before the precipitation is complete; 2ndly. Because a portion of the sulphide of sodium is oxidised and converted into hyposulphite. According to Field, however (Chemical News, i. 62), the process is very accurate, though somewhat tedious.

F. Mohr's method.—The copper-compound having been weighed and dissolved in acid, is mixed, in a porcelain basin, with neutral tartrate of potassium and excess of caustic potash, and then heated with a quantity of milk-sugar or honey, sufficient to precipitate all the copper as cuprous oxide, the completion of the precipitation being indicated by the brown colour which the liquid then acquires. The precipitated cuprous oxide is then filtered, washed with hot water, and gently heated, together with the filter, with a mixture of pure sesquichloride of iron and dilute hydrochloric acid. It is thereby dissolved in the form of protochloride of copper, the sesquichloride of iron being at the same time reduced to protochloride:

In the filtered liquid, diluted to a convenient strength, and heated to about 30°C ., the quantity of iron in the state of protochloride is determined by a graduated solution of permanganate of potassium (see Iron):

and thence the equivalent quantity of copper is readily determined. The presence of lead, zinc, bismuth, manganese, or iron, in the alkaline solution does not interfere with the process; silver or mercury must be separated before the precipitation of the cuprous oxide. (See i. 264.)

Treill's method (Compt. rend. xlvii. 230).—This is similar to the preceding, excepting that the reduction of the cupric to cuprous oxide is effected by adding a solution of sulphite of sodium to the copper solution, previously supersaturated with ammonia. The excess of sulphurous acid is then expelled by boiling with hydrochloric acid, and the copper estimated by means of sesquichloride of iron and permanganate of potassium as above. This method is easier of execution than the preceding, inasmuch as grape-sugar is difficult to wash from the cuprous oxide.

C. Mohr's method.—The copper is precipitated from its neutral solution by metallic

iron ($\text{Cu}^2\text{SO}^4 + \text{Fe}^2 = \text{Fe}^2\text{SO}^4 + \text{Cu}^2$), and the amount of iron in the solution estimated by means of permanganate of potassium.

Fleitmann's method.—The copper is also precipitated by iron, but the precipitate is washed and dissolved in sesquichloride of iron ($\text{Fe}^2\text{Cl}^3 + \text{Cu} = 2\text{FeCl} + \text{CuCl}$), and the iron is determined by permanganate of potassium. This method gives good results. C. Mohr's process is less exact, and is quite inadmissible when iron is also present, as in the greater number of copper ores.

Streng's method.—The cupric oxide in the solution is reduced to cuprous oxide by grape-sugar; the precipitated oxide is dissolved in hydrochloric acid; a solution of starch and iodide of potassium are added; and afterwards a standard solution of acid chromate of potassium, till a blue colour is produced, indicating that the chromate is in excess:

The amount of copper is calculated by the formula:

$$x = \frac{100 \cdot c \cdot C \cdot 12\text{Cu}}{\text{K}^2\text{O} \cdot 2\text{Cr}^2\text{O}^3 \cdot A} = \frac{37920 \cdot c \cdot C}{244 \cdot 4 \cdot A};$$

where C denotes the number of grains-measure of the chromic solution used; c the quantity of acid chromate of potassium in 1 grain-measure of the solution; A the weight of the cupriferous substance dissolved; and x the required percentage of copper.

Brown's method.—The copper solution is treated with iodide of potassium, whereby cuprous iodide is precipitated and iodine set free:

and the free iodine is removed by means of a standard solution of hyposulphite of sodium, whereby iodide and tetrathionate of sodium are produced:

The copper-compound, if solid, an alloy for instance, is dissolved in nitric acid; carbonate of sodium is added till a slight precipitate is formed, and the precipitate is re-dissolved in acetic acid (free nitric acid would vitiate the result by decomposing the iodide of potassium). A quantity of iodide of potassium is next added, equal to, at least six times the weight of the copper to be determined, and then the standard solution of hyposulphite in quantity sufficient to remove the greater part of the free iodine, which point will be indicated by the colour of the liquid changing from brown to yellow. Lastly a clear solution of starch is added, and the addition of the hyposulphite is cautiously continued till the blue colour of the iodide of starch is completely destroyed.—The solution of hyposulphite of sodium is graduated by dissolving a known weight of pure electrotype copper in nitric acid, and proceeding as above, each atom of hyposulphite corresponding to 1 at. free iodine and to $\frac{1}{2}$ at. copper, as shown by the preceding equations. This method of estimating the free iodine is similar in principle to that of Bunsen (i. 265). If the copper-compound contains a large quantity of lead or iron, these metals must be removed before commencing the determination, because the yellow colour of the iodide of lead and the red of the acetate of iron would interfere with the result (Chem. Soc. Qu. J. x. 71). The presence of iron might introduce another source of error, viz. that the sesquioxide of iron would be partially deoxidised by the hyposulphite of sodium. The estimation of copper by this method in many alloys is very rapid and trustworthy.

Field's method.—This process also depends upon the reaction of iodine on cuprous salts. When a solution of iodine in iodide of potassium is added to the solution of a cuprous salt, both the free iodine and that which is in combination unite with the copper. Hence, if the solution of a cupric salt free from nitric acid be reduced to the cuprous state, by mixing it with sulphite of sodium, the excess of sulphurous acid then expelled by boiling with hydrochloric acid, the solution mixed with starch when cold, and a standard solution of iodine in iodide of potassium added from a burette, cuprous iodide will be precipitated; and where the two solutions touch, a bright blue ring will be formed, which disappears at first on agitation, but becomes permanent when the decomposition is complete. An objection to this process, however, appears to be that the cuprous iodide has a great influence on the colour of the iodide of starch, rendering it paler and less distinct. (*Chemical News*, i. 74.)

Scheff's method.—This method is founded on the fact that a solution of sesquichloride of iron mixed with cuprous chloride is not coloured red by sulphocyanate of potassium. Hence, if a cupric solution be boiled with grape-sugar and alkali, till all the copper is precipitated as cuprous oxide, and this oxide be dissolved in hydrochloric acid, the amount of copper contained in it may be determined by adding a

standard solution of ferric chloride, till a drop of the liquid, placed on a white plate, is reddened by sulphocyanate of potassium.

The same method is applicable to the determination of the amount of cuprous oxide in a solution likewise containing cupric oxide. (Ann. Ch. Pharm. cxii. 372.)

4. Separation of Copper from other Metals.

From the metals of the second and third groups (i. 217), and from all non-metallic elements, except selenium and tellurium, copper is easily separated by *sulphydric acid*, which throws it down as sulphide. From the metals of the first group (arsenic, antimony, &c.), and from selenium and tellurium, it may for the most part be separated by the insolubility of its sulphide in the *sulphides of the alkali-metals*. This method cannot, however, be depended upon for the separation of very small quantities of *arsenic and antimony* from copper. Bloxam has shown that it is altogether fallacious when the quantity of arsenic present does not exceed 1 per cent. of the copper. Of tin, much larger quantities may be overlooked, if the separation is based on the solubility of its sulphide in sulphide of ammonium. According to Fresenius, the separation of tin from copper is more easily effected by digesting the sulphide with yellow sulphide of sodium; but to render the separation complete, the digestion must be repeated three or four times.

Antimony is more easily separated from copper than arsenic or tin by means of sulphide of ammonium; but the method does not appear to be capable of detecting less than 0.03 per cent. of antimony in copper.

According to Abel and Field (Chem. Soc. J. xiv. 290) the separation of arsenic from copper may be much better effected by passing sulphydric acid gas, to complete saturation, through the solution of the two metals mixed with excess of ammonia; the copper is then precipitated while the arsenic remains in solution. In this manner $\frac{1}{100}$ per cent. of arsenic may be detected in copper.

When the amount of arsenic is not less than 0.2 per cent. it may also be detected by digesting the sulphides in strong sulphide of ammonium for many hours.

For the detection and estimation of extremely small quantities of arsenic and antimony, such as are often met with in refined copper supposed to be pure (see Table, ii. 37), Abel and Field give the following process.

About 200 grains of the metal are dissolved in nitric acid, a small quantity of *nitrate of lead* is added, equal to about 10 grains of the salt, and subsequently an excess of ammonia and carbonate of ammonia. A precipitate is thereby formed which may consist of oxide, carbonate, arsenate, and antimonate of lead, and oxide of bismuth, the whole of the copper remaining in solution. The precipitate is separated by filtration, thoroughly washed, and digested in a strong solution of oxalic acid, which dissolves the arsenic and antimony. The filtrate is mixed with sulphide of ammonium; or, better, it is rendered alkaline by ammonia and sulphydric acid gas passed into it to saturation. Traces of sulphide of copper then generally separate; after they have been removed, the filtrate is diluted to 8 oz., and slightly acidulated with hydrochloric acid. If any larger amount of arsenic or antimony is present, an immediate precipitate will be formed; if not, the vessel should be exposed for a few hours to a temperature of 140° to 200° F., when the metals, if present, will appear as sulphides, the precipitate being orange-coloured or yellow, according as antimony is present or absent.

The precipitated sulphides are oxidised with strong nitro-muriatic acid, the clear solution is mixed with sal-ammoniac and excess of ammonia, and the arsenic is precipitated by sulphate of magnesium as ammonio-magnesian arsenate. The liquid filtered from this precipitate is slightly acidulated with hydrochloric acid and the antimony is precipitated by sulphydric acid as trisulphide, to be ultimately determined as tetroxide (i. 320). If the presence of antimony and arsenic has been previously ascertained, the precipitation of these metals as sulphides from their solution in oxalic acid may be dispensed with, and the arsenic at once precipitated as ammonio-magnesian arsenate.

A good method of separating copper from arsenic in the analysis of minerals is to evaporate the solution nearly to dryness, add *hypochlorite of sodium* in considerable excess, and boil for about 20 minutes. All the arsenic then dissolves as arsenic acid, while the copper is left behind as black-oxide. (Field, Chem. Soc. J. xiv. 159.)

From bismuth, copper may be completely separated by *cyanide of potassium*, which precipitates the bismuth as cyanide, and retains the copper in solution as potassio-cupric cyanide. If the solution contains a large excess of acid, it should be nearly but not quite neutralised with potash before the cyanide is added. The filtrate is boiled with hydrochloric acid containing a little nitric acid, to convert the copper into chloride, and the copper is then precipitated by potash. The two metals, if precipitated as sulphides, may also be separated by cyanide of potassium, which dissolves the sulphide of copper and leaves the sulphide of bismuth.

If the two metals are dissolved in nitric acid, and no sulphuric acid is present, the separation may be completely effected by adding hydrochloric acid, and then a large quantity of water, which throws down the whole of the bismuth as oxychloride. If the solution is very acid, it should first be concentrated by evaporation. If sulphuric acid is present, the separation must be effected by cyanide of potassium.

The old method of separating copper from bismuth by means of carbonate of ammonia, does not give exact results, some of the copper always remaining with the precipitated carbonate of bismuth, unless the solution and precipitation are repeated several times.

When bismuth and copper exist together in an alloy, they may be separated by heating the alloy strongly in a stream of chlorine. Chloride of bismuth then passes over, and may be received in water, while the copper remains as protochloride, which may be dissolved in water acidulated with nitric acid, and precipitated by potash. (H. Rose.)

For detecting the small quantities of bismuth often found in commercial copper and copper ores, the following method is advantageous. The copper being dissolved in nitric acid, a solution of nitrate of lead (about 5 parts of the salt to 100 of copper dissolved), is added, then ammonia and carbonate of ammonia; the precipitate is washed with ammoniacal water and dissolved in acetic acid; iodide of potassium is added in considerable excess, and the liquid is warmed till the precipitated iodide of lead is redissolved. On cooling, the iodide of lead will be deposited in crystalline scales, which, if free from bismuth, are of a pure gold-yellow colour, but if bismuth is present, assume a dark orange or crimson tint. This test is extremely delicate, even 0.00025 of a grain of bismuth in 100 grns. of copper imparting a dark orange tint to the iodide of lead, while 0.001 gr. imparts a reddish-brown tinge, and 0.01 gr. a bright crimson. (Abel and Field, *loc. cit.*)

From lead, copper may be completely separated by treating the solution with a mixture of *dilute sulphuric acid and alcohol*, which throws down all the lead as sulphate. The filtrate is then boiled to drive off the alcohol, and the copper precipitated by sulphuric acid.

The separation may also be effected by cyanide of potassium, in the manner above described for bismuth.

The separation of these two metals by carbonate of ammonia is never quite complete, still less by caustic potash.

For determining the small quantities of *lead* and *bismuth* found in commercial copper, Abel and Field give the following method, founded on that above described for the estimation of arsenic and antimony.

The nitric acid solution of about 200 grns. of the copper is mixed with a small quantity of solution of phosphate of sodium; ammonia is then added in excess, and the precipitate is purified from copper by washing with ammoniacal water. This precipitate is then dissolved in hydrochloric acid; the solution, rendered alkaline by ammonia, is treated with excess of sulphuric acid; the precipitated sulphides of lead and bismuth are thoroughly washed, and dissolved in dilute nitric acid; and the solution, nearly neutralised with ammonia, is digested with a small quantity of hydrated oxide or basic nitrate of copper, which precipitates the oxide of bismuth, while lead remains in solution. The washed precipitate is dissolved in nitric acid, and the bismuth is separated from the copper by ammonia; the oxide of bismuth thus obtained is purified by washing, and its weight determined in the usual way. The solution containing the nitrates of lead and copper is mixed with carbonate of sodium and excess of acetic acid, and the lead is precipitated as chromate by acid chromate of potassium. [It might also be precipitated by sulphuric acid and alcohol.] If the copper contains iron, that metal will be precipitated together with the bismuth. In this case, the precipitate must be redissolved in an acid, and the bismuth precipitated as sulphide by sulphuric acid.

From cadmium.—The best method of separating copper and cadmium is to mix the solution with *cyanide of potassium*, till the precipitate first formed redissolves, and pass sulphuric acid gas through the liquid. Sulphide of cadmium is then precipitated, while the copper remains dissolved as sulphide. The filtrate is then boiled with hydrochloric and a little nitric acid, till all the hydrocyanic acid is expelled and the copper is precipitated by potash.

Copper may also be separated from cadmium by *carbonate of ammonia*, in which carbonate of cadmium is insoluble; also by *sulphocyanate of potassium*, which precipitates the copper (ii. 58), but not the cadmium.

From silver, copper is separated by precipitating the silver as chloride.

For the separation of copper from mercury, gold, platinum, and the allied metals, see those metals.

5. Valuation of Copper Ores.

1. *By the dry way.*—The ordinary method of assaying copper ores, consists of a series of processes, similar in principle to the operations of smelting on the large scale. Oxidised ores and furnace-products, if moderately rich, are melted with black flux (a mixture of nitre and burnt tartar), whereby a button of metallic copper is obtained, which, if necessary, may be subsequently refined. Poorer oxidised ores and slags are first melted with iron pyrites, to obtain a regulus containing cuprous sulphide, which is then treated as below.

Sulphuretted ores and furnace-products, if rich, are first roasted in a muffle, to convert the sulphides into oxides. Poorer ores, like those of Cornwall, containing from 6 to 10 per cent. of copper, are first fused with a mixture of nitre and borax, whereby a portion of the sulphur is removed; the siliceous and earthy matters are separated in the form of a vitreous slag, and a button of regulus is obtained, containing the whole of the copper as sulphide, which may then be roasted. The roasted ore—or regulus—is next melted in a crucible, with black flux and a mixture of borax and glass; the more oxidable metals then pass into the slag, and the copper is reduced to a button of *coarse copper*, which may be refined either by fusing it with borax in a current of air, or by expelling it with lead.

This process does not yield very exact results, the percentage of copper which it shows being always less than that obtained by the wet method of assaying. For details, see *Ure's Dictionary of Arts, Manufactures and Mines*, i. 839; *Percy's Metallurgy*, i. 454.

Plattner's method.—This method, which is exact, but somewhat difficult of execution, serves to determine the quantities of copper, lead, bismuth, cobalt, and nickel, existing in ores, slags, alloys, &c.: it involves the following series of operations.

a. *Roasting.*—100 cents* of the ore, containing sulphides or sulphates, is roasted on a roasting test (*fig. 142*), first *per se*, then with carbonate of ammonia, till all the sulphur is expelled. Ores containing gypsum, heavy spar, or alkaline sulphides, and in which the metals are united with sulphur or arsenic, are prepared for roasting by fusing 100 cents of the ore with 100 cents of vitrified borax or glass, and 10 cents of colophony, under a layer of 300 cents common salt, in a covered crucible heated for $\frac{1}{2}$ to $\frac{3}{4}$ hour, in a muffle or air-furnace: a regulus is thereby obtained containing the metals. If the metals are in the form of oxides, associated with gypsum or heavy spar, from 10 to 30 cents of metallic arsenic must be added to the preceding mixture. The sulphide of sodium, which is produced by the action of the sulphur on the borax, and passes into the regulus, is washed out with hot water.

Fig. 142.

b. *Conversion of the metals into Arsenides.*—The roasted ore or regulus is triturated with 100 cents of metallic arsenic, and heated for 8 or 10 minutes in a covered assay crucible (*fig. 143*), placed in a closed red-hot muffle, as long as combustible arsenic vapours are evolved. Some of the metals are thereby converted into arsenides, viz. Cu^4As , Pb^4As , Co^4As , Ni^2As , and Fe^3S ; part of the iron is converted into ferroso-ferrie oxide; undecomposed sulphate of lead into sulphide; antimonious oxide into arsenide of antimony; oxide of bismuth into arseniferous metallic bismuth, while the oxide of zinc remains unaltered.

Fig. 143.

Substances not originally containing sulphur, such as black copper, nickel-silver, slags containing cobalt and nickel, &c., are treated in the finely divided state (filed, laminated, or pulverised), in quantities of 50 to 100 cents, with 100 cents of metallic arsenic as above. The product is either a sintered button or a fused mass.

c. *Union of the resulting metallic arsenides into a whole, and separation of the Lead and Bismuth by fusion with appropriate fluxes.*—If the crucible used in the preceding operations is free from cracks, and gives a clear ringing sound when struck, the mass contained in it is covered with 10 to 20 cents of iron wire (according to the amount of lead present), a mixture of 200 cents of black flux, and 50 to 100 cents of vitrified borax (the quantity being greater as the amount of earthy matter in the assay is less), and the whole is covered with 300 cents of purified common salt, and a lump of charcoal. If the crucible has been injured in the preceding operations, a new one must be taken. The crucible, with its cover on, is heated in the

* The cent here spoken of, is not the weight so-called by the Cornish assayers, (= 4 grains), but that which in German assaying is called a *pound*, 100 of which make a *Prober-centner*, equal to 3.75 grammes (or 57.86 grains) at Freiberg, and 3.654 grammes in the Oberharz.

muffle-furnace for 25—30 minutes, or in the air-furnace rather longer, to a temperature gradually raised to the melting point of copper. A successful operation yields a well-fused slag of dark green to black colour, covered with a grey crust of common salt, and at the bottom a regulus, on which, if the substance under examination contains lead, that metal is found to have separated either on the bottom or at the side. In the former case, the lead is removed with the knife; in the latter, the regulus, with the lead side uppermost, is broken up in a mortar, the malleable lead then separating from the brittle arsenic compound, which is mixed with a few cents of colophony, and reserved for further treatment. The lead contains nearly all the silver in the ore, together with the bismuth and a little antimony, but no copper. If lead is absent, the bismuth separates in like manner on the surface of the regulus; but, being brittle, is not so easily separated from the arsenides. In this case, it is necessary to add from 10 to 20 cents of granulated lead, as well as 15—25 cents of iron; the excess then gives approximately the quantity of bismuth. It must, however, be remembered that about 4 per cent. of lead is lost in the process.

d. Separation of the Arsenide of Iron and of the Zinc from the Arsenides of Cobalt, Nickel, and Copper by oxidising fusion on a Scorifier.—The arsenides are placed,

Fig. 144.

together with 50 to 75 cents of borax, on a scorifier (*fig. 144*), surrounded with glowing coals at nearly a white heat, and fused at a strong heat with the muffle closed. After a minute or two the muffle is partially opened, and as soon as the assay has acquired a bright vaporising surface, it is brought a little nearer to the orifice of the muffle, and the temperature is so regulated

that small films of oxide may form upon the surface, and pass into the borax. If the temperature is raised too high, the assay becomes bright, and if it be kept too low, the entire surface becomes oxidised. The process is complete when the surface becomes tranquil, and fumes of arsenic begin to escape. At that stage, the whole of the iron and zinc are separated, the latter by scorification and volatilisation. If the assay becomes covered with a crust before the temperature falls, there is a deficiency of borax, and the process must be repeated on a new scorifier with fresh borax. The button thus obtained is left to cool partially, then completely quenched in water, and carefully cleaned from slag by tapping it with a hammer. If the assay has been removed from the muffle at the proper time, the slag will be quite free from cobalt, nickel, and copper.

e. Removal of the excess of Arsenic by volatilisation.—The metallic button still contains excess of arsenic, which is expelled by mixing it, according to its size, with $\frac{1}{2}$ to 1 cent of borax-glass; laying it, wrapped up in thin paper, on a lump of charcoal having a cavity about half an inch deep, or on a scorifier made of powdered coke and pitch; melting it in a closed muffle; and, when the metal exhibits a shining surface, and begins to give off arsenic vapours, exposing it, with the muffle open, to a moderate heat till it no longer gives off vapours of arsenious acid with rapidity, and such vapours are no longer perceptible on taking the scorifier out of the muffle. The button, which then solidifies with a dull black surface, is weighed; it contains the definite compounds, Co^4As , Ni^4As , and Cu^6As .

The borax-glass dissolves the basic arsenite of cobalt, which is apt to form on the surface of the melted assay if the temperature is not kept high enough, and might hinder the volatilisation of the excess of arsenic. This salt is again reduced to the metallic state as soon as it comes in contact with the carbonaceous support.

f. Separation of the Arsenides of Cobalt from the Arsenides of Nickel and Copper, and determination of the amount of Cobalt.—The weighed button of regulus wrapped up in paper, is laid upon a scorifier containing from 10 to 30 cents of borax, surrounded with hot coals and heated nearly to whiteness; the muffle is closed; and the assay quickly brought to coruscation. The scorifier is then brought nearer to the opening of the muffle; a few pieces of charcoal are laid in front of it; and the arsenide of cobalt, which is the most oxidable of the three arsenides present, is left to be scorified by the borax,—at a temperature at which the fused assay exhibits a clean but not specular surface,—till the surface becomes covered with a green film of arsenite of nickel. If the substance under examination does not contain cobalt, this appearance is observed in the preceding operation, *e*. The loss of weight which the regulus has sustained, consists of Co^4As , containing 61 per cent. of cobalt.

g. Separation of the Arsenide of Nickel from the Arsenide of Copper.—To scorify the arsenide of nickel, the button of regulus still containing Ni^4As and Cu^6As , is treated with borax in the manner above described, till the melted metal becomes bright, no more green films forming on its surface, and it begins to give off arsenic vapours from the decomposition of the arsenide of copper. The chief point to be attended to in this operation is the due regulation of the temperature, which must be lower in proportion as the assay contains a larger proportion of the easily fusible ar-

senide of copper. The loss of weight consists of Ni^4As , and a portion of arsenic volatilised from the arsenide of copper; the nickel cannot, therefore, be calculated directly from this loss, but must be estimated after the amount of copper has been determined. The separation of the arsenide of nickel from the arsenide of copper may be effected with sufficient accuracy, even if the proportion of copper is below 1 per cent.

h. Volatilisation of the Arsenic combined with the Copper, and determination of the proportions of Nickel and Copper.—The button of regulus, wrapped up in paper, is laid upon a glowing charcoal scorifier; the muffle is closed for a while; and as soon as the button is fused, the scorifier is brought near to the mouth of the muffle, which is heaped up with red-hot coals to the height of about $1\frac{1}{2}$ inch; and the assay is kept at a temperature about equal to that required for the cupellation of silver, till films of basic cuprous arsenite begin to show themselves here and there on the clean surface of the metal. It is then exposed to a higher temperature, till it exhibits the bluish green colour of pure copper, and the films which form upon it, make their appearance no longer on the sides, but at the top. The assay is then taken out of the fire and cooled. The button of copper, whatever its colour and texture, must be malleable, and have a small quantity of cuprous oxide on its surface.

The weight of the copper button gives directly the proportion of copper in the assay. To determine the nickel, the copper is calculated as Cu^6As ; the resulting weight is deducted from the known weight of the arsenides of nickel and copper together, and the difference gives the weight of the Ni^4As , which contains 61 per cent. of nickel.

The process of assaying just described may be greatly shortened if one or more of the metals above considered are absent. If, for example, the cupriferous substance is free from nickel and cobalt, as is the case with most copper ores and many products obtained in copper smelting, the operations *f* and *g* become unnecessary, and the process is reduced to the separation of arsenide of iron, including more or less antimony and zinc (*c*) from the arsenide of copper, and the separation of the arsenic from the copper by volatilisation. (Plattner, *Beitrag zur Erweiterung der Probirkunst*, Freiberg, 1849; *Kerl's Hüttenkunde*, ii. 140.)

II. *Assaying of Copper Ores in the wet way.*—The ore being dissolved in nitric acid, the determination of the copper may be made by either of the methods given on pages 57—60. Of the methods by *weight analysis*, however, the one that is generally, indeed almost exclusively, employed, is the precipitation of the copper by iron, as it has the advantage of not requiring any special treatment for separating the copper from the iron in the ore. More exact results would be obtained by the use of pure zinc as the precipitant (p. 57).

Of the *volumetric methods*, that of Parkes is the one most generally used for the valuation of copper ores, as it likewise is not interfered with by the presence of iron, which nearly all these ores contain. Brown's process is exact and expeditious, but it requires the removal of iron and lead. It is, however, unaffected by the presence of arsenic, antimony, tin, or zinc, and is therefore very useful for the analysis of alloys.

An expeditious method of obtaining an approximate estimate of the quantity of copper in an ore or slag, is to dissolve a given quantity of it in nitric acid, mix the solution with excess of ammonia, and compare the colour with those of a series of standard solutions, prepared in a similar manner. (Jacquelin.)

6. Atomic Weight of Copper.

The atomic weight of copper has been determined by reducing a weighed quantity of the protoxide with hydrogen, and weighing the residual metal. In this manner, Berzelius, in 1820 (Pogg. Ann. viii. 182), obtained, as a mean of two experiments, the number 31.65. Erdmann and Marchand (J. pr. Chem. xxi. 385) found, as a mean of five closely agreeing experiments, made with cupric oxide obtained from the nitrate, the number 31.73, which may be received as very near the truth. Dumas (Ann. Ch. Phys. [3] lv. 129) by the same method, and from the weight of cuprous sulphide produced from a given quantity of copper, obtained numbers varying between 31.5 and 32.1, whence he regards 31.75 as the true atomic weight.

COPPER, EMERALD. Syn. with DIOPHASE.

COPPER, FLUORIDES OF. *Protofluoride of Copper*, or *Cupric Fluoride*, is formed by dissolving cupric oxide or its carbonate in excess of aqueous hydrofluoric acid (metallic copper is not sensibly dissolved by the acid), and evaporating the resulting blue solution. As the excess of acid goes off, small, light blue crystals separate from the liquid. If the quantity of cupric carbonate is sufficient to neutralise the greater part of the acid, the compound separates out during the digestion; with a still larger quantity of carbonate, the oxyfluoride $\text{Cu}^2\text{F}^2\text{O} + \text{H}^2\text{O}$ is formed (Berzelius). The crystals, which are but sparingly soluble in cold water, are decomposed by hot

water, yielding an acid solution and the insoluble oxyfluoride. The crystals heated with sulphuric acid yield 116 per cent. of cupric sulphate, and when ignited with excess of lead-oxide give off 26.3 per cent. of water (Berzelius). Protofluoride of copper combines with the fluorides of the alkali-metals, forming black compounds.

The *Hemifluoride*, or *Cuprous Fluoride*, Cu^2F , is obtained by treating cuprous oxide with aqueous hydrofluoric acid, washing the product with alcohol, then pressing and drying. It is a red powder, which melts when heated, appearing black while in the liquid state, but recovering its red colour on cooling. In the dry state it is permanent in the air; but when moist it is converted, first into a yellow mixture of cupric fluoride and hydrated cuprous oxide:

and afterwards into green cupric oxyfluoride:

It is insoluble both in water and in excess of hydrofluoric acid, but soluble in strong hydrochloric acid. In the latter it forms a black solution, from which it is precipitated by water in the form of a powder, which is white at first but afterwards becomes rose-coloured. (Berzelius, Pogg. Ann. i. 21.)

Borofluoride of Copper, CuBF^1 (see i. 634).

COPPER, GREY. (See TETRAHEDRITE).

COPPER, HYDRIDE OF. Cu^2H . When a solution of cupric sulphate is heated with hypophosphorous acid to about 70°C ., hydride of copper is deposited as a yellow precipitate, which soon turns red-brown. It gives off hydrogen when heated; takes fire in chlorine gas; and when treated with hydrochloric acid, is converted into cuprous chloride, with evolution of a double quantity of hydrogen, the acid giving up its hydrogen as well as the copper-compound:

This action is remarkable, inasmuch as metallic copper is but very slowly acted upon by hydrochloric acid. It affords, indeed, a striking instance of the polarity of atoms alluded to in the articles CHEMICAL AFFINITY (i. 857), and CONTACT ACTION (ii. 12).

COPPER, INDIGO. See COPPER, SULPHIDES OF (p. 74).

COPPER, IODIDES OF. *Cupric Iodide*, CuF , is not known in the free state. An *ammonio-cupric iodide*, $2(\text{CuI}.2\text{NH}^3) + \text{H}^2\text{O}$, is produced when cuprous iodide, moistened with ammonia, is exposed for some time to the air, a blue solution being then formed, which, when mixed with alcohol, yields small, dark-blue tetrahedrons of the ammonio-iodide (Rammelsberg, Pogg. Ann. xlviii. 162). According to H. Hahn, it forms crystals belonging to the trimetric system, with the faces $\infty \text{P} \infty . \infty \text{P} . \text{P} \infty . \frac{3}{2} \text{P} \infty . \frac{1}{3} \text{P} \infty . \text{P}$. Ratio of axes = 0.3362:1:1.462 (Jahresber. d. Chem. 1859, p. 217). According to Berthelot, the same compound is obtained by mixing a concentrated ammoniacal solution of ammonio-cupric chloride, or sulphate, with iodide of potassium. It is soluble, without decomposition, in ammonia and in a small quantity of water, but a large quantity of water, especially if hot, decomposes it, with separation of a green oxyiodide. Alcohol and ether do not act upon it in the cold, but decompose it when heated. This compound exposed to the air gives off ammonia, and leaves green oxyiodide. When heated, it first gives off iodide of ammonium, then detonates and leaves a brown-red residue containing cuprous iodide.

Cuprous Iodide, Cu^2I , is produced: 1. By heating finely divided copper with iodine. 2. By precipitating a solution of cuprous chloride in hydrochloric acid with iodide of potassium, or by adding iodide of potassium to the solution of a cupric salt mixed with sulphite or hyposulphite of sodium. 3. By precipitating a dissolved cupric salt with iodide of potassium, half of the iodine being set free:

The precipitate must be washed with alcohol, to free it from adhering iodine. 4. By precipitating the aqueous solution of 1 at. cupric sulphate and at least 1 at. ferrous sulphate, with iodide of potassium (Soubeiran, J. Pharm. xii. 427);

Cuprous iodide, obtained by precipitation, is a brownish-white powder. When heated, it gives off 4 per cent. of water,—agreeing with the formula $2\text{Cu}^2\text{I.H}^2\text{O}$,—and at a red heat fuses into a brown mass, which yields a green powder. It is but

imperfectly decomposed by ignition in a stream of *hydrogen gas* (H. Rose, Pogg. Ann. iv. 110). When ignited with *peroxide of manganese*, it is resolved into iodine vapour and cupric oxide (Soubeiran). With *nitric acid*, it yields vapour of iodine, nitric oxide gas, and cupric nitrate; and with *strong sulphuric acid*, it yields iodine vapour, sulphurous acid gas, and cupric sulphate:

Cuprous iodide boiled with *water*, and *zinc*, *tin*, or *iron*, yields metallic copper and a dissolved iodide of the other metal (Berthelot, J. Pharm. xiv. 614). *Aqueous fixed alkalis* form metallic iodides and separate cuprous oxide; a similar reaction is produced by *carbonate of potassium* or *sodium*, carbonic acid being likewise evolved. Cuprous iodide is not decomposed by baryta, strontia, lime, or alumina. (Berthelot).

Ammonio-cuprous iodide, $\text{Cu}^2\text{I} \cdot 2\text{NH}^3$. When dry ammonia-gas is passed over cuprous iodide, the compound absorbs ammonia, becoming hot, and acquiring a brown colour; but on applying a gentle heat, the whole of the ammonia is driven off (Rammelsberg). When plates of copper are enclosed in a bottle together with a cupric salt strongly supersaturated with ammonia, the liquid being frequently shaken till it loses its colour, and then poured into a bottle containing aqueous iodide of potassium, which must be afterwards closed, ammonio-cuprous iodide separates, partly in colourless shining prisms, partly as a white crystalline powder. It cannot be dried without decomposition, as it gives off ammonia when exposed to the air. The colourless liquid from which the compound has separated, turns blue in the air from formation of ammonio-cupric iodide. (Levol, J. Pharm. [3] iv. 328.)

COPPER, NITRIDE OF. Cu^6N . This compound is formed, together with water, when dry ammonia-gas is passed over very loosely coherent cupric oxide heated to 250°C . The product, which generally contains more or less undecomposed oxide, and sometimes a little nitrate, is a dark green, sometimes nearly black powder, which at 300°C is resolved into its constituents, with slight explosion. The temperature at which this decomposition takes place varies, however, with the nature of the surrounding gas; in oxygen gas it takes place at comparatively low temperatures; in air it requires a higher temperature, and in ammonia gas still higher. *Sulphuric acid* decomposes it with violence, giving off nitrogen and leaving metallic copper; other acids act in a similar manner, those which, like *nitric acid*, oxidise the copper, acting still more violently. In dry *hydrochloric acid gas* it yields sal-ammoniac and cupric chloride. *Chlorine* produces cupric chloride, with evolution of nitrogen. *Aqueous ammonia* does not appear to eliminate gas from the compound, but becomes blue by contact with it. (Schrötter, Ann. Ch. Pharm. xxxvii. 131.)

When dry ammoniacal gas is passed over red-hot copper, the copper becomes crystalline and brittle, but does not appear to take up any gas (Gm. v. 444). From Dick's experiments, it appears that copper is not rendered brittle by heating in ammonia-gas, unless it contains cuprous oxide, in which case the brittleness appears to be due to the porosity resulting from the reduction of the oxide by the hydrogen of the ammonia. (Percy's Metallurgy, i. 278.)

When a ball of copper connected with the positive pole of a six-pair Grove's battery is made to dip into one end of a long glass trough containing solution of sal-ammoniac, and a platinum plate connected with the negative pole into the other end, the sal-ammoniac being kept in excess, the liquid becomes blue, and a nitride of copper collects at the negative pole, in the form of a chocolate-coloured aggregation, which, after washing and drying, has a density of 5.9. Ten grains of this substance give off 0.214 cubic inches of nitrogen gas when heated, leaving metallic copper. (Grove, Phil. Mag. [3] xix. 100.)

COPPER, ORES OF. (See page 19.) The following synonyms require special notice:

Black Copper ore	.	.	Native black oxide.
Blue Copper ore	.	.	Azurite or blue carbonate (i. 783).
Emerald Copper ore	.	.	Diopside, $\text{Cu}^2\text{SiO}^3 + \frac{2}{3}\text{aq}$. (See SILICATES.)
Grey Copper ore	.	.	Tetrahedrite (<i>q. v.</i>)
Green Copper ore	.	.	Malachite or green carbonate (i. 783).
Indigo Copper ore	.	.	Native protosulphide (ii. 74).
Octahedral Copper ore	.	.	Native red oxide (ii. 70).
Variiegated Copper ore	.	.	Purple copper (ii. 80).
Velvet Copper ore	.	.	Native sulphate of copper and aluminium. (See LETTSOMITE and SULPHATES.)
Yellow Copper ore	.	.	Copper pyrites (ii. 79).

COPPER, OXIDES OF. *a. Protoxide or Cupric oxide, Cu^2O or CuO .* *Black oxide of copper; Deutoxyde de cuivre; Kupferoxyd.*—This oxide is found native as *Melaconite or Black Copper (Kupferschwärze)*. It occurs abundantly at Keweenaw Point, Lake Superior, in cubes (perhaps pseudomorphs of red copper ore), with truncated angles; more generally massive. Specific gravity, 6.25 (Whitney), 5.952 (Rammelsberg). Hardness = 3. Colour, dark steel grey in the crystals, black or greyish-black when massive.

Cupric oxide is prepared: 1. By continued ignition of copper in contact with the air. 2. By exposing cupric sulphate to an intense red heat, or the carbonate or nitrate to a moderate red heat. A convenient mode of preparing it for use in organic analysis is to ignite copper smithy-scales, moistened with a sufficient quantity of nitric acid to convert the whole of the metal and red oxide into black oxide. As thus obtained, it is less hygroscopic than when prepared by igniting the nitrate. The heat must not be raised too high, or the oxide will fuse, and will then be difficult to pulverise.—3. According to Ficinus, cupric oxide may be easily prepared by exposing a mixture of 1 pt. copper filings and 2 pts. deliquesced cupric nitrate to the air, till the whole is converted into a basic salt, and then igniting this salt.—4. When caustic potash is added by drops to a boiling solution of a cupric salt till the acid is saturated, the whole of the copper is precipitated as anhydrous black oxide, which may be freed from potash by washing with boiling water.

Cupric oxide prepared as above has the form of brown-black brittle scales and granules, or of a brownish-black powder, which, when strongly heated, assumes for a while a pure black tint. At a full red heat, it melts and solidifies to a mass having a crystalline fracture. By heating it to commencing redness in a silver crucible with from 4 to 6 times its weight of hydrate of potassium, washing the fused mass with water, and separating the flocculent cupric oxide from the crystalline portion by levigation, it may be obtained in regular tetrahedrons having a strong lustre. (Becquerel, *Ann. Ch. Phys.* li. 122.)

Jenzsch (*Pogg. Ann.* cvii. 647) found crystals of cupric oxide imbedded in cavities in the hearth of a calcining furnace at Freiberg; they were iron-black, shining, of specific gravity 6.451, nearly as hard as fluor-spar, and belonged to the trimetric system, exhibiting the faces ∞P . $\dot{P} \infty$. $\dot{P} \infty$. $\frac{1}{2}P$. Inclination of faces: ∞P : ∞P = $99^\circ 39'$; ∞P : $\dot{P} \infty$ = $113^\circ 58'$; ∞P : $\dot{P} \infty$ = $122^\circ 58'$. They were all twin-crystals, the face of combination being ∞P .

Cupric oxide is reduced to the metallic state by gentle ignition with *hydrogen* or *charcoal*; by hydrogen even at the temperature of boiling linseed oil. (Schrötter.)

It is likewise reduced to the metallic state by *potassium* and *sodium*, at temperatures somewhat below the melting points of those metals, and with vivid incandescence. With fused *cyanide of potassium* it yields copper and cyanate of potassium (Liebig). When gently ignited with *metallic copper*, it is converted into cuprous oxide. With phosphorus at a red heat, it yields phosphide and phosphate of copper. Mixed with *phosphoric oxide*, it detonates slightly on the approach of a red-hot coal, and is converted into cupric phosphate and brightly glowing fused globules of phosphide of copper (Leverrier). A mixture of cupric oxide with excess of *sulphur* is resolved at a red heat into cuprous sulphide, sulphurous anhydride, and a trace of cupric sulphate:

If, on the contrary, the cupric oxide is in excess, cuprous oxide and cupric sulphate are produced, and only a trace of sulphurous anhydride, excepting when the heat is raised to the point at which the cupric sulphate is decomposed (Max Jordan, *J. pr. Chem.* xxviii. 222):

When protoxide of copper is boiled with a solution of *stannous chloride*, stannic oxide is precipitated, and cuprous chloride dissolved (Proust; A. Vogel, *Kastn. Arch.* xxiii. 85). *Hydrated ferrous* and cupric oxides are converted by mutual decomposition into hydrated ferric and cuprous oxides; the latter of which may be dissolved out by ammonia (Levol, *Ann. Ch. Phys.* lx. 320; also *J. pr. Chem.* xiv. 115):

In presence of potash or soda, and with the aid of heat, cupric oxide is decomposed by *arsenious anhydride*, the products being cuprous oxide and arsenate of potassium. The decomposition is effected by mixing 160 pts. (2 at.) of cupric oxide with 100 pts. (rather more than $\frac{1}{2}$ at.) of arsenious anhydride, and with excess of soda, and digesting the mixture at a gentle heat, with frequent agitation, till all the protoxide of copper is converted into hemioxide: the solution contains arsenate of sodium:

When ammonia is used in place of soda, only half of the protoxide of copper is converted into hemioxide: the rest remains dissolved in the ammonia, forming a blue solution, and no decoloration takes place till potash or soda is added. A mixture of arsenious acid with carbonate of potassium or sodium or quick-lime does not convert the protoxide of copper into the hemioxide (Bonnet, Pogg. Ann. xxxvii. 300). When *protosulphide of iron* is fused with protoxide of copper, sulphide of copper is formed (Karsten). Protoxide of copper is reduced to the state of hemioxide by boiling it with various organic substances, *e. g.* with *oil of turpentine*.

Hydrated Cupric Oxide, or *Cupric Hydrate*, CuHO , or CuO.HO , is formed by precipitating a dissolved cupric salt in the cold, with a slight excess of dilute caustic potash, quickly washing the blue precipitate with cold water, and drying it at the ordinary temperature of the air. The hydrate generally turns black from admixture of anhydrous cupric oxide, even during the washing and drying. According to Palmstedt, it is more durable when obtained by the action of caustic potash on carbonate of copper previously well washed with water. After drying, it forms greenish-blue friable lumps, having a conchoidal fracture; its taste is strongly metallic. In the dry state it remains undecomposed, even at 100°C ., but at a somewhat higher temperature it is converted into anhydrous black oxide; thus, if the hydrate be heated on paper, the change takes place at a temperature not high enough to char the paper. It is converted into the black oxide, with considerable diminution of volume, when kept for some time under water; also, by boiling in solution of caustic potash. Alcohol does not decompose the hydrate, either in the fresh or in the dry state (Proust, Ann. Ch. Phys. xxxii. 41). Much of the *Blue verditer* or *Bremen green* which occurs in commerce, consists of hydrated cupric oxide, prepared by precipitating a solution of sulphate of copper with caustic potash of 15°B ., washing the precipitate, again treating it with caustic potash of 15° — 18°B ., and lastly washing it thoroughly. The potash-solution must contain a little carbonic acid, in the state, in short, in which it is obtained by slaking 50 pts. of lime in an aqueous solution of 80 pts. of pearlash; otherwise the colour will be spoiled. (Gentele.)

According to Frémy (Ann. Ch. Phys. [3] xxiii. 161), hydrated cupric oxide, obtained by precipitating a solution of cupric sulphate in the cold with a large excess of potash, and then drying in vacuo, contains $\text{Cu}^2\text{H}^2\text{O}^3$, or CuO.2HO .

Cupric Oxygen-salts.—Cupric oxide has a strong affinity for acids, dissolving in them easily, and with evolution of heat, even after ignition; the hydrate and carbonate dissolve with still greater facility. The last-mentioned compounds likewise dissolve in ammoniacal salts, and liberate the ammonia on boiling. The anhydrous cupric salts are mostly white; the hydrated salts have a blue or green colour. They are for the most part soluble in water, and the solutions have a metallic taste and reddén litmus. At a red heat they give off their acid, provided the acid is volatile; the sulphate, however, requires a strong heat to decompose it. For their behaviour with reagents and before the blowpipe, see page 55.

Ammonio-cupric Oxide.—Cupric oxide appears to unite with ammonia in more than one proportion. A dark azure-blue liquid is formed by exposing an ammoniacal solution of cuprous oxide to the air; or by bringing copper filings in contact with aqueous ammonia and a sufficient quantity of air,—or cupric oxide, either anhydrous or hydrated, with aqueous ammonia; or by allowing aqueous ammonia mixed with a few drops of sal-ammoniac solution to trickle through copper-turnings. If all acids, even carbonic acid, be excluded, the ammonia, according to Berzelius, appears to dissolve scarcely a trace of the anhydrous oxide; but on adding a drop of the solution of an ammoniacal salt, the oxide is abundantly dissolved (compare Wittstein, Repert. lvii. 32). The product is a dark azure-blue liquid. *Phosphorus* decolorises it, by forming a compound of cuprous oxide and ammonia, and ultimately precipitates the copper in the metallic state; zinc and cobalt likewise precipitate the copper. *Iron* reduces the copper imperfectly; arsenic, tin, and cadmium reduce it sparingly, and lead exhibits but mere traces of reduction (Fischer, Pogg. Ann. viii. 492). According to Wetzlar (Schw. J. l. 101), iron exerts no action on the pure solution, but slowly precipitates metallic copper from the solution mixed with sal-ammoniac, common-salt, nitre, or sulphate of potassium, nodules composed of copper and ferrous hydrate forming on its surface at isolated points, and extending till the liquid is decolorised. A large excess of ammonia prevents this precipitation, especially if the solution be mixed with nitrate or sulphate of potassium. *Sulphurous acid* added to the solution of cupric oxide in ammonia, throws down nearly all the copper in the form of red-brown cuprous oxide, containing small portions of sulphurous acid [and ammonia?] (A. Vogel). The liquid, when diluted with a large quantity of water deposits the cupric oxide in the form of hydrate. *Potash*—of which a larger quantity is required in proportion as the ammonia is in greater excess—likewise precipitates the cupric oxide, at least after a while, in the form of hydrate

[containing potash?], the precipitation, according to Berzelius, being complete; on boiling the liquid, black oxide of copper is immediately precipitated.

When ammonia, not in excess, is added to cupric salts, the precipitate usually consists of a basic salt free from ammonia; Kane, however (Ann. Ch. Phys. [2] lxxii. 283), on one occasion, by precipitating a solution of cupric chloride with ammonia, obtained a blue precipitate resembling hydrated cupric oxide, which was easy to wash, and did not lose ammonia during the washing. This precipitate underwent no change at $149^{\circ}\text{C}.$; but at a somewhat higher temperature, it was decomposed with a slight hissing noise, yielding nitrogen gas, ammonia, a large quantity of water, and a red mixture of copper and cuprous oxide. It was found to be free from chlorine, and to consist of $4\text{NH}^3.3\text{Cu}^2\text{O} + 6\text{H}^2\text{O}$.

Malaguti and Sarzeau (Ann. Ch. Phys. [3] ix. 431) obtained the compound $4\text{NH}^3.\text{Cu}^2\text{O} + 4\text{H}^2\text{O}$, in fine blue crystals by passing ammonia-gas to complete saturation through water in which basic cupric chromate was suspended, crystallising out a portion of the cupric chromate, and leaving the mother-liquor under a bell-jar together with a mixture of slaked lime, sal-ammoniac, and lumps of quick-lime, so that it might evaporate in an atmosphere of ammonia. Blue crystals of basic cupric chromate then formed, together with green crystals of ammonio-cuprous oxide. These crystals deliquesce and give off ammonia when exposed to the air, and when heated, decompose with incandescence, leaving metallic copper. When a number of them lying together are heated, so that one begins to glow, the incandescence extends to the others, and vermicular tubes of copper are formed, covered here and there with oxide.

The solution of cupric oxide in ammonia, also the ammoniacal solution of basic cupric sulphate or hyposulphate, dissolves cellulose (cotton, linen, hemp-fibre, paper, &c.), this solvent power increasing with the amount of copper in the solution, and the cellulose is precipitated in the amorphous state by acids, salt, sugar, &c. (Schweizer, J. pr. Chem. lxxii. 109; lxxvi. 344; Peligot Compt. rend. xlvii. 1034.) According to Erdmann (J. pr. Chem. lxxvi. 385), the cellulose is not actually held in solution, but merely swollen and held in suspension, like starch in water (i. 820).

HEMIOXIDE OF COPPER, or CUPROUS OXIDE, $\text{Cu}^2\text{O} = \text{Cu}^2\text{O}$, or Cu^2O , also called *Dioxide*, *Suboxide*, and *Red oxide of copper* (*Protoxide de cuivre*, *Kupferoxydul*).—This oxide is found native in two forms; 1. Red copper, (*Rothkupfererz*), which occurs crystallised in the regular system, generally in octahedrons and with octahedral cleavage: also massive, granular, sometimes earthy. Specific gravity = $5.85-6.15$. Hardness = $3.5-4$. Colour red, of various shades, with adamantine, submetallic, or earthy lustre; subtransparent or subtranslucent; occasionally crimson-red, by transmitted light. Streak brownish red, shining. Fracture conchoidal, uneven. Brittle. It occurs in the Bannat, in Thuringia, in Tuscany, in the Isle of Elba in cubes; in Cornwall, at Chessy, near Lyons, where crystals sometimes an inch in diameter are found embedded in lithomarge; at Ekatherinenburg in Siberia; abundantly in South Australia; in the Lake Superior region, and several other localities in North America. When found in large quantities, it forms a valuable ore of copper (Dana, ii. 101).—2. As Copper-bloom, Chalotrichite, or Capillary red oxide of copper (*Kupferblüthe*), which crystallises in the trimetric system, forming prisms with the acute and obtuse edges truncated; observed planes, $\infty \text{P} \cdot \infty \bar{\text{P}} \cdot \infty \bar{\text{P}} \cdot \infty$. It is usually found in fine capillary crystallisations, grouped or reticulated. Cleavage rhomboidal, perfect. Specific gravity = 5.8 . Colour cochineal and crimson-red. Occurs at Rheinbreitenbach, Moldawa, and Nischne Tagilsk. (Dana, ii. 122.)

Preparation.—1. By igniting 4 pts. of copper filings with 5 pts. of the protoxide, or 29 pts. copper filings with 24 pts. anhydrous cupric sulphate.—2. By heating 100 pts. of crystallised cupric sulphate with 57 pts. of crystallised carbonate of sodium, till the water of crystallisation is entirely expelled, and heating the residue to bright redness with 25 pts. copper filings.—3. A mixture of 5 pts. cuprous chloride (obtained by evaporating a solution of cupric chloride and fusing the residue) and 3 pts. anhydrous carbonate of sodium is fused at a gentle heat, and the cooled mass is lixiviated with water to dissolve out the sodium-salts: cuprous oxide then remains as an amorphous powder, of a fine red colour (Wöhler and Liebig, Pogg. Ann. xxi. 581).—4. A solution of equal parts of cupric sulphate and sugar, is mixed with a sufficient quantity of soda-ley to dissolve all the copper, and gently heated; cuprous oxide then separates in the form of a crystalline powder (Mitscherlich, J. pr. Chem. xix. 430).—5. A very fine-coloured oxide is obtained by pouring a cold saturated solution of cupric sulphate into an excess of potash-ley; leaving the precipitated cupric hydrate to settle; then, after washing and pressing, diffusing it, while still moist, through 7 times its weight of water in which 3 parts of sugar are dissolved; adding a solution of 2 pts. hydrate of potassium in a quantity of water equal to that which has been used for dissolving the sugar; agitating the mixture strongly; straining it through linen; and heating it over the water-bath, with brisk agitation. Cuprous oxide is then deposited, and, after

being well washed, exhibits a fine red colour.—6. Cuprous oxide may be obtained in small shining cubical crystals, by filling a test-tube with a neutral solution of cupric nitrate, placing a small quantity of cupric oxide at the bottom, introducing a clean strip of copper-plate, closing the tube air-tight, and leaving it to itself for a few months (Becquerel). The oxide is sometimes found in a similar form on the surface of antique bronzes which have been buried in the earth for a long time.

In whatever way cuprous oxide may be prepared, its colour is finer and more approaching to crimson, in proportion as it is purer and more finely divided. The crystals, whether natural or artificial, yield a crimson powder by trituration.

Cuprous oxide is reduced to the metallic state by gentle ignition with *charcoal* or *hydrogen*; also by *potassium* at a temperature a little above the melting point of the latter. It imparts a ruby-red colour to *glass-fluxes*, if fused in such a manner as to avoid oxidation. It dissolves in excess of *hydrochloric acid*, forming a solution of cuprous chloride, which is decomposed by water. Most other acids, viz. *sulphuric*, *phosphoric*, *acetic*, *oxalic*, *tartaric*, and *citric acid*, decompose it, forming cupric salts and separating metallic copper; *nitric acid* converts it into cupric nitrate. Hence there are but few cuprous oxygen-salts; indeed the only such salts known are the sulphites, and the double sulphites of cuprous and the alkali-metals, produced by treating cupric solutions with alkaline sulphites (ii, 56). With *bromine-water*, it yields cupric bromide and cupric oxide.

Hydrated Cuprous oxide, or *Cuprous hydrate*, $4\text{Cu}^{\text{I}}\text{O} \cdot \text{H}^{\text{I}}\text{O}$?—When a solution of cuprous chloride in hydrochloric acid is poured into excess of soda or potash-ley, or when recently precipitated cupric hydrate is boiled for a few minutes with a solution of milk-sugar containing a small quantity of carbonate of sodium, the liquid then diluted with water, and the precipitate washed, cuprous hydrate is obtained as an orange-yellow powder, which oxidises to cupric hydrate, on exposure to the air. It retains its water at 100°C ., but gives it up completely at 360° , without change of colour; it does not, indeed, assume the red colour of the anhydrous oxide, prepared by the methods previously described, till it is heated to commencing whiteness.

Ammonio-cuprous oxide.—When cuprous oxide or hydrate, or a mixture of cupric oxide and copper-filings, is placed, together with excess of ammonia, in a stoppered bottle, a colourless liquid is obtained, which oxidises so quickly on exposure to the air, that it exhibits a blue colour while being poured in a thin stream from one vessel to another (Bergmann, *Opuscula*, iii. 389; Proust).

SESQUIOXIDE OF COPPER. *Cupric acid*, $\text{Cu}^{\text{II}}\text{O}^3$?—Not known in the separate state. Some of its salts have been obtained in the state of solution, by passing chlorine gas into potash or soda-ley in which hydrated cupric oxide is diffused; but they cannot be obtained in the solid state, inasmuch as they are decomposed, with violent evolution of oxygen, soon after their formation. Cuprate of calcium has however been obtained in the form of a beautiful rose-coloured substance, by mixing chloride of lime with a solution of cupric nitrate; it decomposed but slowly (Krüger, *Pogg. Ann.* lxxii. 445). According to Crum (*Ann. Ch. Pharm.* lv. 213), the oxygen-compound of copper contained in this salt is a sesquioxide, $\text{Cu}^{\text{II}}\text{O}^3$.

PEROXIDE OF COPPER.—1. Formed by agitating the hydrated protoxide with a large excess of very dilute peroxide of hydrogen at a temperature of 0°C .—2. By mixing cupric nitrate with excess of aqueous peroxide of hydrogen, and precipitating the copper at 0°C . by caustic potash added in moderate excess. The resulting peroxide of copper is washed with cold water, pressed between bibulous paper, and dried in vacuo. Yellowish-brown powder (or olive-green, if contaminated with hydrated cupric oxide), tasteless, and without action on vegetable colours. Contains nearly twice as much oxygen as the protoxide. At a temperature short of 100°C ., it gives off oxygen, and is converted into protoxide; in the moist state, it decomposes in the course of 12 hours, even at ordinary temperatures the decomposition being greatly accelerated by the presence of strong caustic potash. It is insoluble in water. With acids, it forms ordinary cupric salts and peroxide of hydrogen (Thénard). It is perhaps not a higher oxide of copper, as Thénard supposes, but rather a compound of cupric oxide with peroxide of hydrogen.

COPPER, OXYBROMIDE OF. A solution of cupric bromide, treated with a quantity of ammonia, not sufficient for complete precipitation, yields a hydrated oxybromide, in the form of a pale green powder, which gives off its water when gently heated, and at a higher temperature gives off bromine, and leaves a grey compound of cupric oxide with cuprous bromide. (Löwig.)

Bromine-water forms, with cupric oxide, an insoluble olive-green substance, which is probably a mixture of cupric hypobromite and oxybromide. It liberates nitrogen from ammonia, does not discharge vegetable colours, is decomposed by the weakest

acids, with evolution of bromine, and at 100° C. gives off oxygen, bromine, and water, and is converted into cupric oxybromide. (Balard, J. pr. Chem. iv. 179.)

COPPER, OXYCHLORIDES OF. Four of these compounds (cupric oxychlorides) are known both in the anhydrous and hydrated states.

a. Cu^3ClO , or $\text{CuCl.Cu}^2\text{O}$. An aqueous solution of cupric chloride, treated with a quantity of potash not sufficient to decompose the whole of it, yields a pale green precipitate, consisting of $\text{Cu}^3\text{ClO.2H}^2\text{O}$, which gives off its water when strongly heated, leaving the anhydrous compound in the form of a black powder. This, when moistened with water, is converted into a bright green powder, containing $2\text{Cu}^3\text{ClO.3H}^2\text{O}$; and this last hydrate, heated to 133° C., gives off $\frac{2}{3}$ of its water, leaving a chocolate-coloured powder, consisting of $\text{Cu}^3\text{ClO.H}^2\text{O}$. (Kane, Ann. Ch. Phys. lxxii. 277.)

b. $\text{Cu}^3\text{ClO}^3 = 2\text{CuCl.3Cu}^2\text{O}$. The anhydrous compound, which is obtained by gently heating the hydrate, forms a brown powder; at a red heat, it gives off oxygen, and is converted into a compound of cupric oxide and cuprous chloride: $2\text{CuCl.3Cu}^2\text{O} = 2(\text{Cu}^2\text{Cl.Cu}^2\text{O}) + \text{O}$. (Proust.)

This oxychloride occurs in nature, associated with various quantities of water, as *Atacamite* (i. 429). Hydrates are also prepared by the following processes: 1. The anhydrous compound is converted into the hydrate by contact with water. 2. Moist cuprous chloride exposed to the air, is converted into a green mixture of hydrated protochloride, which may be extracted by water, and hydrated cupric oxychloride:

3. By digesting aqueous protochloride of copper with the hydrated protoxide; or by mixing it with a small quantity of alkali, sufficient, however, for the precipitation of the dissolved salt. 4. By exposing copper-foil to the air, moistening it repeatedly with hydrochloric acid or solution of sal-ammoniac, and exhausting the product with water. The artificially prepared salt is a pale green powder. It is prepared, by the last process, on the large scale, and constitutes the pigment called *Brunswick green*, which has the advantage of not being affected by sunlight. When gently heated, it gives off water, and is converted into the black anhydrous compound. Cold sulphuric acid turns it brown, and separates protochloride of copper. When heated, it gives off hydrochloric acid. It is insoluble in water, but easily soluble in acids. (Gm. v. 441.)

c. $\text{Cu}^3\text{ClO}^2 = \text{CuCl.2Cu}^2\text{O}$. This compound remains as a green hydrate when the ammonio-chloride, NH^3CuCl , is treated with water. When heated, it gives off its water, and becomes chocolate-brown, and if afterwards exposed to the air, regains a portion of the water which it has lost.

COPPER, OXYFLUORIDE OF. $\text{Cu}^4\text{F}^2\text{O.H}^2\text{O}$, or $2\text{CuF.Cu}^2\text{O} + \text{H}^2\text{O}$.—Pale green insoluble powder, formed by digesting aqueous hydrofluoric acid with excess of cupric carbonate, or by decomposing cupric fluoride (ii. 65), with boiling water. (Berzelius.)

COPPER, OXYGEN-SALTS OF. For the general properties of these salts, see ii. 55, 56; for the particular descriptions, see the several ACIDS.

COPPER OXYSULPHIDES. The compound $\text{Cu}^2\text{S}^3\text{O}$, or $5\text{Cu}^2\text{S.Cu}^2\text{O}$, is obtained, according to Pelouze, by dropping sulphide of sodium into an ammoniacal solution of a cupric salt, heated to 75°—80° C. till the blue colour just disappears, then quickly collecting and washing the resulting precipitate. If the temperature is allowed to rise during the precipitation to 95°—100° C., an oxysulphide of different composition is obtained, which, if boiled with a cupric salt containing excess of ammonia, decolorises and reduces it to a cuprous salt.

An oxysulphide is likewise formed when sulphide of copper is heated in a solution of a cupric salt, most readily if the solution is alkaline.

The brown substance which forms in the first instance, when copper is heated with oil of vitriol, for the preparation of sulphurous acid, has the composition $2\text{Cu}^2\text{S.Cu}^2\text{O}$. By the further action of the acid, which abstracts copper, this compound is converted into $2\text{Cu}^2\text{S.Cu}^2\text{O}$; and when the evolution of gas is at an end, the residual black substance has the composition $\text{Cu}^2\text{S.Cu}^2\text{O}$. (Mauméné, Ann. Ch. Phys. [3] xviii. 311; Handw. d. Chem. iv. 735.)

COPPER, PHOSPHATES OF. Three cupric phosphates occur as natural minerals, viz.:

Libethenite . . .	$4\text{Cu}^2\text{O.P}^2\text{O}^5 + \text{H}^2\text{O}$	or	$\text{Cu}^3\text{PO}^4.\text{CuHO}$.
Phosphocalcite . . .	$6\text{Cu}^2\text{O.P}^2\text{O}^5 + 3\text{H}^2\text{O}$	or	$\text{Cu}^3\text{PO}^4.3\text{CuHO}$.
Thrombolite . . .	$5\text{Cu}^2\text{O.3P}^2\text{O}^5 + 10\text{H}^2\text{O}$	or	$\text{Cu}^3\text{PO}^4.2\text{CuPO}^3 + 5\text{H}^2\text{O}$.

(See these Minerals; also PHOSPHATES.)

COPPER, PHOSPHIDES OF. Copper and phosphorus unite readily at high temperatures. By carefully dropping phosphorus on melted copper in a crucible, the metal may be made to take up as much as 11 per cent. of phosphorus. Phosphorus increases the fusibility and hardness of copper, and when present in large quantity, renders it brittle at ordinary temperatures. Copper containing 11 per cent. of phosphorus is extremely hard, and can scarcely be touched by a file. It has a more or less steel-grey colour, and is susceptible of a fine polish, but speedily tarnishes, especially in a London atmosphere. (*Percy's Metallurgy*, i. 279.)

Several definite phosphides of copper have been prepared by H. Rose (*Pogg. Ann.* iv. 110; xiv. 188; xxiv. 321, 331).

a. Dicupric Phosphide, Cu_2P .—Greyish black crystalline substance, obtained by passing hydrogen gas over dicupric phosphate (Cu^2HPO_4), at a very strong red heat.

A mixture of dicupric phosphide with chlorate of potassium and cuprous sulphide or levigated coke, to increase its conducting power, is used as a fuse for firing charges of gunpowder by magneto-electricity. (Abel, *Chem. Soc. J.* xiv. 183.)

b. Tricupric Phosphide, Cu_3P , is obtained by passing phosphoretted hydrogen gas, (α) over heated protochloride of copper, $3\text{CuCl} + \text{H}^3\text{P} = \text{Cu}_3\text{P} + 3\text{HCl}$, or (β) through a solution of cupric sulphate (H. Rose, *Pogg. Ann.* xiv. 188; xxiv. 321). The first process yields it in the form of a black powder, which, when strongly ignited in a close vessel, is converted into a greyish-black metallic-looking mass, but does not assume the red colour of copper at any temperature. By the second process, it is obtained in black flocks, which, after gentle heating in vacuo, assume a red colour, like that of copper precipitated by zinc (H. Rose). It does not fuse at the melting point of glass, but is more fusible than copper. (Landgrebe, *Schw. J.* 411, 464.)

Tricupric phosphide α exhibits a phosphorus-flame on charcoal before the blow-pipe, β does not; α gives off half its phosphorus when very strongly united in a current of hydrogen gas (H. Rose, *Pogg. Ann.* iv. 110). Both varieties dissolve readily in nitric acid, with formation of phosphoric acid, especially α , if not previously heated. Hot strong sulphuric acid dissolves β , with evolution of sulphurous anhydride. If not previously heated, β dissolves in hydrochloric acid more readily than pure copper, with evolution of non-spontaneously inflammable phosphoretted hydrogen (Buff). β , if not previously heated, is permanent in dry air, but when exposed to a moist atmosphere is converted into cupric phosphate. Before the blow-pipe, it burns to a black bead of cupric phosphate, which solidifies to a white enamel on cooling. (Landgrebe.)

c. Tricuprous Phosphide, Cu_3P , or Cu_2^3P .—Produced by passing phosphoretted hydrogen over cuprous chloride or sulphide:

also by passing hydrogen gas over tricupric phosphide, at a very strong red heat. It is a black powder, or, after strong ignition, a light grey mass, having the metallic lustre. On charcoal, before the blow-pipe, it emits a phosphorus-flame. It is insoluble in hydrochloric acid, but dissolves in nitric acid or aqua regia, forming cupric phosphate. (H. Rose.)

COPPER, PURPLE. (See SULPHIDES OF COPPER AND IRON, ii. 80.)

COPPER, RED. (See COPPER, OXIDES OF, ii. 70.)

COPPER, SELENIDES OF. *Cupric Selenide*, Cu^2Se , is obtained by precipitating cupric sulphate with selenhydric acid, in black flakes, which become dark grey when dry, and acquire metallic lustre by pressure. It gives off half its selenium on distillation. (Berzelius.)

Cuprous Selenide, Cu^+Se , or Cu_2^+Se . Found native, as *Berzelianite*, at Skrikerum in Sweden, and near Lehrbach in the Hartz, in soft thin dendritic crusts, with silver-white colour and metallic lustre. The same compound is produced by heating copper with selenium, and by igniting cupric selenide in a close vessel. Before the blowpipe it emits the odour of selenium, and fuses to a grey bead of brittle, easily fusible copper, still retaining selenium. (Berzelius.)

Selenide of Copper and Lead. (See LEAD, SELENIDE OF.)

COPPER, SILICATES OF. The *metasilicate*, Cu^+SiO_3 , occurs native with 1 at. water, as *Dioptase*, and with 2 at. water, as *Chrysocolle*. Other copper silicates of less definite composition are likewise found. (See SILICATES.)

COPPER, SILICIDE OF. Silicon may be melted with copper into a ductile bead before the blow-pipe, and the compound leaves a siliceous skeleton when dissolved in acids (Berzelius). By heating copper to intense whiteness with white sand and charcoal, a compound is obtained perfectly soluble in acids, the solution when evaporated leaving 5 per cent. of silica (Berzelius). Percy, by this process, obtained

a compound containing 1.82 per cent. silicon. It had a specific gravity of 8.70, was malleable while cold, but brittle at a red heat.

A compound containing from 10 to 11 per cent. of silicon is obtained by heating copper foil or filings with silicofluoride of potassium or sodium, and metallic sodium (Deville). It varies in colour from yellow to greyish white, is very hard and brittle, easily pulverised, more fusible than copper, and is readily attacked by nitric acid, either strong or dilute, with separation of a grey powder: the solution gelatinises on evaporation. (*Percy's Metallurgy*, i. 283.)

COPPER, SULPHATE OF. Neutral cupric sulphate, $\text{Cu}^2\text{SO}^4 + 5\text{H}_2\text{O}$ occurs native as *Cyanosite* (*q. v.*); a basic sulphate, $\text{Cu}^2\text{SO}^4.6\text{CuHO}$, also occurs native as *Brochantite* (i. 664). A sulphato-chloride of copper, called *Connellite*, is found in Cornwall (ii. 11). See also SULPHATES.

COPPER, SULPHIDES OF. Copper has a great affinity for sulphur, burning in its vapour, and uniting with it even at ordinary temperatures, when the two substances are triturated together in the finely divided state. There are two well defined sulphides of copper, Cu^2S and Cu^3S , corresponding to the oxides, and four more of less defined constitution, but supposed to contain respectively 2, 3, 4, and 5 at. sulphur to 2 at. copper.

PROTOSULPHIDE OF COPPER, OR CUPRIC SULPHIDE, Cu^2S or CuS . This compound is found native, as *Covellin*, *Indigo copper*, *Blue copper*, or *Breithauptite*, sometimes in hexagonal plates, with very perfect basal cleavage, more commonly massive or spheroidal, crystalline on the surface. It is soft, flexible in thin leaves, of specific gravity 3.8, opaque, of bluish-black colour, with faint resinous lustre. It occurs, with other copper ores, at Leogang in Saltzburg, Keilee in Poland, Langerhausen in Saxony, Mansfeld in Thuringia, and in the fumaroles of Vesuvius, where it forms a sooty deposit or black network, like a spider's web. (*Gm. v.* 422; *Dana*, ii. 65.)

Cupric sulphide is thrown down from cupric salts by sulphydric acid or sulphide of ammonium, as a brown precipitate, which becomes brown-black when collected, and greenish-black on drying; it oxidises very quickly on exposure to the air, acquiring an acid reaction, and, if moist, is completely converted into cupric sulphate (ii. 57). It is likewise produced by triturating cuprous sulphide with cold strong nitric acid, which abstracts half the copper.

When cupric sulphide is treated with hot nitric acid, the copper is oxidised, part of the sulphur is converted into sulphuric acid, and the rest is separated, so that the resulting solution contains both nitrate and sulphate of copper. Hot concentrated *hydrochloric acid* slowly converts it into cupric chloride, with evolution of sulphydric acid, and separation of sulphur; this reaction takes place most easily with the recently precipitated sulphide. Cupric sulphide decomposes *silver-salts*, the copper dissolving, and sulphide of silver being precipitated. It is insoluble in aqueous sulphurous acid, potash, and the fixed alkaline sulphides, slightly soluble in sulphide of ammonium.

HEMISULPHIDE OF COPPER, OR CUPROUS SULPHIDE, $\text{Cu}^3\text{S} = \text{Cu}^2\text{S}$, or Cu^2S , also called *Disulphide of copper*.—Found native, as *Copper-glance*, *Vitreous copper*, or *Redruthite*, in crystals of the trimetric system, with the form of six-sided prisms, $\infty P : \infty \bar{P} \infty . o P$. Ratio of brachydiagonal, macrodiagonal and principal axis, = 0.5822 : 1 : 0.9741. $\infty P : \infty \bar{P} = 60^\circ 25'$. Cleavage very imperfect, parallel to ∞P (Kopp). Twin crystals are of frequent occurrence. It also occurs massive, with granular or compact and impalpable structure. Specific gravity = 5.5—5.8. Hardness = 2.5—3. Colour blackish lead-grey; lustre metallic; streak lead-grey, sometimes shining. Fracture conchoidal. Sectile. Fine crystals of this mineral are found in the Cornish mines; it occurs also in Haddingtonshire, Ayrshire, and Fair Island, Scotland. The compact and massive varieties occur in Siberia, Hesse, Saxony, the Bannat; also in Connecticut, New Jersey, and other parts of the United States; large and brilliant crystals are found at Bristol, Connecticut. Copper pyrites, purple copper, and black copper, occur as pseudomorphs after copper-glance. (*Dana*, ii. 46.)

Cuprous sulphide is prepared: 1. By triturating copper with sulphur. When 64 pts. (2 at.) of finely divided copper, obtained by reducing the carbonate with hydrogen, and 16 pts. ($\frac{1}{2}$ at.) of milk of sulphur are dried together over oil of vitriol, and triturated together in a mortar, so gently that no heat is produced by the friction, they combine as soon as a uniform mixture is attained, and form bluish cuprous sulphide, the combination being attended with a development of heat which raises the mass to redness. If the proportion of the copper to the sulphur be even slightly altered, the experiment fails, even though the mortar be warmed. If the mortar be warmed to 20° to 25° C, it is not necessary to dry the powders previously, and moreover, flowers of sulphur may be used instead of milk of sulphur, only that longer trituration is neces-

sary to induce combination (Winkelblech, Ann. Ch. Pharm. xxi. 34). Sulphide of copper is also formed by triturating copper filings with sulphur and water.—2. Thin copper leaf burns with vivid inflammation in a glass flask in which sulphur has been heated till it volatilises. 8 pts. of copper filings mixed with 3 pts. of pounded sulphur unite, with incandescence, when heated. The same compound is obtained by fusing together plates of copper and pounded sulphur, arranged in a crucible in alternate layers.—3. By igniting protoxide of copper with sulphur.—4. 100 pts. of dry cupric sulphate heated to whiteness in a crucible lined with charcoal, yield 47.6 pts. of cuprous sulphide, mixed with a few granules of the metal. (Berthier, Ann. Ch. Phys. xxii. 236.)

Artificial cuprous sulphide has a density of 5.9775 (Karsten); it is of a blackish lead-grey colour, and fuses much more easily than the metal.

Cuprous sulphide is not decomposed when heated to redness out of contact of air; but if the air has access to it, combustion takes place, and sulphurous anhydride and free cupric oxide are produced. When heated to redness in a current of *aqueous vapour*, it is but slightly decomposed; but at a white heat, it yields large quantities of hydrogen gas and sulphuretted hydrogen, together with sublimed sulphur, and the copper is completely reduced to the metallic state (Regnault, Ann. Ch. Phys. lxii. 378). [There is no statement as to what becomes of the oxygen of the water.] By *phosphoretted hydrogen* gas at a red heat, it is very slowly resolved into $\text{Cu}^{\text{c}}\text{P}$ and sulphuretted hydrogen (H. Rose):

It is not altered by ignition in a stream of hydrogen (H. Rose). It is not decomposed by *chlorine gas* at ordinary temperatures, very slowly when heated (H. Rose, Pogg. Ann. xlii. 540). It dissolves with difficulty in strong boiling *hydrochloric acid*, with evolution of sulphuretted hydrogen and formation of hydrochloric acid and cuprous oxide; in heated *nitric acid*, it dissolves with separation of sulphur, whereas cold nitric acid withdraws half the copper and leaves protosulphide of copper. 100 pts. of cuprous sulphide, ignited with 77 pts. or rather less of *nitre*, yield from 66 to 70 pts. of metallic copper (Berthier). When cuprous sulphide is fused with a mixture of *caustic soda* and *carbonate of sodium*, part of the copper is reduced. The same reducing action is exerted by a mixture of *carbonate of sodium* and *charcoal*, whereas carbonate of sodium or potash alone has no effect. When 100 pts. of cuprous sulphide are fused with 70 pts. of dry carbonate of sodium and with charcoal, one half of the copper is reduced, and the rest combines as sulphide of copper with the sulphide of sodium which is formed. When 1 pt. of cuprous sulphide is heated to whiteness with 4 pts. of carbonate of sodium, in a crucible lined with charcoal, nearly all the copper is reduced. 100 pts. of cuprous sulphide ignited with 400 pts. of dry carbonate of sodium and 30 or 40 pts. of iron, yield at most 60 pts. of copper. Also, when cuprous sulphide is heated to whiteness with *baryta* or *lime* and *charcoal*, part of the copper is reduced, and sulphide of copper and barium or calcium formed at the same time (Berthier, Ann. Ch. Phys. xxxiii. 160). When cuprous sulphide is fused with *protoxide of lead*, the mass boils up and yields sulphurous anhydride, cuprous oxide, which combines with the undecomposed lead-oxide, forming a red shining slag, and metallic lead; 100 pts. of cuprous sulphide and 200 litharge, yield 104 pts. of copper containing lead. With from 300 to 500 pts. of litharge, a grey, semiductile alloy, rich in lead, is obtained. When 1000 pts. of litharge are used, 280 pts. of ductile lead separate out, and 2500 pts. of litharge yield 385 pts. of lead. It is only therefore with this last proportion that the whole of the sulphide of copper is resolved into sulphurous anhydride and cuprous oxide:

Accordingly, 160 pts. (1 at.) $\text{Cu}^{\text{c}}\text{S}$ should separate 624 pts. (6 at.) of lead = 100 : 390 (Berthier, Ann. Ch. Phys. lxxxix. 246). *Metallic lead* exerts no decomposing action on cuprous sulphide when fused with it (Karsten). Cuprous sulphide, ignited with *cupric oxide* is easily converted into sulphurous anhydride and metallic copper, or cuprous oxide. 1 at. $\text{Cu}^{\text{c}}\text{S}$ and 2 at. $\text{Cu}^{\text{c}}\text{O}$ are completely converted into sulphurous anhydride and copper:

With 6 at. $\text{Cu}^{\text{c}}\text{O}$, the only products are sulphurous anhydride and cuprous oxide:

Any excess of cuprous sulphide remains undecomposed. Metallic *iron* decomposes cuprous sulphide, though very imperfectly, yielding copper containing iron, iron

containing copper, and sulphide of copper and iron. *Ferric oxide* exerts but a slight decomposing action, and ferrous silicate none at all. (Gm. v. 421.)

Polysulphides of copper.—An aqueous solution of pentasulphide of potassium forms, with cupric salts, a liver-coloured precipitate, consisting of Cu^2S^5 , which turns black after drying, is not altered by exposure to the air, or by washing with boiling water, and when recently precipitated dissolves in aqueous carbonate of potassium, forming a brown solution.—The disulphide, trisulphide, and tetrasulphide of potassium, form with cupric salts, precipitates of the same colour, likewise soluble in carbonate of potassium, and consisting either of the compounds, Cu^2S^2 , Cu^2S^3 , and Cu^2S^4 , or of mixtures of Cu^2S and Cu^2S^3 . (Berzelius.)

Sulphides of Copper and Antimony. *a. Wolfsbergite. Antimonial Copper, Chalcostibites, Kupferantimonglanz.*—A mineral occurring at Wolfsberg in the Harz, and at Guadiz in Spain, in small aggregated tabular prisms of the trimetric system, exhibiting the faces $\infty\text{P} \cdot \infty\text{P} \cdot \infty\text{P}^2 \cdot \infty\text{P}^3$. Inclination of faces $\infty\text{P} : \infty\text{P} = 101^\circ$; $\infty\text{P}^2 : \infty\text{P}^2 = 138^\circ 12'$; $\infty\text{P}^2 : \infty\text{P}^3 = 112^\circ 24'$. Cleavage very distinct, parallel to ∞P^3 ; less distinct, parallel to ∞P . Specific gravity 4.748. Hardness = 3–4. Lustre metallic. Streak black. Colour between lead- and iron-grey. Opaque. Fracture conchoidal. Before the blowpipe it decrepitates, fuses readily, and on charcoal gives fumes of antimony; after strong heating with soda, it yields a globule of copper.

The mineral is a cuprous sulphantimonite, $\text{Cu}^2\text{Sb}_2\text{S}^3$, or $\left. \begin{matrix} \text{Cu}' \\ \text{Sb}''' \end{matrix} \right\} \text{S}^2$.

	Calculation.		H. Rose. Wolfsberg.	Th. Richter. Guadiz.
	63.3	25.61		
Cu ²	63.3	24.46	25.36
Sb	120.3	46.81	48.30
S ²	64.0	26.34	25.29
Iron	1.39	1.23
Lead	0.56	
	247.6	100.00	99.56	100.18

b. Wolchite. Antimonial Copper-glance, Antimonkupferglanz.—A mineral occurring in the iron mines at St. Gertraud, Carinthia, in short rhombic prisms, cleaving imperfectly parallel to the brachydiagonal; also massive. Specific gravity 5.7–5.94. Hardness = 3. Fracture conchoidal to uneven. Brittle.

The analyses of this mineral differ widely, as the following table will show:—

	Schrötter.	Rammelsberg.	
		16.81	15.23
Sulphur	28.60	15.23
Copper	17.35	42.83
Antimony	16.65	24.41
Arsenic	6.03	
Lead	29.90	15.59
Iron	1.40	0.36
	99.93	100.00	100.11

The mineral is probably nothing but a partially altered Bournonite (i. 651). (Rammelsberg, p. 80; Dana, ii. 82.)

For the *Sulphantimonites of copper and iron*, &c., see TETRAHEDRITE.

Sulphides of Copper and Arsenic.—None of these compounds occur as natural minerals (see SULPHARSENITES and SULPHARSENATES, i. 390, 393). In many varieties of grey copper the antimony is partly replaced by arsenic. (See TENNANTITE.)

Sulphides of Copper and Bismuth. *a. Tannenite, Kupferwismuthglanz.*—Occurs at Tannenbaum, near Schwarzenberg in the Erzgebirg, in thin striated prisms, apparently trimetric. Lustre bright metallic. Colour greyish to tin-white. Heated in an open tube it yields sulphur. Before the blowpipe on charcoal, it fuses easily with intumescence, and yields with soda a globule of copper. Dissolves in nitric acid with deep bluish-green colour.

Schneider found in this mineral (mean of two analyses) 18.83 per cent. S, 62.16 Bi, and 18.72 Cu, which agrees very nearly with the formula $\text{Cu}^2\text{S} \cdot \text{BiS}^3$, or $\left. \begin{matrix} \text{Cu}' \\ \text{Bi}''' \end{matrix} \right\} \text{S}^2$ (calculation 19.08 S, 62.01 Bi, 18.91 Cu). The mineral is, therefore, analogous in constitution to Wolfsbergite. (Rammelsberg, p. 103; Dana, ii. 73.)

b. Wittichenite. Cupreous Bismuth, Kupferwismuthz.—A mineral found in the cobalt mines near Wittichen, in Baden, sometimes massive and disseminated, some-

times in coarse columnar shapes, or aggregates of imperfect prisms (trimetric?), cleaving in one direction. Specific gravity = 5. Hardness = 3·5. Colour steel-grey or tin-white, tarnishing pale lead-grey. Streak black. Fuses easily in an open tube, yielding sulphur and a white sublimate. On charcoal before the blowpipe it decrepitates, melts, forms a yellow deposit, and after reduction with soda a globule of copper. Boiled with hydrochloric acid in a flask, without access of air, it dissolves, with elimination of sulphuretted hydrogen, to a nearly colourless liquid, a certain quantity of admixed metallic bismuth remaining undissolved. If, on the other hand, the air has access to the liquid, the metallic bismuth likewise dissolves after a while. Nitric acid dissolves the mineral with separation of sulphur.

The analysis of this mineral by Schneider (Pogg. Ann. xciii, 305, 472), after deduction of the admixed metallic bismuth, gives 19·42 per cent. S, 43·05 Bi, and 37·53 Cu, agreeing with the formula $3\text{Cu}^2\text{S}.\text{BiS}^3$, or $\frac{\text{Cu}^{2+}}{\text{Bi}^{3+}} \left\{ \text{S}^3 \right\}$ (calculation 19·50 S, 42·98 Bi, and 38·42 Cu). Other analysts have obtained different results, because they overlooked the admixed metallic bismuth (Rammelsberg, p. 104). A grey massive mineral found in the Geistergang at Joachimsthal, containing 9·94 per cent. S, 30·74 As, 45·31 Bi, and 13·04 Cu, appears to be a mixture. (Rammelsberg, *loc. cit.*)

Sulphides of Copper, Bismuth, and Lead. See NEEDLE-ORE.

Sulphides of Copper and Iron. *a. Copper Pyrites. Chalcopyrite, Iowanite, Cuivre pyriteux, Kupferkies.* CuFeS , or $\text{Cu}^+\text{S}.\text{Fe}^+\text{S}$.—This mineral occurs in crystals of the dimetric system, often tetrahedral. The primary form P, for which the length of the principal axis is to that of the secondary axis as 0·985 : 1, the angle of the terminal edges = $109^\circ 53'$, and of the lateral edges = $108^\circ 40'$, occurs in the hemihedral form as a sphenoid (see CRYSTALLOGRAPHY), both alone and in combination, as in *fig. 145*. Cleavage parallel to $2\text{P} \infty$, but generally indistinct. Frequently in twins. It often occurs also massive and impalpable. Specific gravity 4·1–4·3. Lustre metallic. Colour brass-yellow, subject to tarnish, and often iridescent. Streak greenish-black, a little shining, opaque. Fracture conchoidal, uneven. Rather sectile. It decrepitates when heated, acquiring a darker colour, and sometimes giving off a trace of sulphur. Gives off sulphurous anhydride when roasted. On charcoal before the blowpipe it melts, with intumescence and sparkling, to a globule which is dark grey within, black and rough without, and is attracted by the magnet. The roasted globule gives, with fluxes, the reactions of copper and iron. It dissolves in nitric acid, with separation of sulphur.

Fig. 145.

The formula CuFeS requires 34·59 per cent. Cu, 30·52 Fe, and 34·89 S.

Copper pyrites is the principal copper ore in the Cornish mines, where it occurs associated with tin, purple copper, copper glance, galena, grey copper, and blende. The Cornwall copper pyrites is not, however, a rich ore, rarely yielding 12 per cent., generally only 7 or 8, and sometimes only 3 or 4 per cent. of copper. If of a fine yellow colour and yielding readily to the hammer, it may be considered a good ore; but if hard and pale yellow, it is poor, from admixture of iron pyrites. The copper beds of Fahlun in Sweden are also composed chiefly of copper pyrites, which occurs there in large masses, surrounded by a coating of serpentine and imbedded in gneiss. It occurs also at Rammelsberg, near Goslar in the Harz; at Freiberg, in the Bannat; in Hungary; in Thuringia; in Scotland, in Kirkcudbright, Wigtonshire, Perthshire, and Invernesshire; in Tuscany; South Australia; and at numerous localities in the United States.

Copper pyrites is distinguished from iron pyrites, which it somewhat resembles, by

its inferior hardness; it may be cut with the knife, while iron pyrites strikes fire with steel. It differs from gold in being brittle and attacked by nitric acid.

Copper pyrites changes to cupric sulphate on exposure to moisture, especially if heated; it is sometimes also altered to malachite, covellin, chrysocolla, black copper, copper-glance, and oxide of iron.

b. Purple Copper. Erubescite, Variegated Copper, Liver-coloured Copper Ore, Phillipsite, Bornite (Buntkupfererz, Bunter Kupferkies, Cuivre pyriteux hépatique).—This mineral forms crystals belonging to the monometric or regular system, namely, the cube, octahedron, rhombic dodecahedron, and intermediate forms. Cleavage octahedral, indistinct. Twin crystals are of frequent occurrence; also imperfect crystallisations, with granular strongly connected structure. Specific gravity = 4.4—5.003. Hardness = 3. Lustre metallic. Colour between copper-red and pinchbeck-brown, quickly acquiring a parti-coloured tarnish. Streak pale greyish black, slightly shining. Fracture small conchoidal, uneven. Brittle.

Purple copper does not give off sulphur when ignited in a test-tube, but when heated in a tube open at both ends, it yields a large quantity of sulphurous anhydride, but no sublimate. Heated on charcoal before the blowpipe, it acquires a dark tarnish, then becomes black, and red on cooling. At a somewhat stronger heat, it melts to a brittle globule, which becomes magnetic after sufficient blowing, and appears greyish-red on the fractured surface. When roasted for a considerable time, and then treated with a small quantity of borax, it yields a button of copper, and if fused with carbonate of sodium after the sulphur is completely expelled, it yields separate granules of copper and iron. After roasting, it exhibits with fluxes the reactions of cupric and ferric oxides. When moistened with hydrochloric acid, it colours the blowpipe flame blue.

There are several varieties of purple copper. Rammelsberg (*Mineralchemie*, p. 114) arranges them in three groups, containing respectively from 56 to 58 per cent., 60 to 64 per cent., and 70 per cent. copper.

1. Purple copper, containing from 56 to 58 per cent. copper.—*a.* Crystallised, from the Condurra mine near Cambern, Cornwall. *b.* Crystallised, from Redruth, in Cornwall (Chadnew). *c.* Crystallised, of unknown origin (Varrentrapp). *d.* Massive, from Monte Cattini in Tuscany (Bechi). *e.* Massive, from the Mårtenberg mine, Dalarne, Sweden. (Plattner.)

	<i>a.</i>	<i>b.</i>	<i>c.</i>	<i>d.</i>	<i>e.</i>

3. Containing 70 per cent. copper.—*o.* From Eisleben (Plattner). *p.* From Monte Castelli, Tuscany. *q.* From Nadaud, France (Berthier). *r.* From Sangershausen, near Eisleben. (Plattner.)

	<i>o.</i>	<i>p.</i>	<i>q.</i>	<i>r.</i>
Sulphur . . .	22.65	22.3	20.0	22.58
Copper . . .	69.72	70.0	70.0	71.00
Iron . . .	7.54	7.0	7.9	6.41
	99.91	99.3	97.9	99.99

Rammelsberg regards the several varieties of *purple copper* as isomorphous mixtures of the compounds $3\text{Cu}^*\text{S}.\text{Fe}^*\text{S}^3$, and $n\text{Cu}^*\text{S}.\text{Fe}^*\text{S}$. If $n = 0$, this formula is reduced to $3\text{Cu}^*\text{S}.\text{Fe}^*\text{S}^3$, which requires 28.04 per cent. S, 55.60 Cu, and 16.36 Fe, agreeing nearly with analysis *a* of the mineral from the Condurra mine. Any value of n greater than 2 increases the proportion of copper; $n = 3$ gives 25.67 per cent. S, 60.85 Cu and 13.48 Fe, which is very nearly the composition of the minerals *h*, *i*, *j*; and $n = 11$ requires 22.62 per cent. S, 70.40 Cu, and 6.68 Fe, which is nearly the composition of the specimens *o*, *r*.

Purple copper occurs associated with other copper ores. Crystalline varieties are found in Cornwall, mostly in the mines of Tincroft and Dolwath, near Redruth, where it is called by the miners "horse-flesh ore." Massive varieties are found in Ross Island, Killarney, in the cupriferous shale of the Mansfeld district, also in Norway, Siberia, Silesia, the Bannat, and in Pennsylvania, New Jersey, and Connecticut.

c. Cuban. This mineral, found at Barracanao in Cuba, is also monometric, occurring in cubes; also massive. Colour between bronze and brass-yellow. Streak, dark, reddish, bronze, black. Specific gravity = 4.026 (Breithaupt); 4.169 (Booth). Hardness = 4. Melts easily before the blow-pipe, giving off fumes of sulphur. The following analyses have been made of it (deducting silica):

	Scheidthauer.	Eastwick.	Stevens.	Magee.
Sulphur	34.78	39.93	40.11	40.19
Copper	22.96	20.26	21.46	20.71
Iron	42.51	38.90	39.55	39.41
	100.25	99.09	101.12	100.31

The first analysis agrees nearly with the formula $\text{Cu}^2\text{Fe}^4\text{S}^3$, or $\frac{\text{Cu}^2\text{S}}{2\text{Fe}^2\text{S}}\{\text{Fe}^4\text{S}^3\}$, which requires 35.38 per cent. S, 23.38 Cu, and 41.24 Fe; the others, which contain a much larger quantity of sulphur, approach more nearly to the formula $\text{Cu}^2\text{S}.\text{Fe}^4\text{S}^3$, which requires 42.21 S, 20.84 Cu, and 36.94 Fe. (Rammelsberg, p. 118, Dana ii. 681.)

d. Copper regulus. It has already been mentioned that the reguli produced in copper-smelting consist essentially of cuprous sulphide, Cu^2S , associated with sulphides of iron (ii. 27—31 and 34, 35). Field (Chem. Soc. J. xv. 125) regards all copper reguli as compounds of cuprous sulphide in various proportions with 1 at. Fe^4S^3 , 1 at. Fe^2S , and 2 at. Fe^2S . The following table exhibits the composition of some samples of furnace reguli at different stages of the smelting process, as compared with this theoretical view. The first is clean regulus from a furnace; the second is the same after some hours roasting; the third the same after further roasting and skimming. The fifth (with 8 at. Cu^2S) is a specimen of native blue sulphide.

Composition of Copper Regulus.

	With 3 at. Cu^2S .		With 5 at. Cu^2S .		With 6 at. Cu^2S .		With 7 at. Cu^2S .		With 8 at. Cu^2S .		With 12 at. Cu^2S .

COPPER, TELLURIDE OF. Pale red compound. (Berzelius.)

COPPER, TUNGSTATE OF. Found native in a mine in Carrabas County, North Carolina. (Dana, ii. 502.)

COPPER, VANADATE OF. Occurs native, as Volborthite, in Siberia and Thuringia. *Vanadates of copper and lead* are found in the Lake Superior region, and in Chile. (See VANADATES.)

COPPER, VARIEGATED. Syn. with PURPLE COPPER (ii. 77).

COPPER, VITREOUS. Syn. with COPPER-GLANCE (ii. 74).

COPPER-BASES, AMMONIACAL. The ammonio-chlorides, iodides, oxides, &c., of copper already described, and likewise certain ammonio-copper compounds containing sulphuric and other oxygen-acids, may be regarded as salts of ammonium-molecules, in which the hydrogen is more or less replaced by ammonium and by cuprium, or cuprosum, thus $[\text{Am} = \text{NH}^1]$:

1. Chloride of Cuprammonium } $\text{NH}^3.\text{CuCl}$ = $(\text{NH}^3\text{Cu}).\text{Cl}$
(ii. 53)
2. Sulphate of Cuprammonium } $2\text{NH}^3.\text{Cu}^2\text{SO}^4$ = $(\text{NH}^3\text{Cu})^2\left\{\begin{smallmatrix} \text{SO}^2 \\ \text{SO}^2 \end{smallmatrix}\right\} \text{O}^2$
3. Sulphate of Cupricum and } $\text{NH}^3.\text{Cu}^2\text{SO}^4$ = $\frac{\text{NH}^3\text{Cu}}{\text{Cu}}\left\{\begin{smallmatrix} \text{SO}^2 \\ \text{SO}^2 \end{smallmatrix}\right\} \text{O}^2$
Cuprammonium
4. Chloride of Ammo-cupram- } $2\text{NH}^3.\text{CuCl}$ = $\text{N}(\text{H}^2\text{CuAm}).\text{Cl}$
monium

5. Iodide of Ammo-cuprammonium	$2\text{NH}^3.\text{CuI}$	$= \text{N}(\text{H}^2\text{CuAm}).\text{I}$
6. Bromate of Ammo-cuprammonium	$2\text{NH}^3.\text{CuBrO}^3$	$= \text{N}(\text{H}^2\text{CuAm}) \left\{ \begin{array}{l} \text{O} \\ (\text{BrO}^2)' \end{array} \right\}$
7. Nitrate of Ammo-cuprammonium	$2\text{NH}^3.\text{CuNO}^3$	$= \text{N}(\text{H}^2\text{CuAm}) \left\{ \begin{array}{l} \text{O} \\ (\text{NO}^2)' \end{array} \right\}$
8. Hydrate of Ammo-cuprammonium	$4\text{NH}^3.\text{Cu}^2\text{O} + 4\text{H}^2\text{O}$	$= 2 \left(\text{N}(\text{H}^2\text{CuAm}) \left\{ \begin{array}{l} \text{O} \\ \text{H} \end{array} \right\} \right) + 3 \text{ aq.}$
9. Hyposulphate of Ammo-cuprammonium	$4\text{NH}^3.\text{Cu}^2\text{S}^2\text{O}^6$	$= [\text{N}(\text{H}^2\text{CuAm})] \left\{ \begin{array}{l} \text{O}^2 \\ (\text{S}^2\text{O}^4)' \end{array} \right\}$
10. Iodide of Ammo-cuprosammonium	$2\text{NH}^3.\text{Cu}^2\text{I}$	$= \text{N}(\text{H}^2\text{CuAm}).\text{I}$
11. Hydrate of Ammo-tricuprammonium	$4\text{NH}^3.3\text{Cu}^2\text{O} + 6\text{H}^2\text{O}$	$= 2 \left(\text{N}(\text{Cu}^3\text{Am}) \left\{ \begin{array}{l} \text{O} \\ \text{H} \end{array} \right\} \right) + 7 \text{ aq.}$
12. Chloride of Diammo-cuprammonium (ii. 53)	$3\text{NH}^3.\text{CuCl}$	$= \text{N}(\text{HCuAm}^2).\text{Cl}$
13. Sulphate of Cupricum and Triammo-cuprammonium	$4\text{NH}^3.\text{Cu}^2\text{SO}^4 + \text{H}^2\text{O}$	$= \text{N}(\text{CuAm}^3) \left\{ \begin{array}{l} \text{O}^2 + \text{aq.} \\ (\text{SO}^2)' \end{array} \right\}$
14. Bromide of Ammo-dicupro-diammonium (ii. 52)	$3\text{NH}^3.2\text{CuBr}$	$= [\text{N}^2(\text{H}^3\text{Cu}^2\text{Am})]''.\text{Br}^2$
15. Bromide of Triammo-dicupro-diammonium (ii. 52)	$5\text{NH}^3.2\text{CuBr}$	$= [\text{N}^2(\text{H}^3\text{Cu}^2\text{Am}^3)]''.\text{Br}^2$
16. Sulphate of Triammo-dicupro-diammonium	$5\text{NH}^3.\text{Cu}^2\text{SO}^4$	$= [\text{N}^2(\text{H}^3\text{Cu}^2\text{Am}^3)]'' \left\{ \begin{array}{l} \text{O}^2 \\ (\text{SO}^2)' \end{array} \right\}$

Pentammonio-cupric Sulphate, or *Sulphate of Triammo-dicupro-diammonium*, $5\text{NH}^3.\text{Cu}^2\text{SO}^4$, is produced when anhydrous cupric sulphate is exposed to the action of dry ammonia-gas, rapid absorption then taking place, attended with rise of temperature and tumefaction. The product is a blue powder, which melts at a moderate red heat, giving off a large quantity of ammonia, together with water and sulphite of ammonium, and leaving cupric sulphate mixed with metallic copper. It dissolves completely in water, forming an azure-blue solution. (Rammelsberg, Pogg. Ann. xx. 150.)

Tetrammonio-cupric Sulphate, or *Sulphate of Cupricum and Triammo-cuprammonium*, $4\text{NH}^3.\text{Cu}^2\text{SO}^4 + \text{H}^2\text{O}$, also called *Cuprosulphate of ammonia*, *Cuprum ammoniacale*, *Kupfersalmiak*, is produced by treating crystallised cupric sulphate, either pulverised or dissolved in water, with ammonia, till the precipitate is completely redissolved. It crystallises by evaporation, or better, on carefully covering the solution with a layer of alcohol, or exposing it to a low temperature, in long thin prismatic crystals of the trimetric system, transparent, and of dark azure-blue colour. On agitating the ammoniacal solution with alcohol, the salt is precipitated in the form of a blue crystalline powder. It must be quickly dried between bibulous paper, and kept in well closed vessels. It dissolves in $1\frac{1}{2}$ times its weight of cold water. When exposed to the air, it gives off ammonia and leaves a green powder, which appears to be a mixture of sulphate of ammonium and tetrabasic cupric sulphate, $\text{Cu}^2\text{SO}^4.3\text{Cu}^2\text{O}$. When heated for some time to a temperature not exceeding 149°C , it gives off 2 at. ammonia and 1 at. water, and leaves sulphate of cuprammonium:

and this residue gradually heated to 205°C . gives off another atom of ammonia, leaving sulphate of cupricum and cuprammonium, $(\text{NH}^3\text{Cu}).\text{Cu}.\text{SO}^4$: and this again, if gradually heated to 260°C . still gives off 1 at. ammonia, and leaves neutral sulphate of copper, Cu^2SO^4 . The aqueous solution of the tetrammonio-cupric salt when exposed to the air, deposits tetrabasic cupric sulphate, which is likewise precipitated when the solution is largely diluted with water. Zinc quickly precipitates metallic copper from the solution; cadmium and lead decompose it more slowly; arsenic decomposes it completely, forming cupric arsenite; bismuth, antimony, tin, and iron have no effect upon it. (Gm. v. 449.)

Neutral Sulphate of Cuprammonium, $(\text{NH}^3\text{Cu})^2.\text{SO}^4$, obtained as above stated by gradually heating the preceding salt to 149°C . is an apple-green powder, which, on exposure to the air, absorbs water and turns blue. If moistened with a small quantity of water, it becomes very hot, and turns blue immediately. An excess of water decomposes it into sulphate of ammonium, tetrammonio-cupric sulphate, and tetrabasic cupric sulphate:

Sulphate of Cupricum and Cuprammonium, $\text{NH}^3\text{Cu}^2\text{SO}^4$, or $\left\{ \begin{smallmatrix} \text{NH}^3\text{Cu} \\ \text{Cu} \end{smallmatrix} \right\} \text{SO}^4$, is the residue obtained by gently heating anhydrous cupric sulphate saturated with ammonia, or by gradually heating tetrammonio-cupric sulphate to 149°C . (Gm. v. 450.)

Diammonio-cupric Nitrate, or *Nitrate of Ammo-cuprammonium*, $2\text{NH}^3\text{CuNO}^3$, is obtained by saturating a hot concentrated solution of cupric nitrate with ammonia-gas, and leaving the solution to crystallise by cooling. It forms blue needle-shaped crystals, which give off a little ammonia when heated, but no water if it has been previously well dried. At a higher temperature it explodes. It dissolves easily in water; a small quantity of acid added to the solution throws down a basic cupric nitrate. (Gm. v. 455.)

Bromate of Ammo-cuprammonium, $2\text{NH}^3\text{CuBrO}^3$, is precipitated in dark blue needles and as a crystalline powder, on adding alcohol to an ammoniacal solution of cupric bromate. It turns green when exposed to the air, dissolves in a small quantity of water, but is decomposed by a larger quantity, with precipitation of cupric hydrate. (Gm. v. 453.)

The corresponding *iodate* is formed in a similar manner.

Tetrammonio-cupric Hyposulphate, or *Hyposulphate of Ammocuprammonium*, $4\text{NH}^3\text{Cu}^2\text{S}^2\text{O}^6$, is produced by supersaturating a somewhat dilute solution of cupric hyposulphate with ammonia. It crystallises in azure-blue rectangular tables, permanent in the air, sparingly soluble in water. (Gm. v. 448.)

The following salts have lately been obtained.

Silicate of cuprammonium	$(\text{NH}^3\text{Cu})^2\text{Si}^2\text{O}^5$
Tungstate of cuprammonium	$(\text{NH}^3\text{Cu})^2\text{W}^2\text{O}^4 + \text{H}^2\text{O}$
Metantimonate of cuprammonium	$(\text{NH}^3\text{Cu})^4\text{Sb}^2\text{O}^7 + 4\text{H}^2\text{O}$
Pyrophosphate of cuprammonium	$(\text{NH}^3\text{Cu})^4\text{P}^2\text{O}^7 + \text{H}^2\text{O}$
Orthophosphate of cupricum and cuprammonium	$(\text{NH}^3\text{Cu})^2\text{Cu.PO}^4$
Arsenate of cuprammonium	$(\text{NH}^3\text{Cu})^2\text{H.AsO}^4 + \text{H}^2\text{O}$
Acetate of cuprammonium	$\text{C}^2\text{H}^3(\text{NH}^3\text{Cu})\text{O}^2 + \text{H}^2\text{O}$
Tartrate of cuprammonium	$\text{C}^4\text{H}^4(\text{NH}^3\text{Cu})^2\text{O}^6$
Tartrate of ammocuprammonium	$\text{C}^4\text{H}^4(\text{NH}^2\text{AmCu})^2\text{O}^6$
Succinate of ammocuprammonium	$\text{C}^4\text{H}^4(\text{NH}^2\text{AmCu})\text{O}^4$
Anisate of ammocuprammonium	$\text{C}^6\text{H}^7(\text{NH}^2\text{AmCu})\text{O}^3 + \text{H}^2\text{O}$

These salts are obtained either by saturating cupric salts with ammonia, or by decomposing monammonio-cupric sulphate, $\text{NH}^3\text{Cu}^2\text{SO}^4$, with barium salts.

Ethylamine seems to form cuprammoniums of analogous composition. (Hugo Schiff, *Compt. rend.* liii. 410; *Ann. Ch. Pharm.* cxxiii. 36.)

COPPER-FROTH. A basic arsenate of copper, $\text{Cu}^3\text{AsO}^4.2\text{CuHO} + \frac{7}{2}\text{aq.}$, also called *Tyrolite* and *Pharmacosiderite*, found native at Falkenstein in the Tyrol, and other localities. (See **TYROLITE**.)

COPPER-GLANCE. Native cuprous sulphide (ii. 74).

COPPER-GLANCE, ANTIMONIAL. (See ii. 75.)

COPPER, GREEN, or *Chrysocola*. A native silicate of copper, $\text{Cu}^2\text{SiO}^3 + \text{aq.}$, occurring in Cornwall, Hungary, Siberia, South Australia, &c., and used as an ore of copper. (See **SILICATES**.)

COPPER-MICA. This term is applied to two very different substances, viz.:
1. A native arsenate of copper of somewhat variable composition ($\text{Cu}^3\text{AsO}^4.5\text{CuHO} + x\text{aq.}$), also called *Tamarite* and *Chalcophyllite*. (See **TAMARITE**.)

2. A *cuprous antimonite*, $3\text{Cu}^2\text{O.Sb}^2\text{O}^3$, or Cu^2SbO^3 , which is sometimes found in refined copper prepared from antimonial ores, and renders it more cold-short than red-short. When copper of this description is dissolved in cold or slightly warmed nitric acid, the cuprous antimonite is left behind, in very thin, regular, six-sided laminae, translucent, having a gold-yellow colour, and becoming brown and opaque while hot. In the flame of the oxyhydrogen blow-pipe, they melt to a black-brown glass. With borax they exhibit a slight intumescence, and form a yellowish-brown glass, turning greenish-blue when mixed with nitre. Strong hydrochloric acid dissolves them more completely than any other acid. The compound gave by analysis (deducting small quantities of lead, silver, iron, silica, and alumina), 57.68 per cent. Cu^2O , and 42.32 Sb^2O^3 (calculation, 58.54 Cu^2O , and 41.16 Sb^2O^3). (Hausmann and Stromeyer, *Schw. J.* xix. 241).

Copper-mica, nickeliferous ($7\text{Cu}^2\text{O}.5\text{Ni}^2\text{O}$). Sb^2O^3 ? This compound is obtained from copper smelted at Goslar. After the copper has been treated with dilute nitric acid, the copper mica is freed from arsenical oxide of antimony — proceeding from

antimonide of copper previously contained in the copper, and decomposed by the nitric acid—by digesting it in a mixture of hydrochloric and tartaric acid. In this manner 100 parts of highly micaceous copper yield 4.16 pts. of pure copper-mica. It forms pale greenish-yellow, translucent, strongly lustrous, regular six-sided laminæ, which assume a transient yellow colour when heated. This compound neither fuses nor suffers any alteration at a red heat. With carbonate of soda on charcoal, it yields a white brittle metal, and covers the charcoal with antimonious oxide. Heated in the outer blowpipe-flame with borax or microcosmic salt, it dissolves immediately, and forms a light green glass. It is scarcely attacked by acids, excepting by concentrated hydrochloric acid, which dissolves it after long boiling. When hydrogen gas is passed over 100 pts. of red-hot copper-mica, a quantity of water is obtained corresponding to 18.19 per cent. of oxygen. (In this reaction 2.55 pts. of the mica—that which contains only nickel and no copper—appear to escape decomposition.) The residue is baked together, but still retains the form of laminæ; it may be decomposed by nitric acid or by chlorine; in either case, the pure nickel-mica remains undecomposed.

Nickeliferous copper-mica gives by analysis (abstracting the nickel-mica) 44.28 per cent. Cu^2O , 30.61 Ni^2O , and 25.11 Sb^2O_3 , the above formula requiring 45.13 Cu^2O , 30.21 Ni^2O , and 24.66 Sb^2O_3 . (Boucher, Pogg. Ann. xli. 335.)

COPPER-NICKEL. Native arsenide of nickel. (See NICKEL.)

COPPER-PYRITES. (See SULPHIDES OF COPPER AND IRON, ii. 77.)

COPPERAS. Protosulphate of iron. (See SULPHATES.)

COPROLITES. The excrements of extinct animals, found in large quantities in certain geological formations, especially in the lias. Their true nature was first pointed out by Buckland. They consist mainly of phosphate and carbonate of calcium, the quantity of phosphate sometimes amounting to between 80 and 90 per cent.; they contain also magnesia, oxide of iron, silica, water, and organic matter, with small quantities of manganese and fluorine. Their composition is, in fact, very much like that of bone, the bony constituents of the excrements having resisted the action of decomposing agents more than the other portions. The quantity of phosphoric acid in coprolites renders them very valuable as manure.

Analyses of Coprolites.

The chalk marl and adjoining strata are also very rich in coprolites and other petrifications containing phosphoric acid, as shown by the following analyses made by Messrs. J. M. Paine and J. T. Way (Journ. Roy. Agr. Soc. vol. ix. pt. 1):

a. The chalk marl with fossils containing a large quantity of phosphoric acid. *b.* The marl itself from which the petrifications have been separated by sifting. *c.* Indurated marl and small fossils which remained on the sieve. *d.* Marl from Bentley with the fossils. *e.* The fossils therefrom. *f.* Petrifications in the upper marly layer of the Upper Greensand. *g.* Soft amorphous bodies in the same. *h.* Petrifications in the Gault, very rich in phosphoric acid. *i.* Petrifications at the junction of the Gault with the Lower Greensand. *k.* A conglomerate of petrifications with sandstone cement. *l.* Green granules from the Lower Greensand.

Petrifications in the Chalk Marl and adjoining Strata.

COPULA. See CONJUGATED COMPOUNDS (ii. 8).

COQUIMBITE. *White Copperas.*—A hydrated ferric sulphate found in the district of Copiapo in the province of Coquimbo, Chile, apparently produced by the weathering of iron pyrites. It forms crystals belonging to the hexagonal system, namely, small six-sided prisms with truncated pyramidal summits, ∞ P. P. ∞ P. Angle of the terminal edges = $128^{\circ} 8'$; of the lateral edges = 58° . Cleavage imperfect, parallel to the prismatic faces. Also in fine-grained masses. Specific gravity = 2—2.1. Hardness = 2.25. Colour white, inclining to brown, yellow, green, and sometimes blue. Lustre vitreous. Transparent or translucent. Taste astringent. Before the blowpipe it first gives off water, then sulphurous acid, and leaves a residue of ferric oxide. It dissolves in cold water and in hydrochloric acid, leaving only a small quantity of silica. The aqueous solution deposits a large quantity of ferric oxide on boiling.

Analyses by H. Rose (Pogg. Ann. xxvii. 310):

	SO ³	Fe ⁴ O ³	Al ⁴ O ³	Ca ² O	Mg ² O	SiO ²	H ² O
Crystalline	43.55	24.11	0.92	0.73	0.32	0.31	30.10 = 100.04
Granular	43.55	25.21	0.78	0.14	0.21	0.37	29.98 = 100.24

These analyses agree nearly with the formula:

[if $f^2 = \frac{2}{3}\text{Fe} = 18\frac{2}{3}$], which requires 42.7 SO³, 28.5 Fe⁴O³, and 28.8 water.

The same salt has been found, also in hexagonal crystals, by Seacchi in the Phlegrean Fields, together with Halotrychin. Rammelsberg (*Mineralchemie*, p. 274) also regards as coquimbite, a mineral from Coquimbo, formerly called *Blakeite*, analysed by Blake (Journ. Bost. Soc. Nat. Hist.), and found to contain 41.37 per cent. SO³, 26.79 Fe⁴O³, 1.05 Al⁴O³, 0.30 Mg²O, 0.82 SiO², and 29.40 water, which agrees nearly with the preceding formula; but it crystallises in regular octahedrons. Dana suggests that it may be an iron alum.

CORACITE. A mineral found on the north coast of Lake Superior, where it forms beds 2 inches thick in syenite. It is amorphous, with rough, conchoidal, resinous fracture. Colour black with grey streak. Specific gravity 4.378. Hardness 4.5. Heated alone before the blowpipe it remains unaltered; with fluxes it gives the reactions of uranium. It appears to be a variety of pitchblende, in which the uranic oxide is partly replaced by alumina (Leconte, Sill. Am. J. [3] iii. 173;

Jahresber. d. Chem. i. 1847-48, 1167). An analysis by Whitney (Sill. Am. J. [2] vii. 434) gave :

U ⁴ O ³	Al ⁴ O ³	Fe ⁴ O ³	Pb ² O	Ca ² O	CO ²	SiO ²	HO	Total.
59.30	0.90	2.24	5.36	14.44	7.47	4.35	4.64	= 98.70

CORAL. Coral rocks consist mainly of carbonate of calcium, with variable quantities of carbonate of magnesium and organic matter, and small quantities of phosphate, sulphate, and fluoride of calcium, alkaline chlorides, oxide of iron and silica. Silliman found in fresh corals only 1 per cent. of magnesia, but in dense coral rock the carbonate of magnesium was found to amount to 38.07 per cent. Another rock, consisting of the débris of corals contained 5.29 per cent. carbonate of magnesium. The presence of the magnesia appears to be due to a double decomposition taking place between the original carbonate of calcium of the rock, and the magnesian salts in sea-water, a process which likewise contributes to the hardening of the rock. (Jahresber. d. Chem. 1847-8, 1291.)

B. Silliman, jun. (Sill. Am. J. [2] xii. 174), found in a considerable number of reef-forming corals, from 2.11 to 9.43 per cent. organic matter; the residue left after the removal of this contained from 97 to 99 per cent. carbonate of calcium, together with soluble silica, lime probably in combination with silica, also carbonate of magnesium, and the other salts above-mentioned.

The red pigment of corals is, according to Trommsdorff, not ferric oxide, but a red resin soluble in oil of turpentine, and after removal from the coral by this solvent, easily soluble also in alcohol and ether, but insoluble in caustic potash. In a red madrepora, Vauquelin found a red colouring matter, which was turned violet by alkalis.

The organic matter of the stems of polypes appears in some cases to consist of chitin or conchiolin.

In *Corallium nobile*, Forchhammer found 2.13 per cent., in *Isis hippurites*, 6.32 per cent. carbonate of magnesium. In *Corallium rubrum* and *Madrepora oculata*, Stratingh and Fyfe found a trace of iodine.

Respecting the composition and alterations of coral rocks, see also Dana (Sill. Am. J. [2] vi. 268). Forchhammer (J. pr. Chem. xlix. 52; Chem. Gaz. 1849, 411.)—Damour (Ann. Ch. Phys. [3] xxxii. 362). Dana (*ibid.*, 410).—Also Jahresber. d. Chem. 1847-8, p. 1291; 1849, p. 813; 1851, p. 865; 1852, pp. 958-961.

CORALLINA OFFICINALIS. *Nodularia officinalis*, *Muscus corallinus s. marinus*.—The shell of a marine radiate animal, formerly used in medicine. According to an analysis by Bouvier (Ann. Chim. viii. 308), it consists of 61.6 per cent. carbonate of calcium, 7.4 carbonate of magnesium, 0.3 gypsum, 1.9 chloride of sodium, 0.2 ferric oxide, 6.6 gelatinous matter, 6.4 albumin, and probably also iodine and bromine. It was used comminuted and mixed with other corals, viz. *C. fragilissima*, *C. cylindrica*, *C. moniformis*, &c.

CORDIERITE. Syn. with DICHOÏTE.

CORIANDER, OIL OF. (Trommsdorff, Arch. Pharm. [2] ii. 114.—Kawalier, J. pr. Chem. lxxviii. 226.)—Coriander seeds, the fruit of *Coriandrum sativum*, contain about 0.37 per cent. of a volatile oil, besides fat, extractive matter, &c. The volatile oil, which is obtained by distilling the bruised fruit with water, is colourless or pale yellow, has an aromatic taste, and when concentrated, smells like the seeds, though more agreeably; in the dilute state it smells like orange-flowers. Specific gravity 0.859 (Trommsdorff), 0.871 at 14° C. (Kawalier). It dissolves in alcohol, ether, and oils, both fixed and volatile. It explodes violently with iodine. With strong nitric acid, it becomes very hot, and forms a resinous mass. Strong sulphuric acid converts it into a brown-red liquid, which carbonises quickly when heated.

Coriander oil is a mixture of several oils, and appears to vary in composition. It contains a volatile oxygenated oil, and a less volatile oil containing little or no oxygen. The crude oil begins to boil at 150° C., an oil then passing over corresponding in composition to the formula C¹⁰H¹⁸O, or C²⁰H¹⁸O²; afterwards the temperature rises, and a less volatile oil distils over, containing, according to Kawalier, C¹⁰H¹⁸O, or perhaps 2C²⁰H¹⁶.HO, or 4C¹⁰H¹⁶.H²O. The crude oil distilled with phosphoric anhydride yields a distillate of camphene, C¹⁰H¹⁶.

Coriander-oil saturated at a low temperature with hydrochloric acid gas, forms a permanent liquid hydrochlorate, which may be purified by washing with weak soda-ley, and drying over chloride of calcium. According to Kawalier, it contains C¹⁰H¹⁸O.Cl², or perhaps 4(C¹⁰H¹⁶.HCl) + H²O.

CORIARIN. A crystalline substance said to exist in the leaves of *Coriaria myrtifolia*. (Peschier, Trommsd. N. J. xvi. 57.)

CORK. The outer bark of the *Quercus suber*, a tree which grows to the height of 30 or 40 feet, in the South of Europe, in the North of Africa, and in the East. It is distinguished by peculiar toughness, softness, and elasticity, which render it indispensable for a variety of purposes.

Cork consists for the most part of a modified form of cellulose, called *suberin*, which remains behind after the cork has been exhausted with alcohol, ether, water, and sulphuric acid.

Chevreul also found in cork a fragrant substance, *cerin* (i. 830), which passed over on distilling the cork with water, a soft resin, a yellow and a red colouring matter, quercitannic acid, gallic acid, and a brown nitrogenous substance, together with 0.7 per cent. calcium, salts of vegetable acids, and 4 per cent. water, which is given off at 100° C.

Cork oxidised with nitric acid yields oxalic, suberic, and ceric acids (i. 830).

CORK, MOUNTAIN. See ASBESTOS (i. 415).

CORNEINE. A compact hornblende rock, of smooth fracture, extremely tough, and sonorous when struck.

CORNEOUS LEAD. Native chloro-carbonate of lead, $2\text{PbCl.Pb}^2\text{CO}^3$; also called *cerusine*. (See LEAD, CHLORIDE OF.)

CORNIN, or CORNIC ACID. A crystallised bitter substance, obtained from the root of *Cornus florida*, by exhausting the root with water, mixing the solution with moist hydrate of lead, evaporating the filtrate to an extract, treating the residue with absolute alcohol, mixing the turbid solution with ether, digesting the filtrate with carbonate of lead, filtering again, distilling off the greater portion of the liquid, and leaving the remaining turbid liquid to evaporate. Cornin is then deposited after 12 hours, in stellate groups of delicate crystals having a satiny lustre.

Cornin dissolves easily in water and in alcohol, sparingly in ether. The solutions are not precipitated by alkalis, tincture of galls, iron-salts, barium-salts, or neutral lead-salts, but give precipitates with basic acetate of lead, and nitrate of silver. Cornin does not exhibit basic properties; it is partly separated from its solutions by charcoal, either vegetable or animal, so that these substances cannot be used to decolorise the solutions. (Geiger, Ann. Ch. Pharm. xiv. 206.)

CORNITE. A name sometimes applied to the compact felspar which constitutes the base of porphyry.

CORNOVIN. A resin obtained from the bark of an East Indian tree, called *Coroa* or *Cornova*. It is brownish-yellow, of oily consistence, inodorous, has a rough irritating taste, and acid reaction. It dissolves easily in absolute alcohol and in ether, but not in oils. (Trommsdorff, Trommsd. N. J. xxi. 2, 116).

CORNUBIANITE. A fine-grained modification of gneiss, occurring in Cornwall and in the Erzgebirg. It is of a dingy, greenish, yellowish, or reddish-grey colour, striated and spotted. The stratification is indistinct, and recognisable only by the layers of mica, or by the variations of colour and fineness of grain. (Kopp, Handw. d. Chem. ii. [3] 212.)

CORNUS. The following species of this genus of plants have been chemically examined. They do not appear to contain any alkaloids.

Cornus florida.—The bark of this tree, which is used in North America as a febrifuge, contains a bitter crystalline substance, *cornin*,—a tannin which turns iron-salts blue,—an indifferent crystalline resinous body,—gum,—a small quantity of starch,—a colouring matter containing iron and manganese, and lime and magnesia in combination with oxalic acid, and perhaps also with malic and phosphoric acids. The fruit is scarlet-coloured and very bitter.

Cornus mascula.—The unripe fruits contain a large quantity of tannin; the riper fruits are sweet.

Cornus sanguinea (*Dog-wood*).—The fruits, which are very bitter, yield oil when pressed. (Rochleder's *Phytochemie*, p. 115).

CORNWALLITE. An arsenate of copper from Cornwall, containing, according to Lerch, 30.21 per cent. As^2O^3 , 2.16 P^2O^5 , 54.61 Cu^2O , and 13.02 water, therefore $5\text{Cu}^2\text{O}.\text{As}^2\text{O}^3 + 5\text{H}^2\text{O}$, or $\text{Cu}^2\text{AsO}^4.\text{Cu}^2\text{O} + \frac{5}{2}\text{H}^2\text{O}$. Amorphous. Dark green. Specific gravity = 4.166. Hardness = 4.5 (Handw. d. Chem. ii. [3] 212).

CORTEPINITANNIC ACID. An acid obtained, together with several other substances, from the bark of the Scotch fir (*Pinus sylvestris*). Dried in vacuo, it forms a red powder containing $\text{C}^{16}\text{H}^7\text{O}^7 + 3\text{HO}$. Its aqueous solution forms

a deep green colour with sesquichloride of iron. (Kawalier, *Ann. Ch. Pharm.* lxxxviii. 360.)

CORTICIN. An amorphous yellowish substance existing in the bark of the aspen (*Populus tremula*), and perhaps also in other barks. It is tasteless and inodorous, sparingly soluble in water, easily in alcohol and in acetic acid, and is precipitated from the latter solution by water or sulphuric acid. (Braconnot, *Ann. Ch. Phys.* [2] xliv. 296.)

CORUNDELLITE. See MARGARITE.

CORUNDOPHILITE. A hydrated silicate of aluminium and iron, found with corundum in stellate groups at Ashville, Buncombe County, North Carolina. The crystalline form is said to be monoclinic. An analysis (made with only 0.146 gm. of material) gave 34.75 per cent. SiO_2 , 31.25 Fe_2O_3 , 8.55 Al_2O_3 , 5.47 water, and about 2.0 per cent. alkali. (C. U. Shepard, *Sill. Am. J.* [2] xii. 201.)

CORUNDUM. *Sapphire, Ruby, Oriental Amethyst, Oriental Topaz, Adamantine spar, Emery, (Korund, Smirgel, Demantspath, Salamstein, Telésie, Corindon, Rubis d'Orient).*—Native anhydrous alumina, Al_2O_3 . Crystallises in the hexagonal system, isomorphous with the sesquioxides of iron and chromium. Primary form an acute rhombohedron R. Numerous combinations occur, among which may be mentioned R. oR, (figs. 146, 147) and $\infty\text{P}2$. oR. R. $\frac{4}{3}\text{P}2$ (fig. 148).

Fig. 146.

Fig. 147.

Fig. 148.

For the primary form R, the ratio of the vertical to the horizontal axis is as 1.3617 : 1. Angle of the terminal edges = $86^\circ 6'$. For $\frac{4}{3}\text{P}2$ the angle of the terminal edges = $128^\circ 3'$, and of the lateral edges = $122^\circ 18'$. Cleavage imperfect, parallel to R and oR; where it appears perfect, it is probable that combination-faces of different individuals are present. Twin crystals also occur united by the faces R or oR (*Kopp's Krystallographie*, p. 211). Corundum occurs also massive, granular, or impalpable, often in layers, from composition parallel to R.

Specific gravity = 3.9 to 4. Hardness = 9.0. Colour, nearly white, grey, blue (sapphire), red (ruby), violet, yellow, and brown. Lustre vitreous, sometimes pearly on the basal planes oR. Transparent in various degrees down to mere translucence on the edges. Some crystals exhibit a bright opalescent six-sided star when viewed in the direction of the vertical axis (*asteria*). Fracture conchoidal, uneven, or splintery. Brittle.

Corundum is infusible and unalterable before the blowpipe. The powder moistened with cobalt-solution and ignited exhibits a fine blue colour. With borax it slowly forms a clear glass; does not melt with soda. Insoluble in acids, but, by fusion with acid sulphate of potassium, it yields a mass easily soluble in water.

Pure corundum consists entirely of alumina, but it is often mixed with ferric oxide, titanous acid, and other substances, which affect its colour and transparency. *Precious corundum* includes the transparent varieties of pure and brilliant colour, which are cut for gems; the blue variety is sapphire, the red, ruby, the yellow Oriental topaz, the violet Oriental amethyst. *Common corundum* includes the opaque varieties of less pure colour, viz. adamantite spar, which is crystallised and yields a very hard powder, used for polishing diamonds and other gems, and emery, which has a crystallo-granular structure, and is used in like manner for polishing metals, glass, &c.

The following are analyses of corundum by J. L. Smith (*Sill. Am. J.* [2] x. 354; xi. 53; Dana, ii. 112). Mag. stands for magnetic oxide of iron.

	Hard- ness.	Spec. grav.	Al ² O ₃ .	Mag.	CaO.	SiO ₂ .	Water.

Kulah	40	3.89	61.05	27.15	1.30	9.63	2.00 = 101.13

Corundum occurs associated with crystalline rocks. The sapphire, ruby, and other forms of precious corundum, are obtained chiefly from India, China, and Ceylon. Sapphire has been found also at Newton, New Jersey, and a fine ruby in Cherokee County, Georgia (U. S.). Adamantine spar is obtained from China and from the Ural; emery from the island of Naxos, from Smyrna, from Schwarzenberg in Saxony, from the Ural, Spain, Greece, and other places. A boulder of blue massive corundum has been found in Buncombe County, North Carolina. Corundums are also found in numerous other localities imbedded in granite, gneiss, syenite, mica-slate, dolomite, basalt, and other rocks, but seldom large or fine enough to be fit for gems.

Corundum sometimes absorbs water and changes to diaspore. It is also replaced by silica, forming quartz pseudomorphs.

CORYDALINE. An alkaloid existing in the roots of *Corydalis bulbosa*, *C. fabacea*, and *Aristolochia cava*. It was discovered by Wackenroder (Kastn. Arch. [1826] Bd. viii.), and afterwards examined by Peschier (Trommsd. N. J. xvii. 80), Winckler (Pharm. Centr. 1832, p. 38), Ruickholdt (Ann. Ch. Pharm. lxiv. 369), and Müller (Vierteljahrsschrift pr. Pharm. viii. 526).

Preparation.—1. From *Corydalis bulbosa*. The juice expressed from the fresh root is coagulated by heat, precipitated with neutral acetate of lead, and filtered; the lead is separated by sulphuric acid; and the corydaline is precipitated from the filtrate by ammonia, then dried and dissolved in 12 to 16 pts. of alcohol of 80 per cent.; and the solution, after being digested with blood-charcoal, is filtered and evaporated to the crystallising point. By mixing the alcoholic solution with a large quantity of water, the corydaline may be precipitated in the pulverulent form (Winckler). Müller exhausts the root with water containing hydrochloric acid; precipitates the filtrate with carbonate of sodium; redissolves the precipitate in hydrochloric acid; again precipitates with carbonate of sodium; exhausts the washed and dried precipitate with pure oil of turpentine; and agitates the oil with water containing hydrochloric acid. The corydaline then dissolves in the acid and may be precipitated by potash.

2. From the root of *Aristolochia cava*. The root is exhausted with water containing hydrochloric acid; the solution is precipitated by carbonate of sodium; the precipitate treated with alcohol; and the solution left to crystallise by evaporation. This is the easiest mode of preparation. (Ruickholdt.)

Properties.—Corydaline forms light, non-coherent, greyish-white masses, which stain strongly. According to Müller, it is a loose white powder. It is usually said to be tasteless and inodorous, but according to Müller it is bitter when moist. It is insoluble in water, but easily soluble in strong alcohol and ether. From a hot saturated alcoholic solution, it crystallises in shining rhombic prisms; by spontaneous evaporation in scales. Corydaline melts at 100° C. (at 60°—70°, according to Müller); when strongly heated, it turns brown and gives off water and ammonia. Nitric acid colours it deep red, the colour being perceptible even in very dilute solutions. Sulphuric acid dissolves it with deep yellowish-red colour.

Corydaline gives by analysis:

C	H	N	O	
62.4 . .	6.8 . .	4.3 . .	26.5	= 100 (Döbereiner).
60.2 . .	5.9 . .	3.0 . .	30.9	= 100 (Ruickholdt).

Hence have been deduced the empirical formulæ $C^{84}H^{21}NO^{10}$ (Döbereiner);

$C^{15}H^{27}NO^{18}$ (Ruickholdt); Müller, from his own analysis, calculates the formula $C^{18}H^{29}NO^7$. None of these formulæ can be depended upon, as there is no proof that the analyses were made with pure substances.

Corydaline unites with acids, forming salts most of which are colourless and some crystalline (according to Müller, none of them crystallise). They have a very bitter taste and are precipitated by *tannic acid* and by *ammonia*; also by *potash* or *soda*; but the precipitate redissolves in excess of the fixed alkali.

Hydrochlorate of Corydaline forms yellowish-green, brittle, right rhombic prisms with perpendicular terminal faces having a glassy lustre. It contains 10·8 per cent. HCl, and 15·5 per cent. crystallisation-water, and is therefore perhaps $C^{45}H^{27}NO^{18} \cdot 2HCl + 12HO$ (Ruickholdt). The crystals give off 12·5 per cent. water at $100^{\circ}C$., and 3·0 per cent. more at 145° ; at higher temperatures decomposition takes place. The salt dissolves readily in water and in strong alcohol.

Hydrochlorate of corydaline forms a white bulky precipitate with *mercuric chloride*.

Acetate of Corydaline is easily soluble and crystallisable; so likewise is the *neutral sulphate*; with excess of sulphuric acid, a gummy acid salt is obtained by evaporation.

CORYDALIS BULBOSA. In the root of this plant, corydaline was first found by Winckler; afterwards fumaric acid by Wicke (Ann. Ch. Pharm. lxxxvii. 225). Müller (Vierteljahr. pr. Pharm. viii. 526), who has examined the root more minutely, finds no fumaric acid. By distilling the root with water, he obtained a volatile oil and acetic acid; ether extracted from the dried root 2·2 pts. consisting of colouring matter, fixed oil, resin, and a small quantity of corydaline; alcohol extracted 24·6 pts. (corydaline, resin, citric, malic, acetic, tannic and saccharic acids); water extracted 3·4 pts. (albumin, starch, and a small quantity of valeric acid); and hydrochloric acid, 15·5 pts. (pectin and oxalate of calcium), the residue, amounting to 54·2 pts., consisted of a woody fibre and other insoluble matters. The dried root yielded 5·9 per cent. ash, containing in 100 pts. 5·2 pts. K_2O , 10·4 Na_2O , 8·3 CaO , 7·5 MgO , 3·8 Al_2O_3 , 4·1 Fe_2O_3 , 0·1 Mn_2O , 35·7 SiO_2 , 11·3 SO_3 , 9·3 P_2O_5 , 2·0 CO_2 , and 2·3 Cl.

COSSEINE. A name applied by Martin to an organic base, which he supposes to exist in kousoo, the celebrated Abyssinian remedy for tape-worm. Martius, however (Buchner's N. Repert. [2]. iii. 177), was not able to find it.

COTARNAMIC ACID, $C^{11}H^{13}NO^4$, is formed by the action of aqueous hydrochloric, hydriodic, or sulphuric acid on cotarnine, at a temperature of 140° or $150^{\circ}C$.

Like aspartic acid, cotarnamic acid combines with strong mineral acids. The only compound of it which has as yet been obtained pure is the *hydrochlorate*, $C^{11}H^{13}NO^4 \cdot HCl$. This body crystallises in small, pale yellow tufts of silky needles; it is but slightly soluble in cold water, very soluble in hot water; it is less soluble in alcohol and insoluble in ether. When the pure compound is dissolved in hot water, a portion always decomposes, causing an orange precipitate (of cotarnamic acid) to separate; the same precipitate is produced on cautiously adding ammonia or potash to the solution; the hydrochlorate dissolves without alteration in water containing a little free hydrochloric acid. An aqueous solution exposed to the air gradually acquires a beautiful green colour. Nitric acid, added drop by drop to a solution of this compound in hot water, causes it to appear deep opaque crimson by reflected light, and orange-yellow by transmitted light. Evaporated on a water-bath with sulphuric acid, it acquires a fine crimson colour when nearly dry; this colour is destroyed by addition of water, but reappears when the water is again evaporated. (Matthiessen and Foster, *private communication*.)

G. C. F.

COTARNIC ACID, $C^{11}H^{12}O^5$.—This substance is produced by the action of dilute nitric acid on cotarnine at a gentle heat (Matthiessen and Foster, Proc. Roy. Soc. xi. 59), but the conditions necessary for its certain production are not yet known. Methylamine is formed at the same time:

It dissolves easily in water, giving a solution which reacts strongly acid with litmus. Alcohol dissolves it but sparingly, and ether precipitates it from its alcoholic solution. It gives white precipitates with *acetate of lead* and *nitrate of silver*. The *silver-salt* is slightly more soluble in hot water than in cold; it contains $C^{11}H^{10}Ag^2O^5$.

Cotarnine may be regarded as the methylated *imide* corresponding to cotarnic acid. Cotarnic acid, cotarnamic acid, and cotarnine then bear to each other the same relations as malic acid, aspartic acid, and malanile or phenylmalimide:

Cotarnic acid . . .	$C^{11}H^{12}O^5$	Malic acid . . .	$C^4H^6O^5$
Cotarnamic acid . .	$C^{11}H^{13}NO^4$	Aspartic acid . .	$C^4H^7NO^4$
Cotarnine . . .	$C^{11}H^{10}(CH^3)NO^3$	Malanile . . .	$C^4H^4(C^2H^5)NO^3$

G. C. F.

COTARNINE, $C^{12}H^{13}NO^3 + H^2O$, or $C^{14}H^{13}NO^6 + 2HO$.—A non-volatile organic base, obtained by the action of oxidising agents on narcotine. It was first obtained by Wöhler, in 1844 (Ann. Ch. Pharm. l. 19), as a product of the oxidation of narcotine by peroxide of manganese and sulphuric acid; and, almost simultaneously, Blyth (*ibid.* l. 37; Mem. and Proc. Chem. Soc. ii. 168) observed its formation by the action of dichloride of platinum on narcotine. Cotarnine has been further studied particularly by Anderson (Ed. Phil. Trans. xx. [3] 359; Chem. Soc. Qu. J. v. 266; Ann. Ch. Pharm. lxxxvi. 196), and by Matthiessen and Foster (Proc. Roy. Soc. xi. 55; Ann. Ch. Pharm. Supplement B. i. 330; Bullet. de la Société Chim. 1861, 22).

Formation and preparation.—1. Narcotine is dissolved in a considerable excess of dilute sulphuric acid (3 pts. sulphuric acid, 30 pts. water, and 2 pts. narcotine, are good proportions: Matthiessen and Foster, *private communication*), the solution heated to boiling, finely powdered peroxide of manganese (3 pts. Matth. and Foster.) added, and the liquid filtered as hot as possible. (Wöhler directs to boil the mixture with excess of peroxide of manganese and acid as long as gas is evolved; Matthiessen and Foster recommend to add the peroxide of manganese in the proportion given above, as quickly as possible, to the already boiling solution of narcotine, and to filter immediately). The filtrate deposits opianic acid on cooling, and the mother-liquor poured off from the crystals contains sulphate of cotarnine and sulphate of manganese. The manganese is precipitated with carbonate of sodium, the precipitate filtered off, and the filtrate evaporated so as to cause the greater part of the sulphate of sodium contained in it to crystallise out; the addition of potash to the concentrated solution of sulphate of cotarnine then produces a brown granular precipitate of impure cotarnine, which is purified by solution in hydrochloric acid, treatment with animal charcoal, and reprecipitation by potash. Or, chloride of mercury or dichloride of platinum is added to the solution freed from manganese, whereby a precipitate of chloromercurate or chloroplatinate is obtained, which is washed, suspended in hot water, and decomposed with sulphydric acid; the filtrate is then mixed with excess of baryta-water and evaporated to dryness, and the cotarnine is dissolved out of the residue by alcohol. (Wöhler.)

2. Narcotine is boiled with an excess of dichloride of platinum and dilute hydrochloric acid. Red prismatic crystals of chloroplatinate of cotarnine are thus obtained. (Blyth.)

3. Anderson recommends, for the preparation of cotarnine, to act upon narcotine with dilute nitric acid (1 pt. narcotine, 3 pts. nitric acid of specific gravity 1·4, and 8 pts. water) at 49° C. The liquid separated from the teropiammonia (*q. v.*) which is thus formed, gives a crystalline precipitate of cotarnine on the addition of potash.

4. Narcotine treated as in the first method, acid chromate of potassium being however used in place of peroxide of manganese, yields cotarnine in a state of great purity. (Matthiessen and Foster.)

The formation of cotarnine from narcotine takes place according to the equation:

Properties.—Cotarnine forms small, colourless, needle-shaped crystals, grouped in stars. It is only slightly soluble in cold water, but somewhat more so in boiling water; alcohol dissolves it, forming a brownish solution, from which it cannot be obtained crystallised; it dissolves easily in ether and in ammonia; it is almost insoluble in caustic potash. It melts at 100° C., and loses 1 at. of water of crystallisation; at a higher temperature it is charred, and produces a disagreeable smell. Cotarnine has a bitter taste and faintly alkaline reaction.

Crystallised cotarnine contains:

The formula originally proposed for cotarnine by Wöhler, was C²⁶H¹³NO⁵; Blyth gave its formula as C²⁵H¹³NO⁶; Gerhard (Précis de Chimie Organique, 1845, ii. 298) adopted the expression C¹³H¹³NO³ (= C²⁶H¹³NO⁶); Wertheim (Wien. Acad. Ber. vi. 111), believing in the existence of several homologous varieties of cotarnine, gave the formula C¹²H¹³NO³ (= C²⁴H¹³NO⁶) for what he called *methyl-cotarnine*; Matthiessen and Foster regard cotarnine as always of the same composition, and represent it by the formula C¹²H¹³NO³ = (C¹¹H¹⁰O³)^{''} N, that is, as *methyl-cotarnimide*. (See COTARNIC ACID.)

The aqueous solution of cotarnine precipitates ferrous and cupric salts; it gives no coloration with ferric salts (Blyth). It is also precipitated by tannin. (Wöhler.)

Decompositions.—1. *Nitric acid* dissolves cotarnine with red colour, and, if heated, oxidises it, forming oxalic acid, and afterwards apophyllic acid, (*q. v.*) (Wöhler, Anderson, Matthiessen and Foster.) Very dilute nitric acid, gently heated with cotarnine sometimes produces cotarnic acid, C¹¹H¹²O⁵, and methylamine:

2. Heated with *hydrochloric*, *hydriodic*, or dilute *sulphuric acid* to 140° C., in a sealed tube, it yields chloride or iodide of methyl, or methyl-sulphuric acid, and cotarnamic acid, C¹¹H¹³NO⁴ (*p. 88*).

3. With *iodide of ethyl* at 100° C. it yields hydriodate of cotarnine, but no ethylised derivative. (How, Ed. Phil. Trans. vol. xxi.; Ann. Ch. Pharm. xcii.)

SALTS OF COTARNINE. The salts of cotarnine are for the most part very soluble; they are obtained directly, by solution of the base in dilute acids.

Hydrochlorate of Cotarnine, C¹²H¹³NO³.HCl (+ 2½H²O?), is obtained by evaporating its aqueous solution, in the form of long silky crystals, which are very soluble in water. It loses 14·88 per cent. of water at 100° (Blyth): the above formula corresponds to 14·97 per cent. Dried at 100° C. it contains, according to Blyth's analysis, 57·39 per cent. carbon and 5·73 hydrogen; the formula C¹²H¹³NO³.HCl requires 56·36 per cent. C, and 5·48 H.

Chloroplatinate of Cotarnine, C¹²H¹³NO³.HCl.PtCl².—This salt forms, when precipitated in the cold, a lemon-yellow, crystalline precipitate, resembling chloroplatinate of ammonium; when hot solutions of hydrochlorate of cotarnine and dichloride of platinum are mixed together, the double salt separates as the mixture cools, in small, round, transparent nodules, of a reddish-yellow colour (Wöhler). It is obtained in the form of large, dark-red, six-sided prisms, by boiling a solution of narcotine in hydrochloric acid with an excess of dichloride of platinum (Blyth). This salt is very slightly soluble in cold water, but somewhat more so in hot water; it appears, however, to be altered by repeated solution in hot water. It can be boiled with ammonia without undergoing decomposition. Boiled with baryta-water, it is decomposed, and metallic platinum is precipitated.

It contains:

	Calculated.		Wöhler.		Blyth.		Matth. and Foster.		
C ¹²	144	33.84	34.9	34.2	34.4	35.0			
H ¹⁴	14	3.29	3.2	3.5	3.3	3.6

	425.5	100.00							

Blyth dried the salt for analysis at 100°; Matthiessen and Foster at the ordinary temperature, over sulphuric acid *in vacuo*; they could not obtain constant results with the salt dried at 100°.

It sometimes happens that the treatment of narcotine with dichloride of platinum gives rise to another chloroplatinate, which crystallises in long, bright, orange-yellow needles. This salt, which Blyth supposed to contain a peculiar alkaloid, which he named *narcogenine*, C³⁶H¹⁹NO¹⁰, is decomposed when boiled with ammonia, into narcotine and cotarnine, and is probably a double chloroplatinate of these two bases. Blyth's analytical results accord nearly with those required by the formula

Chloraurate of Cotarnine has a beautiful dark red colour.

Chloromercurate of Cotarnine, C¹²H¹⁹NO³.HCl.2HgCl, forms a pale yellow precipitate, which gradually becomes crystalline. It is not precipitated from rather dilute warm solutions, but is deposited on cooling, in small pale yellow prisms. It appears to suffer decomposition by repeated crystallisation. It contains:

COTTON. The filamentous matter attached to the seeds of various species of *Gossypium*, a genus of plants belonging to the Malvaceous order. It consists of hairs springing from the surface of the seed-coat, and filling up the cavity of the seed-vessel in which the seeds lie. These hairs are long weak tubes, which, when immersed in water and examined under the microscope by transmitted light, look like flat, narrow, transparent ribands, entirely distinct from each other, and with a perfectly even surface and uniform breadth, rarely jointed, and if so, having the articulations perpendicular to the length of the tube. The individual tubes are very weak and fragile, and it is only when many are twisted together, that they acquire any appreciable degree of strength. Linen, on the other hand, consists of woody tissue, in the shape of long thick-sided tubes, adhering in bundles, the articulations being always oblique, and the ends of the tubes pointed and overlying each other; moreover, the individual tubes are much stronger than those of cotton. In short, cotton is a development of the parenchymatous tissue, which is the weakest among the elementary organs of a plant; linen, of the woody tissue, which is the strongest: hence the well-known superiority of linen to cotton in strength.

Cotton fibre consists of nearly pure cellulose associated with only 1 to 1½ per cent. of inorganic matter. The following table exhibits the composition of cotton (after deduction of the ash), as compared with that of pure cellulose C⁶H¹⁰O⁵.

Cotton (and linen) may be distinguished from silk and wool by their behaviour with sulphuric and with nitric acids. Silk and wool are turned yellow by immersion in strong nitric acid, whereas cotton and linen remain colourless. When woollen tissues containing cotton or linen are immersed for a quarter of an hour in sulphuric acid, the cotton and linen first swell to a pasty mass, and afterwards dissolve, while the animal fibres remain unaltered. (Böttger, J. pr. Chem. lxxiii. 498.)

Cotton dissolves in *sulphuric acid* more quickly than linen; hence it may be detected

in linen by the following method. The tissue, after being repeatedly washed with rain-water, boiled with water, and dried, is dipped for $\frac{1}{2}$ to 2 minutes in oil of vitriol, then carefully pressed under water with the fingers, washed with water, immersed for a few seconds in aqueous ammonia, carbonate of potassium, or carbonate of sodium, again washed with water, and dried between filtering paper. By this treatment, the cotton fibres are dissolved, while the linen fibres are merely rendered thinner and more translucent, according to the duration of the experiment; after a short immersion the cotton fibres appear transparent, while the linen fibres remain white and opaque.

Another distinction between cotton and linen is that the latter acquires a deep yellow colour by boiling with water containing its own weight of hydrate of potassium, whereas cotton is little or not at all coloured by the same treatment. (Gm. xv. 140.)

Cotton cloth (calico), immersed for 10—30 minutes in syrupy *potash-ley*, and then washed with alcohol of specific gravity 0.825, contracts by $\frac{1}{10}$ after drying, and contains 14.72 per cent. potash, corresponding to the formula $4C^6H^{10}O^3.K^2O$ which requires 14.59 per cent. K^2O (Gladstone, Chem. Soc. Qu. J. v. 17). Calico immersed in *soda-ley* of specific gravity 1.342 and treated in a similar manner, shrinks in drying by $\frac{1}{4}$, and contains 9.68 per cent. soda ($4C^6H^{10}O^3.Na^2O = 9.65$ per cent.). Unwoven cotton forms a similar compound; longer immersion or the use of a stronger solution appears to produce partial solution and decomposition. Cotton also unites with soda in other proportions, but never with a larger quantity than that contained in the compound just mentioned. Water abstracts all the soda from the compounds, and leaves a shrunken tissue which takes more brilliant colours in dyeing than ordinary calico. (Gladstone, *loc. cit.* See also Mercer. Rep. Pat. Inv. 1851, p. 358; Gm. xv. 141.)

Cotton immersed in solutions of *alum* or *acetate of aluminium*, does not separate any alumina; but if the solution of acetate of aluminium, ferric acetate, or any other salt containing a volatile acid be left to dry on the cotton, the acid volatilises after a while, and the base is so firmly fixed on the cotton, though only mechanically, that it cannot be removed by washing with water (Walter Crum, Ann. Ch. Pharm. lv. 223, Compt. rend. xlvii. 961). If the cloth after this treatment be immersed in a coloured solution, such as that of logwood or indigo, the colouring matter forms an insoluble compound with the base, and thus becomes permanently fixed upon the cotton fibre; whereas, if the cloth were merely dipped in the coloured infusion without being previously treated with the metallic salt, or *mordant*, the colour imparted to it would be immediately removed by immersion in water: cotton, flax, hemp, and other vegetable fibres do not, like wool and silk, exert any specific attractive power on the colouring matters mixed with mordants. (See DYEING.)

Culture of Cotton.—Professor Mallet of Alabama has lately published the commencement of an elaborate investigation of the chemical and physical conditions of the cultivation of cotton (Proc. Roy. Soc. xi. 340), from which the following general conclusions are drawn.

The annual cotton plant, as cultivated in America, attains its principal growth during four months, though it continues to develop seed and fibre for a much longer period.

It requires a very finely divided soil through which its rootlets can penetrate with facility; the average mass of soil interpenetrated by the roots of each plant is about 5 cubic feet.

Cotton is not an exhaustive crop, inasmuch as the great mass of the plant—root, stem, branches, leaves, and emptied bolls—remains upon the field and is ploughed into the soil, and nothing is removed but the fibre and the seed; and the greater part of the latter is also returned to the soil, the seed being thickly strewn by handfulls in a continuous row, from which the plants are afterwards thinned. The cotton fibre, which constitutes the salable product, and is absolutely carried off the land, may be looked upon as a very light crop; a bale of 400 to 500 lbs to the acre is sometimes obtained under favourable circumstances, but this is much above the average for upland cotton. The fibre yields from 1 to 1.5 per cent. of ash, so that at the most, $7\frac{1}{2}$ lbs. of mineral matter will be removed annually, which is not half as much as is removed by a crop of wheat of 25 bushels to the acre in the *grain alone*, and less than $\frac{1}{50}$ the amount removed by an average crop of potatoes. Sometimes, however, a considerable portion of the seed is removed from the plantation to be used for the extraction of oil, the cake which remains being exported to Europe for cattle-food. This practice tends greatly to the exhaustion of the cotton soil.

Cotton is decidedly a *sun-plant*, requiring a high summer temperature and plenty of sunshine. A moderate supply of rain is advantageous in the early stage of growth, but heavy rains are injurious even in that stage, and later in the season they are absolutely destructive. A water-soaked soil is decidedly unfavourable, the tap-root not striking down in such soil, and the plant looking small and sickly, and bearing but little cotton. The soil most favourable for cotton cultivation is a finely divided soil capable of absorbing a considerable quantity of aqueous vapour from the atmosphere and retaining it in a state of adhesion or of chemical combination, so as not to render

the soil moist to the touch. Such a soil enables the plant to withstand vicissitudes of weather and season, storing up hygroscopic moisture in damp seasons, and yielding a gradual supply of it to the roots in the latter stage of the growth when seed and fibre are forming. Another essential condition of the soil is the power of gradually absorbing and yielding a considerable quantity of gases, especially ammonia, and of mineral matter withdrawn from solution.

All these conditions are fulfilled in a high degree by the soil of the prairie region of Central Alabama, which is a stiff aluminous clay, containing a moderate amount of organic matter and of the mineral substances needed by the plant as food—of great uniformity, and in an exceedingly fine state of division; above all, possessing a very high capacity for absorbing and retaining heat, moisture, gases, and soluble mineral matter. It was found to be capable of condensing 52 times its own volume of ammonia gas, and the subsoil, which is calcareous, was found to absorb 64 times its own volume of the same gas.

COTUNNITE. Native chloride of lead, PbCl_2 , found in the crater of Vesuvius after the eruption of 1822, in acicular crystals of the trimetric system, and capillary masses, white, having a strong lustre, of specific gravity 5.238, and soft enough to be scratched by the nail.

COUMARAMINE. $\text{C}^9\text{H}^7\text{NO}^2 = \text{N.H}^2.\text{C}^9\text{H}^5\text{O}^2$.—Produced by the action of ferrous acetate (iron filings and dilute acetic acid) on nitrocoumarin. The reaction must be continued for twenty-four hours, and the filtrate concentrated by evaporation; it then, on cooling, deposits coumarin in fine yellowish needles, often several centimetres long. It is nearly insoluble in cold water and in ether, but dissolves readily in boiling water or alcohol. A saturated solution of ferrous acetate appears to dissolve it more readily than cold water. It melts between 168° and 170°C ., and if cautiously raised to a higher temperature, sublimes without decomposition in pale yellow scales. It is rapidly decomposed by boiling potash; the liquid saturated with an acid deposits brown flakes.

Coumaramine unites with acids, forming soluble salts, from which ammonia precipitates the base in a crystalline mass. The *hydrochlorate* forms scales very soluble in water. The *chloroplatinate*, $\text{C}^9\text{H}^7\text{NO}^2.\text{HCl.PtCl}_2$, is a yellow crystalline precipitate insoluble in water. (Chiozza and Frapolli, Ann. Ch. Pharm. xcv. 252.)

COUMARIC ACID. $\text{C}^9\text{H}^5\text{O}^3 = \text{C}^9\text{H}^7\text{O}^2.\text{H.O} = \text{coumarin} + 1 \text{ at. water}$. (Delalande, Ann. Ch. Phys. [3] vi. 343.—Bleibtreu, Ann. Ch. Pharm. lix. 177.)—Prepared by boiling coumarin with strong potash-ley, adding solid potash if necessary, and precipitating by hydrochloric acid. Crystallises in colourless brilliant laminae, having a bitter taste, and soluble in water, alcohol, and ether. It melts at 190°C ., and at a higher temperature decomposes partially, yielding a crystalline sublimate, and leaving a brown residue. By distillation it yields an oil, which reddens ferric salts and appears to unite with potash. Coumaric acid, when pure, does not impart any violet colour to ferric salts. When melted with potash it gives off hydrogen, and yields salicylate and apparently also acetate of potassium:

Coumaric acid decomposes carbonates. The formula of the *coumarates* is $\text{C}^9\text{H}^5\text{O}^2.\text{M}$. *Coumarate of ammonium* does not precipitate barium-salts. *Coumarate of lead* is a white precipitate, pulverulent, and insoluble in water. *Coumarate of silver* is a light yellow pulverulent precipitate, or if formed in presence of ammonia, orange-coloured and flocculent.

COUMARIN. $\text{C}^9\text{H}^6\text{O}^2$, or $\text{C}^8\text{H}^6\text{O}^1$. (Guibourt, *Histoire des Drogues simples*.—Boullay and Boutron-Chaillard, J. Pharm. xi. 480.—Delalande, Ann. Ch. Phys. [3] vi. 343.—Bleibtreu, Ann. Ch. Pharm. lix. 177.—Gm. xiii. 321.)—This substance exists in considerable quantity in Tonka beans, the fruit of *Coumaruma odorata*, or *Dipteryx odorata*, being found in small white crystals between the seed coating and the kernel. It is also found in woodruff (*Asperula odorata*), in *Melilotus officinalis*, in the flowers of sweet-scented vernal grass (*Anthoxanthum odoratum*), in the leaves of *Fuham*, an orchidaceous plant (*Angraecum fragrans*), in the leaves of *Orchis fusca* (Bley), and in the dried leaves of *Liastris odoratissima*, a composite plant growing in the southern parts of North America (Procter, Rép. Chim. app. 1861, p. 143). In some of these plants, the coumarin was originally mistaken for benzoic acid.

Coumarin is easily extracted from Tonka beans by digesting them in strong alcohol. On evaporating the alcohol, a crystalline magma of coumarin is obtained, which may be decolorised and freed from a quantity of adhering oil by means of animal charcoal.

Coumarin is colourless; it crystallises sometimes in small rectangular plates, some-

times in large prisms belonging to the trimetric system, $\infty P : \bar{P} \infty$, with $\infty \bar{P} \infty$ predominant. Inclination of the faces $\infty P : \bar{P} \infty = 100^\circ$ (nearly), $\infty P : \bar{P} \infty = 104.5$ (nearly), $a : b : c = 0.364 : 1 : 1.035$. It melts at 50°C ., and boils at 270° without sensible alteration; has an agreeable aromatic odour, and a burning taste; the vapour acts very strongly on the brain.

Coumarin is nearly insoluble in cold water, but boiling water dissolves it abundantly, and deposits it on cooling in very slender needles. It dissolves without alteration in dilute acids. Strong *sulphuric acid* chars it immediately. Strong *nitric acid* converts it into *nitrocoumarin*, and, after long boiling, into *picric acid*. Heated with excess of *potash*, it yields *salicylic acid* and *coumaric acid*, $\text{C}^9\text{H}^5\text{O}^3$. *Chlorine* and *bromine* form crystalline compounds with coumarin; *iodine* converts it into a bronze-green crystalline substance. With *pentachloride of antimony*, coumarin forms a crystalline compound containing $\text{C}^9\text{H}^5\text{O}^2.\text{SbCl}^5$.

Nitrocoumarin. $\text{C}^9\text{H}^5(\text{NO}^2)\text{O}^2$.—Obtained by projecting coumarin by small portions at a time into cold fuming nitric acid, and precipitating with a large quantity of water. It is then deposited as a snow-white flocculent mass. It dissolves in boiling water, alcohol, and ether, and crystallises from the solution in small white silky needles. Melts at 170°C ., and sublimes undecomposed at a high temperature in nacreous crystals. *Potash* colours it deep red and dissolves it. *Acids* added to the solution throw down unaltered nitrocoumarin. It dissolves in *ammonia*; the solution when boiled evolves ammonia, and on cooling deposits part of the nitrocoumarin in white crystals, not containing ammonia (Bleibtreu). *Ferrous acetate* converts nitrocoumarin into coumaramine. (Frapolli and Chiozza, p. 194.)

The ammoniacal solution of nitrocoumarin, freed from excess of ammonia by boiling, and filtered, forms, with *acetate of lead*, an orange-yellow precipitate, $2\text{C}^9\text{H}^5(\text{NO}^2)\text{O}^2.3\text{Pb}^2\text{O}$, soluble in a large quantity of water, less soluble in alcohol, insoluble in ether, decomposed by acids. With *nitrate of silver*, in like manner, a beautiful orange-coloured precipitate, $\text{C}^9\text{H}^5(\text{NO}^2)\text{O}^2.\text{Ag}^2\text{O}$, is obtained, which explodes when heated. (Bleibtreu.)

COURBARIL RESIN. A name sometimes given to West Indian animé resin, obtained from the *Hymenæa Courbaril*. (See i. 296.)

COUZERANITE. A silicate found in the neighbourhood of Couzeran in the Pyrenees. It contains 52.37 per cent. SiO^2 , 24.02 Al^2O^3 , 11.85 Ca^2O , 1.40 Mg^2O , 5.52 K^2O , and 3.96 Na^2O (Dufrenoy), which is nearly the composition of dipyre (*q. v.*) According to Dufrenoy, the crystals belong to the monoclinic system, whence he refers it to Labradorite; but, according to R. P. Grey, jun., they are dimetric, like those of dipyre, which mineral is also found in the same locality. Specific gravity = 2.69. Hardness = 6.0, or rather above. Colour black to grey. Lustre waxy. Opaque. Melts to a white enamel before the blowpipe. Insoluble in acids. (Handw. d. Chem. ii. [3] 220.—Dana, ii. 206.)

COVELLIN. Native protosulphide of Copper. See COPPER, SULPHIDES OF (ii. 74).

CRAITONITE. See CRICHTONITE.

CRAMBE MARITIMA. *Sea Kale*.—A cruciferous plant, the young sprouts of which contain, according to T. J. Herapath (Chem. Soc. Qu. J. ii. 4), in the fresh state 0.71, in the dry state 9.9 per cent. ash; the leaves 1.7 per cent. in the fresh, and 16.7 per cent. in the dry state. The composition of the ash is as follows:—

		CO^2	SO^3	P^2O^5	K^2O	Na^2O	NaCl
Soluble in water	{ Sprouts	4.2	21.8	5.1	6.7	23.6	trace

	{ Leaves	27.2	trace	1.5	13.1	trace	1.6
							0.1

CRATEGIN. A non-azotised bitter principle, obtained from the fresh branch-bark of the white-thorn (*Crataegus oxyacantha*). It crystallises in greyish-white nodules, like grape-sugar, has a bitter taste, dissolves easily in water, less easily in alcohol, not at all in ether, and does not combine either with acids or with alkalis. (Leroy, J. Chim. Méd. xvii. 3.)

CRATININE. Gmelin's name for CREATININE (*q. v.*)

CRAURITE. See DUFREYNITE.

CREAM. The fatty portion of milk, which rises to the surface when fresh milk is left at rest for twenty-four hours. Berzelius found in 100 pts. of cream from cow's milk, 4.5 pts. of butter, 3.5 casein, and 92.0 serum.

CREAM OF TARTAR. Acid tartrate of potassium (see TARTARIC ACID).

CREATINE. $C^4H^5N^3O^2$, or $C^6H^8N^3O^4$. (Chevreul, J. Pharm. xxi. 234; Pettenkofer, Ann. Ch. Pharm. lii. 97; Liebig, Ann. Ch. Pharm. lxii. 282; Heintz, Pogg. Ann. lxii. 602; lxx. 460; lxxiii. 696; lxxiv. 125; Compt. rend. xxiv. 500; Gregory, Chem. Soc. Qu. J. i. 25; Dessaignes, Compt. rend. xxxviii. 839; xli. 1258; Ann. Ch. Pharm. xevii. 339; J. Pharm. [3] xxxii. 41; Gm. x. 249; Gerh. i. 530; iii. 939; iv. 893.)—An organic base discovered in 1835 by Chevreul in the juice of flesh; more minutely examined by Liebig in 1847.

Sources.—In the muscular flesh of mammalia, birds, amphibia, and fishes. Lean horse-flesh contains 0.070, and the flesh of poultry 0.35 per cent. of creatine. That of the marten yields less than that of poultry, but more than that of other quadrupeds: after horse-flesh follow, in decreasing series, the flesh of the fox, roe-buck, stag, hare, ox, sheep, pig, calf, and pike. Fat animals yield much less creatine than lean ones; *e. g.* a fox fattened on meat for 100 days, yields only $\frac{1}{10}$ as much as one that has been killed in the chase (Liebig). Bullock's heart yields 0.142; the flesh of poultry 0.321; that of the pigeon 0.083, that of cod 0.170; and that of the ray 0.61 per cent. (Gregory). Human flesh yields 0.067 per cent.; that of the alligator likewise contains creatine (Schlossberger, Ann. Ch. Pharm. lxvi. 80; xlix. 344). The flesh of the Rorqual whale (*Balanoptera musculus*) likewise yields a small quantity of creatine. (D. Price, Chem. Soc. Qu. J. iii. 229.)

Städeler, has obtained creatine from the flesh of the dog, pigeon, *Spinax acanthus*, and *Petromyzon fluviatilis* (J. pr. Chem. lxxii. 256). Creatine is likewise found, together with creatinine, in urine; together with creatinine and seroline in blood (Verdeil and Marcet, J. Pharm. [3] xx. 89); and, together with urea, in the brain of pigeons and of dogs. (Städeler.)

It is not yet decided whether creatine exists, as such, in the living animal body, or whether it is formed from creatinine existing therein, by the process of preparation. Creatine and creatinine differ in composition only by the elements of water, and are easily converted one into the other,—creatine into creatinine under the influence of acids, creatinine into creatine, by the action of alkalis, the action in either case being accelerated by heat. Now, in preparing creatine either from flesh-juice or from urine, the usual process is to neutralise with an alkali, and concentrate the liquid by heat; by this process the creatinine existing in the original liquid is sure to be converted partly, if not wholly, into creatine, and it is possible that the whole of the creatine actually obtained may be produced in this way; for there is no simple reaction by which creatine can be detected in the original liquid, in presence of creatinine. From the experiments of Dessaignes (J. Pharm. [3] xxxii. 41), it appears that human urine yields more creatinine and less creatine the more quickly the process of separation is conducted. Liebig (Ann. Ch. Pharm. cviii. 334) found that the fresh urine of a dog which had been fed on meat for some weeks, yielded, when mixed with milk of lime and immediately evaporated, a considerable quantity of creatinine but no creatine, but if left to stand for six weeks before evaporation, it yielded creatine without creatinine. In this case the creatine evidently resulted from the decomposition of the creatinine. Dessaignes is of opinion that the creatine of muscular flesh is likewise produced by the decomposition of creatinine.

Preparation. 1. *From muscular flesh.*—*a.* The aqueous extract of beef is evaporated in vacuo; the residue exhausted with alcohol, and the alcohol evaporated till the creatine crystallises out. The greater portion remains, however, in the mother-liquor, being prevented from crystallising by the presence of foreign bodies (Chevreul). In a similar manner, Schlossberger obtained creatine from the flesh of the alligator and purified the crystals by washing with cold alcohol.

b. The fresh lean muscular flesh of mammalia or birds, is freed as much as possible from fat (which would stop up the press-bag when the meat is subjected to pressure), and chopped up fine; 5 lbs. of it are then well kneaded with an equal weight of water; the liquid is well pressed out in a coarse linen bag; the residue twice treated with water in a similar manner; 5 lbs. of muscular flesh kneaded together with the expressed liquid; the residue kneaded with the third expressed liquid, and then after pressure with 5 lbs. of pure water; and the united liquids are strained through a cloth. The resulting reddish liquid, which reddens litmus, is kept at 100° C., in a large glass flask over the water-bath, till the albumin and blood-red have completely separated in the form of a coagulum, and a sample of the liquid remains clear when boiled.

To decolorise the liquid obtained from some kinds of meat, it must be heated in a basin till it froths up. The liquid is then strained, first through linen, the coagulum being pressed out, then through paper.* The filtrate is then mixed with saturated

* The filtrate obtained from the flesh of the ox, roebuck, hare, or fox, which contains a large quantity of blood, retains a reddish tint; that from veal, poultry, or pike is nearly colourless; game and poultry yield a nearly transparent filtrate, which is very favourable to the obtaining of creatine; horse-flesh and cod yield a turbid filtrate. If the filtrate were evaporated alone, even below 100°, it would become coloured

baryta-water, the addition of that liquid being continued, even after the filtrate has been rendered neutral or alkaline by it, as long as a precipitate of phosphate of barium and phosphate of magnesium continues to form; the filtrate evaporated in a shallow basin over the water-bath to $\frac{1}{20}$; and the thickish residue set aside, first in a warm place to evaporate further, and then, after crystallisation has commenced, in the cold.* The needles thus obtained are separated from the mother-liquor by filtration, washed first with water, then with alcohol, and dissolved in boiling water; and the solution, if coloured, digested with a small quantity of blood-charcoal, then filtered and left to cool, whereupon it yields pure crystals of creatine (Liebig). If a sufficient quantity of baryta-water has not been added, the crystals will be contaminated with phosphate of magnesium. In that case, the hot aqueous solution must be boiled with a small quantity of hydrated oxide of lead; digested, after filtration, with blood-charcoal, which removes the last traces of lead; and the filtrate again left to crystallise. (Liebig.)

c. The chopped flesh of pike, when boiled with water, swells up to a gummy mass, from which the liquid cannot be expressed. A mixture of the chopped flesh with water must therefore be thrown upon a funnel; small quantities of water allowed to run gradually through; and the slightly turbid, acid liquid, which smells and tastes of fish, separated from the soft, white coagulum, precipitated with baryta-water, then filtered and evaporated. It forms on cooling a colourless jelly, in which, in the course of 24 hours, crystals of creatine begin to form. (Liebig.)

The extract of the flesh of poultry or pigeons deposits brown flakes, together with the creatine crystals;—the flesh of bullock's heart often yields but few of the purer crystals, but a considerable quantity of brown flakes, from which boiling water extracts a large additional quantity of creatine. From skate and cod the juice may be easily expressed, after the flesh has been mixed with rather more than equal quantity of water; the jelly ultimately obtained from it, in which the creatine-crystals form, dissolves readily in cold water, and deposits more crystals: the flesh of cod yields the whitest creatine. From the syrupy mother-liquors of crude creatine, chloride of zinc does not form any zincochloride of creatinine, or only a trace; but the mother-liquors obtained in the recrystallisation of crude creatine yield this precipitate on addition of chloride of zinc. (Gregory.)

d. Chopped flesh mixed with coarsely pounded glass, is digested with $1\frac{1}{2}$ times its volume of alcohol at a gentle heat; the liquid is then pressed out and distilled, the residue treated with basic acetate of lead, the excess of lead separated by sulphydric acid, and the clear liquid evaporated to a syrup. On cooling, creatine crystallises out; and after some days the crystalline mass is spread out on unsized paper to absorb the mother-liquor; after which the creatine is dissolved in hot water or alcohol, and recrystallised. (Städeler, J. pr. Chem. lxxii. 256.)

2. *From Zincochloride of Creatinine.*—a. The solution of this compound in boiling water is digested with hydrated oxide of lead, till it acquires a strong alkaline reaction; filtered from the oxide of zinc and oxychloride of lead; digested with a little blood-charcoal, which removes the small remaining quantity of lead, together with fibrin; the filtrate evaporated to dryness; and the remaining mixture of creatine and creatinine, treated with an eightfold quantity of boiling alcohol to dissolve out the latter: the alcohol, on cooling, likewise deposits crystals of creatine, which are added to the undissolved residue of creatine, and the whole is purified by recrystallisation. (The alcohol filtered after cooling deposits creatinine: Liebig.)—b. The boiling aqueous solution of the zinc-compound is treated with baryta-water, which precipitates zinc-oxide, together with the greater part of the adhering fibrin; carbonic acid gas is passed through the filtrate; the liquid again filtered to separate carbonate of barium; the filtrate evaporated to dryness in vacuo; the residue exhausted with alcohol; the baryta which has been taken up by the alcohol as chloride of barium, precipitated by sulphuric acid; the liquid again filtered, boiled with oxide of lead, treated with absolute alcohol to precipitate all the chloride of lead, and filtered from chloride and sulphate of lead; any lead that may yet remain dissolved is removed by sulphuretted hydrogen; and the filtrate is evaporated to dryness over the water-bath (Pettenkofer). The residue thus obtained contains creatinine as well as creatine (Liebig).—c. The boiling aqueous solution of the zinc-compound is mixed with ammonia till it begins to

in consequence of the presence of free acid, which would decompose the creatine, and leave a dark-brown syrup, having the odour of roast meat, which would yield but a very small quantity of creatine, even after long standing. This appears to be the reason why Berzelius (Jahresber. viii. 589) and Fr. Simon (N. Br. Arch. xxvi. 283) did not succeed in preparing creatine.

* The filtrate from poultry remains clear when evaporated, and becomes covered with a film of carbonate of barium if too much baryta-water has been added; that from beef becomes covered, when concentrated to a thin syrup, with a mucous scum which swells up in water, but is insoluble and must be removed; and that from veal or horse-flesh with films which are continually renewed, and must be continually skimmed off.

show turbidity, and then precipitated with sulphide of ammonium; the filtrate evaporated to a small bulk, and mixed with absolute alcohol; and the crystals of creatine, which separate from the liquid after long standing in the cold, are purified by recrystallisation from water (Heintz). The creatinine remains in the alcoholic mother-liquor.

The crystals of creatine obtained by either of these processes may be freed from water of crystallisation by heating them to 100°C. (Liebig.)

Properties.—Anhydrous creatine forms a white opaque mass (Liebig). It is inodorous, has a somewhat bitter taste, and produces a scratching sensation in the throat (Liebig). Neutral to vegetable colours. (Chevreul.)

The composition of creatine dried at 100°C. is as follows:—

Calculation.				Analyses.		
				Liebig. <i>a.</i>	Liebig. <i>b.</i>	Heintz. <i>c.</i>
C ⁴	.	48	36.64	36.66	36.90	36.39
H ⁹	.	9	6.87	6.96	7.07	6.86
N ³	.	42	32.06	32.15	32.61	31.64
O ²	.	32	24.43	24.23	23.42	25.11
C ⁴ H ⁹ N ³ O ²	.	131	100.00	100.00	100.00	100.00

a was obtained from meat; *b*, from zinc-chloride of creatinine prepared from human urine.

The *hydrate*, C⁴H⁹N³O².H²O, forms perfectly limpid prisms, belonging to the monoclinic system. Inclination of the clinodiagonal to the principal axis = 70° 20'. Inclination of the faces ∞P: ∞P in the plane of the orthodiagonal and principal axis = 133° 2' (nearly). Specific gravity of the crystals = 1.35 to 1.34.

Creatine dissolves in 74.6 pts. of *water* at 18°C.; it is very soluble in boiling water and is deposited on cooling in a mass of needles. It dissolves in 9410 pts. of *absolute alcohol*, but is more soluble in *aqueous alcohol*; insoluble in *ether*.

Decompositions.—1. Hydrated creatine, when heated, first gives off its water of crystallisation with decrepitation; then melts without becoming coloured; afterwards emits an odour of ammonia, hydrocyanic acid, and phosphorus; and lastly, gives off yellow fumes, which condense partly to an oil, partly to needle-shaped crystals, and leaves a small quantity of charcoal (Chevreul).—2. The solution of creatine in aqueous *permanganate of potassium* is decolorised by continued digestion, without evolution of gas, the creatine being decomposed and carbonate of potassium formed (Liebig). The aqueous solution of creatine is not decomposed by boiling with *peroxide of lead* (Liebig). It is not coloured by boiling with *mercuric nitrate* (Chevreul).—3. Creatine dissolved in strong *nitric*, *sulphuric*, *phosphoric*, or *hydrochloric acid*, is converted into creatinine by abstraction of H²O, the creatinine then combining with the acid (Liebig). But if these acids are dilute, the creatine remains unaltered, even after long boiling, and the solution in cold hydrochloric acid leaves, by spontaneous evaporation, crystals of pure creatine (Liebig). If dry *hydrochloric acid gas* be passed over 149 pts. (1 at.) of hydrated creatine heated to 100°C., the weight first increases by absorption of hydrochloric acid; but if dry air be then passed through the apparatus for some time, water is continuously given off, and the compound diminishes in weight, till it amounts to only 154.16 pts., and contains 38.05 pts. (a little more than 1 at.) hydrochloric acid. Hence 36 pts. (1 at. of water of crystallisation and 1 at. more produced from the creatine) have been given off, and on the other hand, 38.05 pts. (1 at.) hydrochloric acid have entered into combination with the hydrated creatine:

131 pts. (1 at.) of dry creatine, similarly treated with hydrochloric acid gas, take up about 18.04 pts., because, in this case, only 18 pts. (1 at.) water are given off for every 36.4 pts. (1 at.) hydrochloric acid taken up (Liebig).—The colourless solution of creatine in *nitric acid* of specific gravity 1.34 gives off nitrous fumes when heated in the water-bath, and leaves on evaporation a colourless residue (of nitrate of creatinine), which dissolves in water, separates out therefrom in small granules, and does not precipitate dichloride of platinum (Chevreul).—4. By boiling with a small quantity of *baryta* dissolved in water, creatine is resolved into sarcosine and urea, which is then quickly resolved by the baryta into carbonic acid and ammonia (Liebig):

From this decomposition Strecker (Ann. Ch. Pharm. cxviii. 151) infers that creatine

may be regarded as a compound of cyanamide (urea *minus* water) and sarcosine (methyl-glycocine), *i. e.* as $\text{CN} \left\{ \begin{array}{c} \text{C}^2\text{H}^2\text{O} \\ \text{H}^2 \end{array} \right\} \text{N} \cdot \left\{ \begin{array}{c} \text{C}^2\text{H}^2\text{O} \\ \text{CH}^3 \\ \text{H}^2 \end{array} \right\} \text{O};$ or $\left\{ \begin{array}{c} \text{CN} \\ \text{C}^2\text{H}^2\text{O} \\ \text{CH}^3 \end{array} \right\} \text{N}^2 \cdot \left\{ \begin{array}{c} \text{C}^2\text{H}^2\text{O} \\ \text{CH}^3 \\ \text{H}^4 \end{array} \right\} \text{O}.$ An aqueous

solution of creatine saturated at the boiling heat, and mixed with crystals of baryta amounting to 10 times the weight of the creatine, remains clear at first, but, if the boiling be continued, gives off abundance of ammonia; deposits carbonate of barium at the same time; and, if fresh baryta be added from time to time, is ultimately found to contain scarcely any thing but sarcosine and carbonate of barium; and, if the operation be interrupted during the strongest evolution of ammonia, likewise a little urea. A small quantity of another substance, probably urethane, is however produced at the same time: for if the alcohol from which the sulphate of sarcosine has crystallised out, be mixed with water, neutralised with carbonate of barium, filtered and evaporated to a thin syrup, colourless needles and laminæ are obtained which reddened litmus very slightly, fuse and volatilise when heated, without leaving baryta, and dissolve in water, in alcohol, and in 30 pts. of ether; their aqueous solution does not precipitate the salts of barium, calcium, or silver, or neutral acetate of lead, or corrosive sublimate (Liebig).—5. The aqueous solution becomes turbid by long standing (if, according to Liebig, it contains a trace of foreign organic matter), and evolves a sickening ammoniacal odour (Chevreul).—6. When *nitrous gas* is passed into a solution of creatine in nitric acid, an alkali is formed, having the composition $\text{C}^2\text{H}^3\text{N}^5$ (Dessaigues).—7. When an aqueous solution of creatine is heated with *mercuric oxide*, carbonic acid is evolved, and methyluramine ($\text{C}^2\text{H}^7\text{N}^3$) obtained in the form of an oxalate (Dessaigues):

The same transformation is effected by a mixture of peroxide of lead and sulphuric acid (Dessaigues).—8. Hot *nitric acid* decomposes creatine, yielding methyluramine and ammonia (Dessaigues).—9. Creatine heated with *soda-lime*, gives off methylamine. (Dessaigues.)

SALTS OF CREATINE. Creatine is a very weak base, not being capable of neutralising the weakest acids, even when added in very large quantity. (Liebig.)

Sulphate of Creatine, $2\text{C}^2\text{H}^3\text{N}^3\text{O}^2 \cdot \text{SO}^2\text{H}^2$, and the *Hydrochlorate*, $\text{C}^2\text{H}^3\text{N}^3\text{O}^2 \cdot \text{HCl}$, are obtained in fine prisms by dissolving creatine in the proper quantity of acid, and evaporating the solution at 30°C . or in vacuo; they are soluble in water but not deliquescent. (Dessaigues.)

Nitrate of Creatine, $\text{C}^2\text{H}^3\text{N}^3\text{O}^2 \cdot \text{NO}^3\text{H}$.—Obtained by dissolving crystallised creatine in the requisite quantity of nitric acid, and evaporating the solution at 30°C .; or by passing a rapid stream of nitrous gas through water containing an excess of creatine in suspension. The creatine dissolves with tolerable rapidity, and a considerable quantity of small shining crystals of the nitrate are formed, which, when recrystallised by dissolving them in lukewarm water and cooling, form thick short prisms. This salt is less soluble in water than the sulphate or hydrochlorate. The solution has a very sour taste, and is decomposed by ammonia with precipitation of creatine. (Dessaigues.)

From a solution in warm baryta-water, creatine crystallises on cooling without taking up any baryta. (Liebig.)

The aqueous solution of creatine does not precipitate chloride of barium, basic acetate of lead, ferric sulphate, cupric sulphate, nitrate of silver, or dichloride of platinum (Chevreul). It does not precipitate chloride of zinc, unless it contains creatinine (Heintz). The warm non-boiling, aqueous solution, added to chloride of zinc, does not throw down any crystalline compound, but yields the creatine in the separate state on cooling (Liebig). On boiling the mixture, the zinc-precipitate is formed (Heintz), probably from conversion of the creatine into creatinine.

CREATININE, $\text{C}^4\text{H}^7\text{N}^3\text{O}$ or $\text{C}^8\text{H}^7\text{N}^3\text{O}^2$. (Liebig, Ann. Ch. Pharm. lxi. 298 and 324.—Heintz, Pogg. Ann. lxi. 602; lxxiii. 595; lxxiv. 125.)—Heintz and Pettenkofer, in 1844, and nearly at the same time, discovered in human urine a nitrogenous substance which formed a crystalline precipitate with chloride of zinc. The crystalline substance separated from this precipitate was regarded by Pettenkofer as a peculiar compound = $\text{C}^8\text{H}^{16}\text{N}^6\text{O}^3$ [plainly a mixture of creatine and creatinine], by Heintz, at first as an acid, and afterwards as creatine, till Liebig, in 1847, showed that it was a mixture of creatine and creatinine, which latter he had just before discovered and investigated, having obtained it by decomposing creatine with concentrated acids.

Sources.—1. In human urine, to the amount of 0.5 per cent. (Pettenkofer), and,

according to Heintz, likewise in the urine of horses and other mammalia. Socoloff has found it in the urine of horses and of calves. — 2. In muscular flesh. As it occurs in the mother-liquor of the creatine prepared from flesh, and as dilute acids do not convert creatine into creatinine, we cannot suppose that this creatinine of muscular flesh is formed by heating the decoction of the flesh (Liebig, see p. 97). — 3. In blood. (Verdeil and Marcet.)

Formation. — From creatine, by the action of the stronger mineral acids.

Preparation — 1. *From Human urine.* — *a.* Fresh human urine is neutralised with carbonate of sodium, and evaporated below 100° C. to a syrup (till the salts crystallise out, according to Liebig); this syrup is exhausted with alcohol; the filtrate mixed with a concentrated solution (alcoholic, according to Heintz) of chloride of zinc, which at first throws down a brown amorphous precipitate, containing zinc (phosphate of zinc, according to Heintz), then after several hours, crystalline grains; the whole of the precipitate, after standing for some time is collected on a filter (Heintz washes it with weak alcohol); boiled with water, which leaves the amorphous precipitate undissolved; and the filtrate evaporated, — whereupon it yields yellow crystals, which may be freed from adhering salts by repeated boiling with strong alcohol (Pettenkofer). — *b.* Fresh human urine is neutralised with milk of lime; chloride of calcium added as long as a precipitate of phosphate of calcium continues to form; the filtrate evaporated till the salts crystallise out; 32 pts. of the mother-liquor mixed with 1 pt. of chloride of zinc dissolved in the smallest possible quantity of water; the mixture set aside for four days; and the zinc-compound which separates in nodules washed with cold water (Liebig). — *c.* Putrid human urine is boiled with excess of milk of lime till it no longer gives off ammonia; the filtrate is evaporated to a syrup, and mixed as above with chloride of zinc; and the crystals which form after long standing, are washed. (Liebig; see also Dessaignes, J. Pharm. [3] xxxii. 42.)

To purify the crystals, it is not good to use bone-charcoal, which occasions great loss; — but they must be dissolved in hot water; the solution mixed with ammonia till a precipitate begins to form; the precipitation completed by means of sulphide of ammonium; the filtrate highly concentrated and mixed with absolute alcohol; the nearly white crystals of creatine and creatinine, which are obtained by cooling the solution to a low temperature, dissolved in the smallest possible quantity of boiling water; the solution mixed with alcoholic chloride of zinc; and the precipitate, which forms on setting the liquid aside in a cold place, washed with alcohol. The above-mentioned mother-liquor of creatine, which likewise contains sal-ammoniac, also yields, with alcoholic chloride of zinc, a precipitate which, when purified by crystallisation from boiling water, yields the zinc-compound in white crystals. (Heintz; see also Löbe, J. pr. Chem. lxxxi. 170; Rép. Chim. pour 1861, p. 25.)

The zinc-compound is then decomposed with hydrate of lead in the manner described at page 96, and the mixture of creatine and creatinine thus obtained, is digested in the cold with very strong alcohol, which dissolves the creatinine and leaves the creatine: great care must be taken to avoid rise of temperature, otherwise some of the creatine will also be dissolved. (Neubauer, Ann. Ch. Pharm. cxix. 27.)

The quantity of creatinine in urine may be very exactly estimated by precipitation with an alcoholic solution of chloride of zinc. 300 cc. of urine are treated with milk of lime and chloride of calcium as above; the liquid, filtered after standing for two hours, is evaporated to dryness over the water-bath; the residue, while still warm, is digested for 4 or 5 hours with 30 or 40 cc. alcohol of 95°; the liquid is filtered; the residue washed with small quantities of alcohol; the liquid, evaporated if necessary to a volume of 40 or 50 cc., is mixed, after cooling, with 0.5 cc. of an alcoholic solution of chloride of zinc (density 1.2), then briskly agitated, and left to itself for 3 or 4 days in a cellar; and the crystals thus obtained are washed on a weighed filter with a small quantity of alcohol, then dried at 100° C. and weighed. In this manner the quantity of creatinine voided in 24 hours in the urine of a healthy man weighing 54.5 kil. was found to be 1.166 grm., that is to say, 0.0214 grm. per kilogramme.

2. *From Horse-urine.* — The urine, which has an alkaline reaction, is neutralised with hydrochloric acid, evaporated to a small bulk, and then mixed with an additional quantity of hydrochloric acid; the liquid separated from the precipitated hippuric acid is neutralised with milk of lime, and evaporated nearly to dryness over the water-bath; the residue repeatedly boiled out with alcohol; and the alcoholic solution mixed with a small quantity of chloride of zinc: it then gradually deposits a brownish-yellow precipitate of zincochloride of creatinine, from which creatine and creatinine may be obtained as above. (Socoloff, Ann. Ch. Pharm. lxxviii. 243.)

3. *From Calves' urine.* — The fresh urine evaporated to a small bulk over the water-bath, and filtered while hot from the amorphous precipitate thereby formed, yields, after a few days, a crystalline mass consisting of allantoin, together with a large quantity of phosphate of sodium and ammonium; and on washing this crystalline

mass with cold water, and recrystallising the residue, crystals of pure allantoin are obtained. The mother-liquor filtered from the allantoin is mixed with alcohol, which throws down sulphates, mucous matter, the greater part of the phosphates, and a large quantity of colouring matter; and the filtrate, which is still considerably coloured, is freed from the remainder of the phosphoric acid by means of chloride of calcium, and lastly mixed with a concentrated solution of chloride of zinc; it then yields a precipitate of zincochloride of creatine, which continues to increase for several days. (Socoloff.)

4. *From Blood*.—A considerable quantity of fresh ox-blood (about 5 quarts) is freed from fibrin and blood-corpuscles by stirring, and from albumin by heat; then filtered through linen, and evaporated over the water-bath with addition of a little powdered gypsum, which removes an albuminous substance not coagulable by heat, as well as some additional blood-corpuscles, and precipitates the saponifiable fats. The liquid is then evaporated to one-fourth of its bulk, again filtered, and the colourless filtrate evaporated to dryness at a very gentle heat, whereupon nearly all the chloride of sodium crystallises out. On treating the residue with small quantities of absolute alcohol till nothing more is dissolved, and expelling the greater part of the alcohol by heat, the solution yields, on cooling, Boudet's *seroline* (Ann. Ch. Phys. lii. 337), the quantity of which increases on addition of a small quantity of water. The liquid filtered from the seroline yields, on addition of a small quantity of solution of chloride of zinc, sometimes immediately, sometimes after a few hours, a partly crystalline, partly amorphous precipitate, which is but partially soluble in boiling water. The insoluble portion is resinous, and appears to be a compound of chloride of zinc with a peculiar organic substance; the soluble portion consists of the zincochloride of creatinine. The quantity thus obtained is, however, but small. (Verdeil and Marcet, J. Pharm. [3] xx. 89.)

5. *From Muscular Flesh*.—The mother-liquor of creatine is treated with alcohol to precipitate the inosinate of potassium or barium; the filtrate evaporated over the water-bath; the residue boiled out with alcohol, which takes up all the creatinine, together with a little creatine, and leaves a residue consisting chiefly of chloride and lactate of potassium; the filtrate mixed with chloride of zinc; and the crystals of zincochloride of creatinine, which form after a while, decomposed as above with hydrated oxide of lead. (Liebig.)

6. *From Creatine*.—*a*. Hydrochloric acid gas is passed to saturation over creatine heated to 100° in a Liebig's drying apparatus, then dry air as long as water continues to escape; or the solution of creatine in strong hydrochloric acid is evaporated to dryness in the water-bath. The hydrochlorate of creatinine obtained by either of these methods is then dissolved in 24 pts. of water; the solution kept at the boiling heat in a basin; perfectly pure hydrated oxide of lead macerated in water added to it by small portions till it becomes neutral or slightly alkaline, and then three times as much of the hydrated oxide of lead, until the liquid becomes pasty from formation of oxychloride of lead. The liquid is then filtered and the precipitate well washed; the filtrate treated with a small quantity of blood-charcoal to remove any lead that may still remain dissolved; the liquid again filtered, and the filtrate evaporated and cooled to the crystallising point (Liebig).—*b*. The solution of 1 pt. creatine in 1 pt. oil of vitriol and 3 pts. water is evaporated till all moisture is removed; the remaining sulphate of creatinine boiled with water and very pure carbonate of barium, till it becomes alkaline; and the solution filtered and left to crystallise. (Liebig.)

Properties.—Colourless prisms belonging to the monoclinic system. Dominant faces ∞P , oP , $\infty P \infty$. Inclination of the faces $oP : \infty P \infty = 69^{\circ} 24'$; $\infty P : \infty P$ in the plane of the orthodiagonal and principal axis = $98^{\circ} 20'$. Creatinine in the state of concentrated solution has a caustic taste, like that of dilute ammonia. It blues reddened litmus, and reddens turmeric (Liebig). Dissolves in 11.5 pts. of water at $16^{\circ} C$., and much more abundantly in hot water; in 102 pts. of absolute alcohol at 16° , and more abundantly in hot alcohol, from which it crystallises on cooling. (Liebig.)

Calculation.				Liebig.		
				From Urine.	From Flesh.	From Creatine.
C ⁴	.	48	42.48	42.64	41.70	42.54

C ⁴ H ⁷ N ³ O		113	100.00	100.00		100.00

Decompositions.—1. Creatinine, under certain circumstances, takes up 1 at. water, and is reconverted into creatine. The dilute solution of hydrochlorate or sulphate of creatinine slightly supersaturated with ammonia and evaporated, yields a few crystals of creatine (Heintz). Creatinine enclosed in a bottle with sufficient water to dissolve

it, yields in the course of six months a few crystals of creatine; if ammonia be added to the liquid, the quantity of creatine produced is considerably greater. The same transformation takes place in presence of neutral salts, and is accelerated by heat (Dessaigues, J. Pharm. [3] xxxii. 41; see also *Zincochloride of Creatinine, infra*). 2. Creatinine is decomposed by *mercuric oxide* in the same manner as creatine (p. 98), yielding methyluramine (Dessaigues); also by permanganate of potassium (Neubauer). 3. *Nitrous acid* passed into the aqueous solution of creatinine converts it, with evolution of carbonic acid, into the nitrate of a very weak base, $C^6H^{10}N^6O^3$ (Dessaigues, *loc. cit.*; see also page 102):

4. Heated with *iodide of ethyl* and alcohol or ether, it yields iodide of ethyl-creatinine and hydriodate of creatinine.

Sulphate of Creatinine. $2C^4H^7N^3O$.—An aqueous solution of creatinine saturated at a boiling heat and mixed with dilute sulphuric acid till it acquires a strong acid reaction, leaves on evaporation a white mass, whose solution in hot alcohol becomes turbid on cooling, then clear, and deposits transparent, colourless, quadratic tables, which remain transparent at 100° . (Liebig.)

Hydriodate of Creatinine. $C^4H^7N^3O.HI$, is produced, together with iodide of ethyl-creatinine, in the preparation of that compound (p. 102), and remains in the mother-liquor after the latter has crystallised out. It is very soluble in water and in alcohol, and may be obtained, by repeated crystallisation from water, in large transparent, somewhat yellowish crystals. The aqueous solution mixed with acetate of sodium and chloride of zinc, yields a precipitate of zinc-chloride of creatinine. (Neubauer.)

Hydrochlorate of Creatinine. $C^4H^7N^3O.HCl$. *Preparation* (ii. 100, 6).—Crystallises from solution in boiling alcohol in transparent colourless prisms, and, by evaporation of the aqueous solution, in transparent laminae which redden litmus. Dissolves very readily in water. (Liebig.)

Zincochloride of Creatinine. $C^4H^7N^3O.ZnCl$. *Preparation*.—1. (p. 100).—2. By mixing creatinine and chloride of zinc in the state of concentrated aqueous solutions. Both processes yield, with greater rapidity as the mixture is more concentrated, delicate needles united in nodules, or prisms (Pettenkofer), belonging to the monoclinic system, with terminal faces inclined $82^\circ 30'$ to the principal axis (K. Schmidt, Ann. Ch. Pharm. lxi. 332). The crystals give off only a trace of hygroscopic water at $120^\circ C$. When the creatinine is separated from this compound by means of hydrated oxide of lead or sulphide of ammonium (p. 99), more than $\frac{1}{2}$ of it is found to be converted into creatine, and in larger proportion, apparently, as the solution of the zinc-compound used was more dilute. If, therefore, after the creatine has been separated from the resulting liquid by evaporation and cooling, with addition of alcohol, the mother-liquor containing the rest of the creatinine be repeatedly precipitated with chloride of zinc, and the precipitate decomposed, &c., nearly all the creatinine may be converted into creatine (Heintz and Dessaigues). Zinc-chloride of creatinine dissolves sparingly in alcohol, but is insoluble in strong alcohol and in ether (Pettenkofer). It dissolves in 9217 pts. alcohol of 98° , and in 5743 pts. alcohol of 87° . (Neubauer.)

Chloride of zinc likewise combines with *hydrochlorate of creatinine*, forming the compound $C^4H^7N^3O.HCl.ZnCl$, which is obtained in large crystals, very soluble and strongly acid to the taste, by dissolving the zinc-chloride of creatinine in hydrochloric acid, and evaporating to a syrup (Dessaigues, J. Pharm. [3] xxxii. 43). The solution mixed with acetate of sodium, yields a precipitate of zinc-chloride of creatinine. (Neubauer, Ann. Ch. Pharm. xx. 267.)

Creatinine also forms with *chloride of cadmium*, a crystallised compound $C^4H^7N^3O.CdCl$, more soluble in water than the zinc-compound, and sometimes appearing to crystallise with 1 at. water. (Neubauer.)

With *cupric salts*, creatinine forms crystallisable double salts of a fine blue colour. (Liebig.)

When mixed in aqueous solution with *corrosive sublimate*, it immediately forms a white curdy precipitate, which changes in a few minutes to a mass of delicate colourless needles (Liebig). With *mercuric nitrate*, it forms a crystalline compound, $2(C^4H^7N^3O.HgNO^3).Hg^2O$, which, when decomposed by sulphydric acid, yields fine crystals of nitrate of creatinine. (Neubauer.)

With concentrated solution of *nitrate of silver*, it coagulates immediately into a mass of delicate white needles, which dissolve readily in hot water, and crystallise out again unchanged on cooling (Liebig). According to Neubauer, they contain $2(C^4H^7N^3O.AgNO^3).Ag^2O$.

The clear mixture of dilute hydrochlorate of creatinine and *dichloride of platinum* (or of hydrochloric acid, creatine, and dichloride of platinum), yields, by slow evapo-

ration, transparent, aurora-red prisms, and by quicker evaporation, granules which dissolve readily in water, less quickly in alcohol, and contain 30.53 per cent. platinum, whence they probably consist of $C^4H^7N^3O.HCl.PtCl^2$. (Liebig.)

Ethyl-creatinine. $C^6H^{12}N^3O = C^4H^7(C^2H^5)N^3O$ (Neubauer, Ann. Ch. Pharm. xix. 51; xx. 257).—The iodide of this base, $C^6H^{12}N^3OI$, is produced by enclosing 30 grms. of creatinine with rather more than an equivalent quantity of iodide of ethyl and about 40 per cent. of absolute alcohol, in a sealed tube and heating the mixture to $100^\circ C$. for several hours. A crystalline pulp is thus obtained, which, when purified by several recrystallisations from absolute alcohol, yields the iodide in long shining needles, very soluble both in water and in alcohol.

By treating the iodide with oxide of silver, carefully avoiding an excess, and evaporating the filtrate in vacuo, a radio-crystalline mass is obtained, consisting of the hydrate of ethyl-creatinine $C^6H^{12}N^3O \left\{ \begin{matrix} O \\ H \end{matrix} \right\} + \frac{1}{2} aq.$ very soluble in water and alcohol, insoluble in ether. From solution in warm absolute alcohol it crystallises on cooling, in fine needles, grouped in nodules. It is not deliquescent. The aqueous solution is strongly alkaline, has a bitter taste, precipitates sesquichloride of iron and salts of aluminium, and expels ammonia from its salts when heated with them.

The chloride $C^6H^{12}N^3OCl$ is obtained by slightly supersaturating the aqueous solution of the base with hydrochloric acid, and evaporating, as a crystalline mass composed of interlaced needles, very soluble in water and alcohol, insoluble in ether. The solution, mixed with dichloride of platinum, yields the chloroplatinate, $C^6H^{12}N^3OCl.PtCl^2$, in fine prisms.

Hydrate of ethyl-creatinine, heated in a sealed tube with iodide of ethyl, does not yield a compound containing another atom of ethyl, but merely iodide of ethyl-creatinine and alcohol:

Hence ethyl-creatinine may be regarded as an ammonium-base, and creatinine itself as a tertiary amine, $N.(C^4H^7N^2O)'''$.

Bases produced from Creatine and Creatinine by the action of Nitrous Acid.

a. $C^6H^{10}N^3O^3$. (Dessaignes, Compt. rend. xli. 1258; Ann. Ch. Pharm. xcvii. 339).—When nitrous acid gas is passed into an aqueous solution of creatinine, carbonic acid escapes, the liquid becomes brown and turbid, and after a few hours the nitrate of the base, $C^6H^{10}N^3O^3$, separates in small yellowish indistinct crystals, which become thick if left for some time under the liquid. The reaction is:

This compound, which appears to be likewise formed in small quantity by the action of nitrous acid on creatine, is a very weak base, its salts being partially decomposed even by solution in water. Ammonia added to the solutions throws down the base as a white, amorphous, tasteless powder, insoluble in water, but soluble in dilute acids at a gentle heat. Some of the salts crystallise from their solutions on cooling. The hydrochlorate, $2C^6H^{10}N^3O^3.3HCl + 6H^2O$, forms long deeply striated prisms; the chloroplatinate, which is moderately soluble in water, forms large crystals, consisting of $2C^6H^{10}N^3O^3.3HCl.3PtCl^2 + 6H^2O$.

B. $C^4H^4N^2O^3$. (Dessaignes, loc. cit.)—Produced, together with oxalic acid and chloride of ammonium, by heating the base **a** with hydrochloric acid:

Crystallises in long shining prisms or laminae; dissolves slowly in cold water, easily in hot water, slightly in ether; has an unpleasant, almost metallic taste; melts and volatilises without decomposition, and burns with flame without leaving any residue. It has a slight acid reaction; does not precipitate the salts of calcium, barium, lead, copper, or zinc, or chloride of mercury, or nitrate of silver in dilute solution. Dessaignes regards this body as identical with that which Liebig observed to be produced, together with sarcosine, by the action of baryta on creatine at the boiling heat (p. 97). Städeler (Ann. Ch. Pharm. cxviii. 151) points out that it has the composition of methyl-parabanic acid, $C^3H(CH^3)N^2O^3 = N^2.(CO)''(C^2O^2)'''.CH^3.H$.

γ. C^3H^5N . (Dessaignes, Compt. rend. xxxviii. 839).—When nitrous acid is passed into a solution of creatine in nitric acid, a large quantity of gas is evolved, and on neutralising with potash, separating the greater part of the nitrate of potassium by crystallisation, and adding nitrate of silver, crystals are obtained, consisting of $C^3H^5N.AgNO^3$. They dissolve in hot water, and after several crystallisations assume the form of long white needles. When decomposed by excess of hydrochloric acid,

they yield the nitrate, $C^3H^5N.HNO_3$, in the form of a fibrous mass of small prisms having a very sour taste. The *chloromercurate* crystallises in long prisms.

CREDNERITE. *Cupriferrous Manganese.* $3Cu^2O.2Mn^4O^3$ —A mineral found near Frederichsrode in the Thüringer Wald, together with psilomelane and hausmannite. It occurs in crystallo-laminar aggregations, cleaving with moderate distinctness in two directions parallel to the sides of a monoclinic prism, very distinctly parallel to the base. Fracture uneven. Colour iron-black. Streak black. Lustre vitreous, strongest on the perfect cleavage-face. Opaque. Specific gravity = 4.9 to 5.1. Hardness = 4.0—4.5. Thin laminae melt, at the edges only, when strongly heated before the blowpipe. With borax it forms a dark violet glass; with phosphorus-salt a green glass, becoming blue on cooling, and copper-red in the inner flame. Hydrochloric acid dissolves it, with evolution of chlorine, forming a green solution.

Analyses *a, b, c*, by Rammelsberg (Pogg. Ann. lxxxiv. 559); *d* by Credner (*ibid.* lxxiv. 555).

	Mn ² O	O	Cu ² O	Ba ² O	Ca ² O	H ² O	Gangue.	
<i>a.</i>	64.24	8.83	23.73	2.01	—	—	—	= 98.81
<i>b.</i>	56.29	8.58	32.35	3.08	0.76	—	—	= 101.06
<i>c.</i>	52.55	5.78	40.65	1.48	—	—	—	= 100.46
<i>d.</i>	51.06	—	42.73	0.52	0.63	0.25	0.63	= 95.82

The formula $3Cu^2O.2Mn^4O^3$ requires 42.9 per cent. Cu^2O , and 57.1 Mn^2O ; the mineral often contains excess of oxide of manganese.

CRENIC and APOCRENIC ACIDS. (Berzelius, Pogg. Ann. xiii. 84; Mulder, Ann. Ch. Pharm. xxxvi. 243).—Organic acids existing, according to Berzelius, in vegetable mould and in the ochreous deposits of ferruginous waters. (The word *crenic* is derived from *κρήνη*, a spring.) They were first obtained from the mineral water of Porla in Sweden. According to Berzelius, the yellow deposit which forms in ferruginous waters contains these acids in the form of basic salts. They are extracted by boiling the deposit with potash, filtering, supersaturating the liquid with acetic acid, and adding a solution of acetate of copper, as long as a dark brown precipitate continues to form. This precipitate contains the apocrenic acid. The liquid is filtered, saturated, or slightly supersaturated with carbonate of ammonium, and acetate of copper again added as long as a greenish-white precipitate is produced. The precipitation is completed by heating the mixture which contains the crenic acid to 80° C.; the crenic acid is more abundant than the apocrenic. Both precipitates are decomposed by suspending them in water, and passing a stream of sulphuretted hydrogen through the liquid.

The *crenic* acid is isolated by evaporating the filtered liquid in vacuo. The product thus obtained still retains a certain quantity of earthy crenates, from which it may be separated by means of absolute alcohol, which dissolves the acid and leaves the salts, and evaporating the alcohol in vacuo. As thus obtained, it is pale yellow, uncrystallisable, transparent, hard, and fissured; its taste is acid at first, afterwards astringent. With the alkalis it forms neutral and acid salts, which are uncrystallisable, soluble in water, insoluble in alcohol, and resemble vegetable extracts in appearance. They are yellow, and turn brown in the air from formation of apocrenic acid.

Apocrenic acid is brown, sparingly soluble in water, more soluble in absolute alcohol, and has a very astringent taste. The apocrenates of the alkalis resemble the crenates, excepting that they are black.

Both acids displace acetic acid by evaporation. Apocrenic acid dissolves immediately in alkaline acetates. The ferrous salts of both acids are soluble in water, but their ferric salts are insoluble.

According to Berzelius, both crenic and apocrenic acid contain nitrogen and give off ammonia by dry distillation. Mulder supposes that the nitrogen found in them is in the form of an ammonium-salt, and may be completely removed by acetic acid. Mulder represents crenic acid by the formula $C^{12}H^{12}O^5$, and apocrenic acid by $C^{12}H^{12}O^{12}$; but these acids have not yet been obtained in a sufficiently definite state to enable us to fix their formulæ.

CREOSOL. The principal constituent of wood-creosote (p. 104).

CREOSOTE. (Reichenbach [1832], Schw. J. lvi. 301, 345; lxvii. 1, 57; lxviii. 352. Ettling, Ann. Ch. Pharm. vi. 209. Laurent, Compt. rend. xi. 124; xix. 574. Deville, Ann. Ch. Phys. [3] xii. 228. Gorup-Besanez, Ann. Ch. Pharm. lxxviii. 231; lxxxvi. 223. Völekel, *ibid.* lxxxvi. 93; lxxxvii. 306. Hlasiwetz, *ibid.* cvi. 339. On the Preparation of Creosote: E. Simon, Pogg. Ann. xxxii. 129. Hübschmann, Ann. Ch. Pharm. xi. 40. Köne, *ibid.* xvi. 63. Krüger, Buchner's Repert. Pharm. xlviii. 273. Buchner, *ibid.* xlix. 84. Cozzi, *ibid.* lv. 693.)—The substance known in commerce by the name of *creosote* is often

merely hydrate of phenyl more or less impure; but the true creosote extracted by Reichenbach from wood-tar is a perfectly distinct body, and does not exhibit all the characters of hydrate of phenyl. It is to the true creosote that wood-vinegar, tar-water, soot, and wood-smoke owe their power of arresting the putrefaction of meat and other animal substances. The name *creosote* is derived from *κρέας*, flesh, and *σώζειν*, to save.

Preparation.—When wood-tar is distilled till the residue acquires the consistence of a pitchy mass, the liquid collected in the receiver is formed of several distinct layers, the lowest of which contains the creosote. On saturating it with carbonate of sodium and leaving it at rest, a yellowish oil rises to the surface. This oil is decanted, and rectified in a glass retort, the lighter portion of the distillate being rejected and the heavier portion collected and ignited with potash-solution of specific gravity 1.12. The creosote then dissolves in the alkaline liquid, while the hydrocarbons with which it is mixed remain undissolved. The alkaline solution is decanted and boiled for some time in contact with the air, to resinise a foreign substance dissolved in the potash, after which the liquid is filtered and the creosote set free by addition of sulphuric acid. The creosote thus obtained is not yet pure; it requires to be again distilled several times with alkaline water, then dissolved in potash, to free the creosote from insoluble hydrocarbons, and separated from the alkaline solution by sulphuric acid. These operations must be repeated till the creosote dissolves in potash without residue, after which the creosote is to be finally distilled at 200°C ., and dried over chloride of calcium.

Properties.—Creosote is a colourless, oily, strongly refracting liquid, having a disagreeable penetrating odour like that of smoked meat, and a burning taste. Specific gravity 1.037 at 20°C . (Reichenbach), 1.040 at 11.5° (Gorup-Besanez), 1.076 at 15.5° (Vöckel). It does not solidify at -27°C . Boils at 203° (Reichenbach); between 203.5° and 208° (Gorup-Besanez), and distils in great part without alteration. When pure it does not become coloured by exposure to the air. It burns with a smoky flame. Does not conduct electricity.

Creosote is sparingly soluble in water, but mixes in all proportions with alcohol, ether, bisulphide of carbon, naphtha, and acetic ether. It dissolves sulphur, phosphorus, selenium, oxalic, citric, tartaric, benzoic and stearic acids, resins, and several colouring matters. With the aid of heat it dissolves several metallic salts, *e. g.* the chlorides of calcium and tin, the acetates of potassium, sodium, ammonium, zinc, &c., and deposits them in the crystalline state on cooling.

It imparts a blue colour to *ferric salts*, and reduces nitrate of *silver*, and the salts of *mercury, gold, and platinum*. When dropped on recently prepared oxide of silver it produces a kind of explosion, the silver being partly reduced, and oxalate of silver formed, together with several resinous compounds.

The composition of creosote is not yet definitely fixed. The following are the analyses which have been made of it:

	Ettling.		Gorup-Besanez.			
C . . .	75.72	74.53	75.32	75.72	74.78	74.68
H . . .	7.80	7.87	7.84	7.94	7.98	7.84
O . . .	16.48	17.60	16.84	16.34	17.24	17.48
	100.00	100.00	100.00	100.00	100.00	100.00

	Deville.			Vöckel.		
C . . .	72.30	72.54	72.92	72.48	72.53	72.35
H . . .	7.60	7.60	8.16	7.04	7.10	7.16
O . . .	20.10	19.86	18.92	20.48	20.37	20.49
	100.00	100.00	100.00	100.00	100.00	100.00

Gorup-Besanez deduces from his analyses the formula $\text{C}^{13}\text{H}^{16}\text{O}^2$ (calc. 76.47 C; 7.84 H). Vöckel gives the formula $\text{C}^{12}\text{H}^{14}\text{O}^2$ (72.72 C; 7.07 H); neither of these formulæ agrees well with the analyses. According to Hlasiwetz, creosote is a compound ether derived from an acid, $\text{C}^8\text{H}^{10}\text{O}^2$, which, when treated with bases, forms salts having the composition $\text{C}^8\text{H}^9\text{MO}^2$, and yielding the acid itself when distilled with dilute sulphuric acid (see p. 105).

Decompositions.—Creosote is decomposed by *chlorine*, with evolution of hydrochloric acid and formation of a chlorinated compound, which is decomposed by distillation. *Bromine* is absorbed in large quantity by creosote, yielding, according to Deville, a crystalline acid, having the composition of creosote in which half the hydrogen is replaced by bromine. *Iodine* dissolves in creosote, forming a brown liquid.

When creosote is acted upon at a gentle heat by a mixture of *hydrochloric acid* and *chlorate of potassium*, the action being continued for several days, and arrested as

soon as an abundant evolution of chlorine takes place, a crystalline mass is obtained from which cold alcohol extracts a substance crystallising in large rhomboidal tables, leaving another compound in the form of yellow scales. (Gorup-Besanez).

The rhomboidal tables give by analysis 39.8 per cent. C, and 1.9 H, which Gorup represents by the formula $C^{13}H^1Cl^3O^3$, designating the compound as *pentachloroxylin*. Gerhardt, however (*Traité*, iii. 24), prefers the formula $C^8H^1Cl^3O^2$ (calc. 40 per cent. carbon, and 2 hydrogen); according to which it is homologous with trichloroquinone. The yellow scales give by analysis (mean) 36.7 C, 1.5 H, and 50.6 Cl, which Gorup represents by the formula $C^{13}H^1Cl^6O^3$ (*hexachloroxylin*), while Gerhardt gives the formula $C^8H^1Cl^4O^2$, homologous with tetrachloroquinone. When the yellow scales are suspended in water and sulphurous acid gas passed through the liquid, the scales are converted into brownish-white four-sided prisms, which dissolve in a mixture of alcohol and ether, yielding a yellow solution, which, by spontaneous evaporation, deposits long violet needles and reddish prisms, the latter containing about the same quantity of carbon as the yellow scales, but more hydrogen (2.23 to 2.39 per cent.). Hence these products would appear to be related to the yellow scales in the same manner as the chlorinated hydroquinones are to the chlorinated quinones. All these compounds require further investigation, but their formation is sufficient to show that creosote from wood-tar is a very different thing from hydrate of phenyl, the so-called *coal-tar creosote*.

Creosote partakes of the nature of an acid; it dissolves in caustic alkalis, and is decomposed by potassium, with elimination of hydrogen. Two potassium-salts have been formed, also sodium, ammonium, barium, lead, ethyl, and benzoyl-salts.

Potassium-salts.—*a. Neutral*, $C^8H^1KO^2.2H^2O$. Obtained by heating creosote with solid hydrate of potassium to about $130^\circ C$. in an atmosphere of hydrogen, and crystallising the product from ether. It is then obtained in thin soft prisms or scales, of dazzling whiteness and satiny lustre. It dissolves readily also in water and alcohol, crystallising from the aqueous solution in soft interlaced needles. When thoroughly freed from mother-liquor by pressure and dried, it may be preserved without alteration; otherwise it quickly turns bluish-green, and ultimately brown on exposure to the air. The same is the case with all the creosote-salts; hence the necessity of excluding the air during their preparation.—*B. Acid salt*, $C^8H^1KO^2.C^8H^{10}O^2$. Obtained by treating creosote with potassium in an atmosphere of hydrogen, and crystallising from ether. Resembles the neutral salt in appearance and in most of its properties, but is decomposed by water. (Hlasiwetz.)

Sodium-salts.—Creosote behaves with sodium and hydrate of sodium much in the same manner as with potassium and its hydrate; but the sodium-salts have not yet been obtained in definite form. (Hlasiwetz.)

Barium-salt, $2C^8H^1BaO^2 + 3H^2O$.—Prepared like the neutral potassium-salt. Forms dazzling white scales, having a satiny lustre, quite inodorous, and permanent when pure. Gives off its water at $100^\circ C$. (Hlasiwetz.)

Lead-salt, $4C^8H^1PbO^2.Pb^2O + 2H^2O$.—The neutral potassium-salt mixed with acetate of lead yields a bulky white precipitate, which, when dried in vacuo, exhibits this composition. (Hlasiwetz.)

Ethyl-compound, $C^8H^1(C^2H^5)O^2$.—Obtained by heating the neutral potassium-salt with iodide of ethyl in a sealed tube, distilling, removing the last traces of iodine by agitation with silver, and rectifying. Oily liquid, having a slight yellowish tinge and faint aromatic odour.

A *benzoyl-compound*, $C^8H^1(C^7H^5O)O^2$, appears to be formed by treating the neutral potassium-salt with chloride of benzoyl. (Hlasiwetz.)

Creosol, $C^8H^{10}O^2$.—By decomposing the neutral potassium-salt of creosote with dilute sulphuric acid, washing with water, rectifying, and collecting the portion which distils over at $219^\circ C$. (which is by far the larger portion, small quantities only distilling at lower and at higher temperatures), a colourless oil is obtained, agreeing in composition with the formula $C^8H^{10}O^2$ (69.6 C, and 7.2 H). It is of the consistence of creosote, refracts light strongly, has an aromatic odour like that of vanilla, and burning taste; anhydrous; but little altered by keeping. Specific gravity 1.0894 at $13^\circ C$. Vapour-density 4.98 (by calculation to 2 vols. 4.79). It is not more soluble in water than creosote; mixes in all proportions with alcohol, ether, glacial acetic acid, and alkaline leys. In a freezing mixture, it becomes viscid, but not solid. It reduces nitrate of silver, producing a specular deposit of the metal. Does not unite with the acid sulphites of the alkali-metals, but forms with ammonia, either in the state of gas or in strong aqueous solution, a crystalline salt, sparingly soluble in water, and having the composition $C^8H^1(NH^1)O^2.C^8H^{10}O^2$, analogous to the acid potassium-salt above described. With potash and baryta it behaves like creosote, yielding the salts $C^8H^1KO^2$ and $C^8H^1BaO^2$; the preparation of which is moreover much easier with this oil than with creosote. *Bromine* acts violently on it, forming a crystalline com-

pond, containing $C^{16}H^{15}Br^5O^4$. The same compound is formed by the action of bromine on crude creosote; it does not however solidify at once, but forms a crystalline pulp, from which the pure compound may be obtained by dissolving the pulp in a small quantity of acetic acid, leaving the solution over night, and pressing the deposited crystals to free them from mother-liquor. It is formed by the replacement of 5 at. hydrogen by bromine in a double molecule of creosol.

Trichloroercosol, $C^8H^7Cl^3O^2$, is formed by introducing creosol into a large flask filled with chlorine. The whole solidifies in about 24 hours, and the product may be purified by crystallisation from acetic acid. (Hlasiwetz.)

It appears then that creosote consists mainly of an oil capable of forming salts with bases, and having the composition $C^8H^{10}O^2$. This oil (creosol) is likewise contained in the product of the destructive distillation of guajac resin—this product consisting, according to Hlasiwetz, of *guajacol*, $C^7H^8O^2$, and the homologous compound, *creosotogujacol* or *creosol*, $C^8H^{10}O^2$. Creosote itself is probably a compound of the form $C^8H^9(R)O^2$ or $C^{16}H^{19}(R)O^4$, in which R denotes a radicle free from oxygen. (Hlasiwetz, *loc. cit.*)

CRESOTIC ACID. $C^8H^8O^3 = \begin{matrix} C^8H^7O^2 \\ H \end{matrix} \bigg\} O$. (Kolbe and Lautemann, Ann. Ch. Pharm. cxv. 203.)—An acid isomeric with carbocresylic acid, produced by the action of sodium and carbonic anhydride on cresylic alcohol ($C^7H^8O + CO^2 = C^8H^8O^3$). The resulting mixture of carbocresylate and cresotate of sodium is treated with hydrochloric acid, whereby the carbocresylic acid is resolved into carbonic anhydride and cresylic alcohol, while the cresotic acid remains undecomposed, and may be washed out by means of a strong solution of carbonate of ammonia, the liquid on evaporation yielding the pure acid in fine large prisms. The acid dissolves sparingly in water, easily in alcohol and ether. It melts at $153^\circ C$. and solidifies at 144° . By mixing it with salicylic acid (which melts at 159°), a mixture of lower melting point is obtained: a mixture of 1 pt. cresotic acid and 4 pts. salicylic acid was found to melt at 139° .

Cresotic acid produces a deep violet colour with sesquichloride of iron. When heated with *caustic baryta*, it is resolved into carbonic anhydride and cresylic alcohol.

CRESOXACETIC ACID. $C^9H^{10}O^3$?—An acid produced by the action of monochloroacetic acid on cresylate of sodium. Its copper salt, $C^9H^9CuO^3 + aq.$, is green, and sparingly soluble. (Heintz, Berl. Akad. Ber. 1860, p. 464.)

CRESS, OIL OF. The herb of *Lepidium rudérale* and the inodorous seed of *Lepidium rudérale*, *L. sativum*, and *L. campestre*, bruised and macerated in water, yield by distillation a milky water, from which, by repeated fractional rectification in glass vessels (copper would exert a decomposing action), a yellow oil may be obtained. This oil, after further rectification, is colourless, but turns yellow again on exposure to light. It is heavier than water, neutral, exhibits the refreshing but somewhat alliaceous odour and biting taste of water-cresses, and, when its vapour is inhaled in rather large quantity, produces dryness in the throat and headache. It cannot be distilled undecomposed without water. By oxidation with nitric acid, it yields sulphuric acid. With mercurous nitrate it forms a black precipitate of sulphide of mercury; with corrosive sublimate a white precipitate; with nitrate of silver, sometimes white, sometimes black; with dichloride of platinum in alcoholic solution, an orange-yellow precipitate after a while. Aqueous potash and ammonia have no action on this oil. It dissolves with red colour in oil of vitriol, and may be separated again by water. It dissolves slowly in water, readily in alcohol and ether. (Pless, Ann. Ch. Pharm. lviii. 36.)

The fresh leaves of *Lepidium latifolium* yield by distillation with water, a neutral oil heavier than water, together with a milky, strong-smelling and sharp-tasting water, which loses its sharpness by exposure to the air, and likewise in a few hours after being mixed with chlorine (whereupon it precipitates chloride of barium); it gradually forms a black precipitate with nitrate of silver; blackens metallic silver after a while; and is deprived of its taste and odour by charcoal powder. (Stendel, Diss. de acredine nonnull. vegetab. Tübingen, 1805.)

CRESYLIC ALCOHOL. *Hydrate of Cresyl.* $C^7H^8O = C^7H^7.H.O$.—This alcohol, homologous with hydrate of phenyl, was discovered in 1854 by Williamson and Fairlie (Chem. Soc. Qu. J. vii. 232), and further investigated by Duclos (Ann. Ch. Pharm. cix. 135). It occurs in variable quantity in the so-called coal-tar creosote, and is obtained by subjecting the portion of that liquid which boils between 200° and $220^\circ C$. to fractional distillation (Fairlie). It likewise exists, together with hydrate of phenyl and other compounds, in the tar of fir-wood, and is obtained therefrom by treating the oil which passes over in fractional distillation between 150° and 220° , with weak soda-ley, to separate hydrocarbons, supersaturating the alkaline liquid with sulphuric acid, and repeating the treatment with soda-ley and sulphuric acid, till the oil becomes perfectly

soluble in the alkaline liquid. The oil thus obtained is a mixture of phenylic and cresylic alcohols, which are separated by fractional distillation, the former boiling at 187° C.

Cresylic alcohol is a colourless, strongly-refracting liquid, which boils at 203° C. in the air (the same as wood-tar creosote, p. 104), and at 200° in an atmosphere of hydrogen. Analysis gave 77.4 to 77.7 per cent. carbon, and 8.05 to 2.20 hydrogen (calculation, 77.8 C, and 7.11 H). It is isomeric with benzylic alcohol (i. 578).

Cresylic alcohol is slightly soluble in water, and mixes in all proportions with alcohol and ether. According to Fairlie, it is quite insoluble in ammonia; but according to Duclos, it dissolves in ammonia as easily as phenylic alcohol.

Cresylic alcohol is decomposed by repeated distillation, a portion being apparently converted by the oxidising action of the air into hydrate of phenyl, C^6H^5O ; but in an atmosphere of hydrogen it may be distilled any number of times without alteration. Strong nitric acid at ordinary temperatures attacks it with explosive violence; but when treated with well-cooled nitric acid, it yields a red solution containing trinitrocresylic acid, $C^7H^5(NO_2)_3O$, homologous with picric acid. With dilute nitric acid it forms only a brown tarry mass (Fairlie); according to Duclos, the product is mononitrocresylic acid. With strong sulphuric acid, cresylic alcohol becomes rose-coloured, and forms sulphocresylic acid, $C^7H^5O.SO_3$. With pentachloride of phosphorus, cresylic alcohol yields chloride of cresyl, C^7H^5Cl (boiling at 197°C.), and phosphate of cresyl, which latter is converted by acetate of potassium into acetate of cresyl, and when distilled with ethylate of potassium, yields cresylate of ethyl $C^7H_7.C^2H_5O$, and phosphate of potassium. Mixed with an equal bulk of strong potash-ley, it forms, in the course of 24 hours, a few small crystals, apparently consisting of cresylate of potassium, C^7H^5KO (Fairlie). In contact with chloride of calcium or chloride of zinc, it appears to be converted into phenylic alcohol (Gladstone, *Chemical News*, ii. 98.)

Cresylic alcohol, treated with potassium or sodium, gives off hydrogen and forms a brownish mass, which, on cooling, solidifies to a mass of slender needles of cresylate of potassium or sodium, difficult to purify by crystallisation from ether (Duclos). Cresylate of sodium treated with monochloroacetic acid yields cresoxacetic acid. (Heintz, p. 207.)

Derivatives of Cresylic Alcohol.

Nitrocresylic Acid, $C^7H^5NO_3 = \left. \begin{matrix} C^7H^5(NO_2)_2 \\ H \end{matrix} \right\} O$.—When very dilute nitric acid is gradually added to an aqueous solution of cresylic alcohol heated to 60° or 70° C., the liquid acquires an aromatic odour and yellowish-brown colour, without giving off red vapours, and ultimately deposits nitrocresylic acid in oily drops, which sink to the bottom of the vessel; they are washed with water and dried in vacuo.

Nitrocresylic acid is a yellowish-brown syrupy liquid, inodorous, bitter, easily soluble in alcohol, colours the skin yellow. It appears to unite with alkalis. (Duclos, *loc. cit.*)

Dinitrocresylic Acid, $C^7H^5N_2O_5 = \left. \begin{matrix} C^7H^5(NO_2)_2 \\ H \end{matrix} \right\} O$.—This acid is prepared, not directly from cresylic alcohol, but by the action of nitric acid on sulphocresylic acid. A solution of 1 vol. sulphocresylic acid in 5 or 6 vols. water, or an equally dilute solution of cresylic alcohol in a small quantity of sulphuric acid, is heated with a small quantity of nitric acid diluted with its own bulk of water; the liquid is filtered from a resinous body which separates on cooling; and the filtrate is heated to boiling with addition of nitric acid. Dinitrocresylic acid then separates as a yellow oil, which dissolves in alcohol, but does not crystallise by evaporation. When slowly heated, part of it appears to sublime undecomposed; when quickly heated it detonates. (Duclos.)

Dinitrocresylate of Ammonium is easily soluble, but difficult to crystallise. (Duclos.)

Trinitrocresylic Acid, $C^7H^5N_3O_7 = \left. \begin{matrix} C^7H^5(NO_2)_3 \\ H \end{matrix} \right\} O$.—Discovered by Fairlie, more fully investigated by Duclos. Homologous with trinitrophenic or picric acid. It is obtained—1. By adding fuming nitric acid in small portions to coal-tar creosote containing cresylic alcohol, in a vessel surrounded with ice. The liquid then assumes a deep red colour, and after the addition of a volume of nitric acid equal to that of the creosote, separates into two layers, the upper deep red, the lower black and tarry; the upper contains the trinitrocresylic acid (Fairlie).—2. By heating a dilute solution of sulphocresylic acid with nitric acid, filtering from the resinous body which separates, again heating the filtrate with nitric acid, and evaporating. The dinitrocresylic acid which first separates, is then converted, by the continued action of the nitric acid, into trinitrocresylic acid, which is found, together with oxalic acid, in the crystalline residue obtained on cooling. The oxalic acid is removed by washing, and

Croceetin, $C^{34}H^{46}O^{11}$, or $C^{84}H^{23}O^{11}$.—To obtain this substance pure, the crocin should be boiled with the acid in an atmosphere of hydrogen or carbonic acid, as both crocin and croceetin easily absorb oxygen.

Croceetin is a dark red amorphous powder, slightly soluble in water, easily in alcohol. It turns blue in *sulphuric acid*, like crocin. Its solution forms a yellow precipitate with *lead-salts*. Stuffs mordanted with tin-salt acquire, by boiling in a solution of croceetin, a dingy greenish yellow colour, which by treatment with ammoniacal water is converted into a brilliant yellow colour, unaltered by light and air. The yellow robes of the Chinese mandarins are dyed with the fruit of the *Gardenia*. (Handw. d. Chem. ii. 2^{te} Aufl. ii. [3] 226.)

CROCIDOLITE (from *κροκίς*, wool). A silicate occurring in asbestos-like fibres, also massive, in the Griqua country, beyond the Orange river, South Africa, and in the micaceous porphyry of Wakenbach in the Vosges. Specific gravity = 3.2–3.265. Hardness = 4. Colour and streak, lavender-blue to leek-green. Opaque. Fibres somewhat elastic. Melts easily before the blow-pipe to a black, shining, opaque, somewhat frothy glass, attracted by the magnet. Single fibres melt in the flame of a spirit-lamp. With borax it forms a green transparent bead, changing to brown on addition of nitre.

Analyses: *a.* from Africa, by Klaproth (Beitr. vii. 237); *b.* from Africa, by Stromeyer (Pogg. Ann. xxiii. 153); *c.* from Wakenbach, by Delesse (Ann. Min. [3] x. 307).

	SiO ²	Fe ² O	MnO	Mg ² O	Cu ² O	Na ² O	K ² O	H ² O	Cl	P ² O ⁵ .
<i>a.</i>	50.0	40.5	—	—	1.5	5.0	—	3.0	—	—
<i>b.</i>	51.22	34.08	0.10	2.48	0.03	7.07	—	4.80	—	—
<i>c.</i>	53.02	25.62	0.50	10.14	1.10	5.69	0.39	2.52	0.51	0.17

From these analyses, Rammelsberg (*Mineralchemie*, p. 476) deduces the formula $7M^{2}O.9SiO^{2} + (1\frac{1}{2} \dots 3)H^{2}O$. Taking the larger amount of water, and supposing 2 at. to be basic, this formula may be reduced to $(M^{1}H^{1})Si^{2}O^{7} + aq.$, or $9R^{2}SiO^{3} + aq.$, which is the formula of a metasilicate. The mineral is perhaps formed from soda-hornblende (arfvedsonite), by abstraction of lime.

A somewhat similar mineral occurs at Stavern in Norway.

CROCOISITE. Native chromate of lead (i. 934).

CROCONIC ACID. $C^{5}H^{2}O^{5} = (C^{5}O^{3})^{2}.H^{2}O^{2}$.—(L. Gmelin [1825], Pogg. Ann. iv. 37; Handbook, x. 388. Liebig, Pogg. Ann. xxxiii. 90. Heller, J. pr. Chem. xii. 230; Ann. Ch. Pharm. xxiv. 1; xxxiv. 232. Will, Ann. Ch. Pharm. cxviii. 177.)

When the compound of carbonic oxide and potassium, obtained by passing the dry gas over melted potassium,—or, as a secondary product, in the preparation of potassium by heating carbonate of potassium with charcoal—is immersed in water, inflammable gas is evolved, and a strongly alkaline yellowish-red solution is formed, which, when left to evaporate at a gentle heat, becomes pale yellow and deposits long yellow needles of croconate of potassium, while oxalate of potassium remains in the mother-liquor. These two salts are not, however, the immediate products of the action of air and water on the compound of potassium and carbonic oxide, their formation being preceded by that of a red salt, the rhodizonate of potassium, the solution of which decomposes, during evaporation, into croconate, oxalate, and probably also carbonate of potassium. The relations between these several products are not exactly known.

The black mass produced in the preparation of potassium should be exposed to the air for several weeks before it is dissolved in water; it then gradually acquires a red or yellow colour and dissolves in water without explosion; but if it has been exposed to the air for a few hours only, it takes fire in contact with water (because it contains free potassium), and produces a violent explosion which shatters the vessel.

Croconic acid is obtained in the free state by digesting the potassium-salt with a mixture of sulphuric acid and absolute alcohol for several hours, then filtering, and leaving the solution to evaporate.

It cannot be conveniently prepared by decomposing the lead-salt with sulphuric acid, as the decomposition is never complete, or by decomposing the lead or copper salt with sulphuretted hydrogen, as in that case peculiar sulphur-compounds are formed which are troublesome to separate.

Croconic acid crystallises in anhydrous, orange-yellow, transparent prisms and granules (Gmelin); in golden-yellow laminae or granular crystals containing $C^{2}H^{2}O^{5} + 3H^{2}O$, which become opaque and crumble to a yellow powder when left over oil of vitriol, and more quickly when heated to 100° C. (Will). It is inodorous, has a strongly acid taste, and reddens litmus. It dissolves easily in water,

forming a yellow solution, which gradually becomes colourless; easily also in *alcohol*. (Gmelin.)

Croconic acid is not altered by a temperature of 160°C ., but when more strongly heated, it gives off white and yellow irritating vapours and leaves a small quantity of easily combustible charcoal. In combination with potash it is quickly decomposed by *permanganate of potassium* in presence of sulphuric acid, being entirely converted into carbonic acid. (Will.)

The solution of the potassium-salt is completely decolorised by *nitric acid* and by *chlorine* (Gmelin, Liebig), with evolution of nitric oxide free from carbonic acid in the former case (Gmelin, Will), without evolution of gas in the latter (Will). In both cases a new acid, leuconic acid, is produced:

The croconates, $\text{C}^5\text{M}^2\text{O}^5$, are yellow (hence the name of the acid). Many of them are anhydrous (Will). They decompose below a red heat, with glowing and sparkling, giving off carbonic oxide and carbonic anhydride, and leaving a mixture of charcoal and metallic oxide, carbonate or metal. They withstand the action of air and light, even their aqueous solutions not being altered by exposure to the air. The croconates of the alkali-metals and some others are soluble in water; they all dissolve with decomposition in nitric acid (*vid. sup.*) Some of the croconates of the heavy metals are soluble in *alcohol* and *ether*. (Heller.)

Croconate of Aluminium.—Yellow crystals easily soluble in water and alcohol. (Heller.)

Croconate of Ammonium.—Reddish-yellow needles soluble in water and alcohol. (Heller.)

Croconates of Antimony.—Croconate of potassium added to a solution of trichloride of antimony in hydrochloric acid forms a lemon-yellow precipitate, soluble in excess of chloride of antimony. (Gmelin.)

Croconate of Barium, $2\text{C}^5\text{Ba}^2\text{O}^5 + 3\text{H}^2\text{O}$ (Will).—Yellow pulverulent precipitate, insoluble in water and in alcohol (Gmelin). Does not give off its water at 200°C . (Will.)

Croconate of Bismuth.—Lemon-yellow precipitate soluble in excess of nitrate of bismuth (Gmelin). Contains 55.68 per cent. Bi^2O^3 . (Heller.)

Croconate of Cadmium.—Yellow pulverulent precipitate, somewhat soluble in water and alcohol. (Heller.)

Croconate of Calcium.—Lemon-yellow crystals sparingly soluble in water and alcohol (Gmelin). They contain $\text{C}^5\text{Ca}^2\text{O}^5 + 3\text{H}^2\text{O}$, and give off their water completely at 160°C . (Will.)

Croconate of Cobalt.—The potassium-salt mixed with an aqueous cobalt-salt yields, after a few hours, dark-brown transparent crystals, with beautiful violet reflex; soluble in water and alcohol. (Heller.)

Croconate of Copper, $\text{C}^5\text{Cu}^2\text{O}^5 + 3\text{H}^2\text{O}$, is deposited in prismatic crystals on mixing the hot solutions of croconate of potassium and cupric chloride. The crystals belong to the trimetric system. Dominant form, ∞P , with the faces $\infty\text{P}\infty$. Inclination of ∞P : ∞P in the brachydiagonal principal section = 108° . Cleavage parallel to ∞P . The crystals have a fine deep blue colour by reflected light, and appear orange-coloured by transmitted light. They give off 13.8 per cent. (= 2 at.) water at 100°C ., the remaining atom not being given off till the salt is heated to a temperature at which it undergoes complete decomposition, giving off carbonic oxide and carbonic anhydride, yielding an acid distillate, the latter portions of which form a black precipitate with nitrate of silver, and leaving a residue of copper and charcoal. The salt, heated in the air to a temperature below redness, burns with a glimmering light and slight sparkling, leaving first a red powder of metallic copper, afterwards cupric oxide. Fuming nitric acid sets it on fire with vivid sparkling.

Croconate of copper dissolves very sparingly in cold water, rather more in boiling water, forming an acid solution, which forms with potash a blue precipitate soluble in excess of the alkali. *Ammonia* produces a similar reaction, and likewise dissolves the crystals. The aqueous solution forms but a slight deposit of copper upon *iron*, unless hydrochloric acid is also present. (Gmelin.)

Croconates of Iron.—Croconate of potassium forms with aqueous *ferric* chloride a clear black mixture, which in thin layers exhibits a garnet-red colour (Gmelin): it deposits indistinct, very dark-coloured crystals, soluble in water and alcohol (Heller). The potassium-salt, added to *ferrous* sulphate forms a dark yellowish

liquid, which afterwards deposits brown flakes, changing, after some hours, to dark brown crystals, blue by reflected light; they resemble the copper-salt in form, and are soluble in water and alcohol. (Heller.)

Croconate of Lead.— $\text{C}^{\text{Pb}}\text{O}^5 + 2\text{H}^2\text{O}$ (Will), is obtained by pouring, first acetic acid, then a hot dilute solution of acetate of lead, into a solution of croconate of potassium. It is a micaceous, golden-yellow precipitate, which gives off its water at 180°C . (Will.)

Croconate of Magnesium.—Dark brown prisms. (Heller.)

Croconate of Manganese.—By evaporating the acid with manganous acetate, or leaving the potassium-salt for some time in contact with manganous sulphate, dingy yellow crystals are obtained, having a faint blue reflex. (Heller.)

Croconate of Mercury.—The potassium-salt added either to mercuric or mercurous nitrate, forms a yellow precipitate.

Croconate of Nickel.—By evaporating croconic acid with sulphate of nickel, light brown grains are obtained, soluble in water and alcohol. (Heller.)

Croconates of Potassium. *a. Neutral,* $\text{C}^{\text{K}}\text{O}^5 + 2\text{H}^2\text{O}$.—Prepared by cautiously dissolving in water the black mass obtained as an accessory product in the preparation of potassium,—filtering,—concentrating the filtrate over the water-bath, and leaving it to crystallise,—pressing the yellow needles thus obtained,—and recrystallising from hot water (Gmelin). Crystallises in slender needles or prisms of an orange yellow colour, which effloresce and give off their water at a temperature considerably below 100°C ., or when treated with oil of vitriol, and become lemon-yellow. At a high temperature the salt carbonises. Nitric acid and chlorine decolorise it, and convert it into leuconate of potassium (p. 108). It is moderately soluble in water, especially in hot water; insoluble in absolute alcohol. The aqueous solution reduces chloride of gold when heated with it; with mercuric chloride it forms, after a while, a white precipitate, probably consisting of calomel.

β . Acid salt, $\text{C}^{\text{H}}\text{KO}.\text{C}^{\text{H}}\text{O}^5 + 2\text{H}^2\text{O}$.—Obtained by adding to a solution of the neutral salt, a quantity of sulphuric acid, not sufficient to decompose it completely. Forms prisms more deeply coloured than the neutral salt, and having an acid reaction. (Gmelin.)

Croconate of Silver, $\text{C}^{\text{Ag}}\text{O}^5$, is precipitated in aurora-red flakes, insoluble in water.

Croconate of Sodium, obtained by neutralising the acid with carbonate of sodium, forms rhomboidal prisms less deeply coloured than the potassium-salt, and containing water of crystallisation. Very soluble in water, sparingly in alcohol. (Heller.)

Croconate of Tin.—The potassium-salt, added to a solution of stannous chloride throws down a large quantity of an orange-yellow powder (Gmelin); it decomposes, with violence when heated, and is sparingly soluble in water (Heller). Stannic chloride is not precipitated by croconate of potassium.

Croconate of Uranium.—The hyacinth-red mixture of croconic acid or croconate of potassium with uranic nitrate yields, by spontaneous evaporation, yellowish-red, transparent crystals, easily soluble in water and in alcohol. (Heller.)

Croconate of Zinc.—Crystalline grains soluble in water and alcohol.

Croconate of Zirconium.—Yellow crystals soluble in water and alcohol. (Heller.)

CROCOXANTHIN. A peculiar yellow colouring matter, said to exist pure in the flowers of *Crocus luteus*, mixed with other substances in the stigmata of *Crocus sativus* and *Crocus multifidus*, and in other plants. It is a golden-yellow amorphous body, of considerable colouring power, easily soluble in water and alcohol, but insoluble in ether. It is not altered either by acids or by bases,—a character which distinguishes it from other yellow colouring matters, such as xanthin. &c.; forms yellow lakes with several metallic oxides, and may be fixed on tissues. (Filhol, J. Pharm. [3] xlviii.)

CROCUS. A term applied by the older chemists to many metallic compounds; thus, oxysulphide of antimony (i. 328) was called *Crocus Antimonii*, or *Crocus metallorum*; sesquioxide of iron, *Crocus Martis* and *Crocus Martis aperitivus*: cuprous oxide, *Crocus Veneris*, &c.

CROCUS SATIVUS. See SAFFRON.

CRONSTEDTITE. *Chloromelan.*—A hydrated ferrous silicate, containing also small quantities of magnesia and manganese, found in a vein of silver ore at Příbram in Bohemia, accompanying pyrite, siderite, calcite, and limonite; also at Wheal Maudlin in Cornwall, with pyrite and siderite. It crystallises in the hexagonal system, forming six-sided prisms, with the basic terminal face, generally in diverging groups; also

reniform and amorphous. Cleavage basal, very distinct. Colour raven-black. Streak dark-green. Opaque, with strong vitreous lustre. Rather brittle; thin laminae, somewhat flexible. Specific gravity = 3·3 to 3·4. Hardness = 2·5. Before the blowpipe it swells up a little, and melts on the edges to a blackish-grey magnetic slag. With borax and phosphorus-salt it gives the reactions of iron, silica, and manganese; with soda, that of manganese. It gives off water when heated in a test-tube. Decomposed by hydrochloric or sulphuric acid, forming a jelly of silica.

Analysis, by Kobell (Schw. J. lxii. 199):

SiO ²	Fe ² O	Fe ⁴ O ³	Mg ² O	Mn ² O	H ² O
22·45	27·18	35·35	2·88	5·08	10·70 = 103·64,

agreeing approximately with the formula $3(2\text{Fe}^2\text{O} \cdot \text{SiO}^2) \cdot 2(\text{Fe}^4\text{O}^3 \cdot 3\text{H}^2\text{O})$, or $3\text{Fe}^4\text{SiO}^4 + 4(\text{Fe}^2)^m\text{H}^3\text{O}^3$.

CROSS-STONE or **CRUCITE**. Syn. with CHIASTOLITE (i. 868).

CROTON OIL. *Oleum crotonis*.—A fatty oil existing, to the amount of about 50 per cent. in the seeds of *Croton Tiglium*, a plant of the Euphorbiaceae order. It is usually obtained by strongly pressing the bruised seeds between hot plates, —sometimes by digestion with alcohol or sulphide of carbon.

The properties of croton oil differ to a certain extent according to the mode of preparation. The oil obtained by pressure has a more or less yellow or brown colour, and a peculiar rancid odour; its taste is mild at first, but afterwards burning. It is somewhat viscid, especially when old, and deposits more or less of a dirty white body. It is a powerful drastic purgative, and irritates and reddens the skin. The latter property is due to a peculiar oily body, called *crotonol*, $\text{C}^9\text{H}^{14}\text{O}^2$. The purgative action was formerly ascribed to a volatile acid of the oleic series, *crotonic acid*; but subsequent investigations have shown that this is not the case; the exact nature of the purgative principle is not known. According to Mayer (N. Jahrb. pr. Pharm. x. 318), a volatile, highly irritating substance, which affects the lining membranes of the nose and mouth, is evolved during the pressing of croton seeds between warm plates; this substance also remains to be investigated.

Brandes, who first examined croton oil, supposed that it contained a small quantity of an alkaloid, to which he gave the name *crotonine*; he obtained it by digesting the alcoholic extract of croton seeds with water and magnesia. According to Weppen, however, this supposed alkaloid is nothing but a magnesia-soap of croton oil.

The most exact investigation of croton oil has been made by Th. Schlippe (Ann. Ch. Pharm. cv. 1). To obtain the oil, the seeds were first pressed between warm plates, and the remaining cake, after being comminuted, was exhausted with alcohol of 85 per cent. in a displacement apparatus, so arranged that the alcohol which ran off could be distilled back again. After this process had been repeated four times, the receiver contained two layers of liquid, the lower of which was oily, and contained 14 pts. oil to 1 pt. alcohol, the upper mobile, containing 23 pts. alcohol to 1 pt. oil. The residual mass, still saturated with alcohol, was pressed, and yielded a considerable quantity of oil surmounted by a layer of alcohol. From this and the preceding portions the alcohol was distilled off. In this manner four portions of oil were obtained. (1.) The portion obtained by warm pressure; (2.) That which was displaced and dissolved by the alcohol; (3.) That displaced by the alcohol but not dissolved, forming the lower layer above mentioned; (4.) The portion expressed from the residue. Of these the second exerted the strongest irritating action on the skin; this action was much weaker in the third, and weakest in the first and fourth.

Croton-oil obtained by pressure was found to contain stearic, palmitic, myristic, and lauric acids, two acids of the oleic series, whose formulæ lay between $\text{C}^{17}\text{H}^{32}\text{O}^2$ and $\text{C}^{10}\text{H}^{18}\text{O}^2$, —also crotonic and angelic acids, together with glycerin and other substances.

The alcoholic extract of croton-seeds, diluted with water and evaporated to remove the alcohol, became turbid on cooling, and deposited a dirty yellow crystalline body, which has not been further examined, but is perhaps the purgative principle of the seeds. This body is decomposed during the saponification of croton oil, and yields a peculiar black resin (*vid. sup.*)

CROTONIC ACID. $\text{C}^4\text{H}^6\text{O}^2 = \text{C}^4\text{H}^5\text{O} \cdot \text{H} \cdot \text{O}$, or $\text{C}^8\text{H}^6\text{O}^4$. (Pelletier and Caventou, J. Pharm. iv. 289. —Caventou, *ibid.* xi. 110. —Buchner, Repert. Pharm. xix. 185. —Schlippe, Ann. Ch. Pharm. cv. 1).—This acid, which belongs to the oleic series, $\text{C}^n\text{H}^{2n-2}\text{O}^2$, and occupies the intermediate place between acrylic acid $\text{C}^3\text{H}^4\text{O}^2$, and angelic acid, $\text{C}^5\text{H}^8\text{O}^2$, is obtained by the saponification of croton oil. The oil extracted by pressure is saponified with soda-ley; the alkaline liquid is treated with common salt, which separates a soap containing palmitate, stearate, myristate, and laurate of sodium, leaving crotonate and angelate in solution; this soap is washed

with brine; and the mother-liquor, together with the washings, is supersaturated with tartaric acid. It then becomes colourless and deposits yellow flocks,—a product of the decomposition of the supposed purgative principle mentioned in the last article,—which cake together to a black resin. The filtered liquid is then distilled; the distillate, containing crotonic, angelic, and hydrochloric acid, is neutralised with baryta, and evaporated to dryness; and the residue is again distilled with dilute tartaric acid. Crotonic acid then distils over first, together with water, and afterwards angelic acid crystallises in the neck of the retort. The saturation of the liquid distillate with baryta, and the decomposition by tartaric acid, are repeated till the distillate no longer contains hydrochloric acid; the liquid is then finally neutralised with baryta; the excess of baryta removed by carbonic acid; the filtrate evaporated to dryness; and the residue decomposed by heating it with strong phosphoric acid. As the liquid cools, the crotonic acid rises to the surface, and may be separated by means of a pipette.

Crotonic acid is a colourless, oily liquid, having a somewhat pungent odour and an acid taste. It dissolves with moderate facility in pure water, but is insoluble in saline water. When carefully heated with *hydrate of potassium*, it gives off hydrogen, and forms acetate of potassium:

The *crotonates* are inodorous. The *potassium-salt* forms rhomboïdal prisms, permanent in the air, sparingly soluble in alcohol of specific gravity 0.85. The *barium-salt* is very soluble in water and in alcohol, and separates by concentration in nacreous crystals, the powder of which excites powerful irritation in the throat. The *magnesium-salt* is granular and sparingly soluble in water.

Crotonate of ammonium forms a cream-coloured precipitate with *ferrous sulphate*; white with *silver* and *lead* salts; bluish-white with salts of *copper*. It does not precipitate ferric sulphate or chloride of mercury.

CROTONOL. $C^9H^{14}O^2$. (Th. Schlippe, Ann. Ch. Pharm. cv. 1.)—Contained in croton oil. To prepare it, the oil is shaken up with a quantity of alcoholic soda sufficient to form a milk; the mixture is gently heated for some hours; water or brine is added; and the oily layer which then rises to the surface, is completely removed by repeated filtration through wet filters. On mixing the filtrate with water and hydrochloric acid, another oil separates out, which is dissolved in cold alcohol, digested with hydrate of lead, till its acid reaction is neutralised (whereby a flocculent precipitate is formed which afterwards coagulates into a greasy mass), then mixed with a little soda and a large quantity of water. The milky liquid thereby produced becomes clear after a while and deposits an oil, which is to be washed with water, then dissolved in ether, and the ethereal solution again washed with water, and evaporated in vacuo. It then leaves crotonol amounting to 4 per cent. of the oil.

Crotonol forms a colourless or faintly yellow viscid mass of the consistence of turpentine. It has a faint peculiar odour, and is the part of croton-oil which irritates the skin, not the purgative principle.

It cannot be distilled without decomposition, even in vacuo or in a stream of carbonic acid gas. When distilled with water, either pure or containing sulphuric acid, it yields first a colourless, then a black oil, which cannot be distilled at 200° even in vacuo, and leaves a black resin which forms with alcohol a turbid solution precipitable by acetate of lead. A solution of crotonol in absolute alcohol does not form crystals with *ammonia*. Crotonol does not combine with acid *sulphite of sodium*. With melting *sodium* it gives off gas with violence, then becomes thicker and resinous. By boiling with caustic *potash* or *soda*, it forms a brown resin which no longer reddens the skin. The alcoholic solution of crotonol does not precipitate metallic salts.

CROUPI OIL. *Toloucina oil*.—A fatty oil obtained from the seeds of *Carapa Toloucina*, a tree twenty feet high, growing on the Gold Coast. The seeds are first dried and smoked, then bruised, boiled with water, and the oil which separates is collected. The oil has a bitter taste, apparently due to the presence of a foreign basic substance, and a repulsive odour; it dissolves completely in ether, but is separated by alcohol into two parts, the solid portion, together with the basic substance, dissolving, while a liquid oil remains undissolved. Croupi oil is used by the natives of the West Coast of Africa for burning, and as a remedy against intestinal worms. (Handw. d. Chem. 2^{te} Aufl. ii. [3] 231.)

CROWN GLASS. See GLASS.

CRUCILITE. See STAUROLITE.

CRUCITE. Syn. of CHIASTOLITE (i. 868).

CRUSTACEA. The shells of crustacea contain organic and inorganic matter in

nearly equal quantities, the inorganic portion consisting mainly of carbonate of calcium with a smaller quantity of phosphate. Fremy (Ann. Ch. Phys. [3] xliii. 47) found in the shell:

	Ca^3PO^4 .	Ca^2CO^3 .	Organic matter.
Of the sea-crab . . .	6·7	49·0	44·3
Of the land-crab . . .	6·7	56·8	36·5

The organic portion consists mainly of chitin (i. 874.)

CRYOLITE. Native fluoride of sodium and aluminium, $3\text{NaF}.\text{Al}^2\text{F}^3$. Found in large quantity at Evigtok, in the Arksut-fjord, in West Greenland, where it forms a bed 80 feet thick and 300 feet long; also, with chiolite, lithia-mica and fluor spar, at Miask, in the Ural. Crystallises in the dimetric system. Specific gravity = 2·9–3·08. Hardness = 2·5. Colourless and transparent when pure. At the surface of the bed just mentioned, the mineral is white, but below the surface it exhibits a continually darker colour, and at last almost black: the colour is, however, destroyed by a moderate heat. Cryolite melts below a red heat and forms an opaque glass on cooling. It is very slightly soluble in water. It is used for the extraction of aluminium, and also for the preparation of caustic soda for soap-boiling. (See ALUMINIUM, i. 157.)

CRYPTIDINE. $\text{C}^{11}\text{H}^{11}\text{N}$. An organic base contained in that portion of the bases from coal-tar (*q. v.*) which possesses the highest boiling point (above 274°C). It has not been obtained pure, its composition having been determined only by the analysis of the platinum-salt, which crystallises in yellow needles. It is homologous with chinoline, $\text{C}^9\text{H}^9\text{N}$, and lepidine, $\text{C}^{10}\text{H}^9\text{N}$. (C. Gr. Williams, Chem. Gaz. 1856, 283.)

CRYPTOLIN. An organic liquid, found together with brewstolin (i. 663) in cavities of topaz, chrysoberyl, quartz-crystals from Quebec, and amethyst from Siberia. The two liquids sometimes occur in the same cavities, but they are not miscible. Cryptolin, when exposed to the air, speedily hardens into a yellowish, transparent, resinous body, not volatilisable by heat, or soluble in alcohol or in water, but dissolving rapidly and with effervescence in sulphuric acid. Nitric and hydrochloric acid also dissolve it. Index of refraction nearly the same as that of water. (Dana, ii. 471.)

CRYPTOLITE (from *κρυπτος*, concealed). Native phosphate of cerium, Ce^3PO^4 , discovered by Wöhler (Ann. Ch. Pharm. lvii. 268) in the rose-coloured apatite of Arendal in Norway, from which it is separated by dissolving the apatite in nitric acid, the cryptolite then remaining undissolved, in very small hexagonal crystals. (See PHOSPHATES.)

CRYSTALLIN, or *Globulin*. An albuminous substance, contained in the crystalline lens of the eye, and supposed by Berzelius to be identical with the albuminous constituent of the blood-corpuscles. (See GLOBULIN.)

CRYSTALLINE. An old name for aniline or phenylamine.

CRYSTALLISATION. A crystal is a solid body, bounded by plane surfaces, disposed according to a regular law of symmetry, the form thus produced being essentially related to the composition and properties of the body, so that the minutest particles into which the body can be mechanically divided exhibit either the same form, or one related to it by determinate laws. This essential connection between form and composition distinguishes a crystal from a regular form artificially produced, as by carving or modelling. All crystals cleave in certain directions more easily than in others, and all, excepting those which belong to the regular system (see CRYSTALLOGRAPHY), refract light doubly.

To enable a body to assume the crystalline state, its particles must possess a certain freedom of motion: hence, the fluid state is for the most part, an essential preliminary to crystallisation. Sometimes, indeed, an amorphous solid—that is to say, one which has no definite structure, either crystalline or organised—passes spontaneously into the crystalline state without previous liquefaction. This is the case with plastic sulphur, vitreous arsenious acid, and barley-sugar, which gradually change from transparent amorphous solids to opaque aggregates of minute crystals. But generally speaking it is in the passage of a body from the liquid or gaseous to the solid state that the regular and symmetrical arrangement of the molecules takes place, which constitutes crystallisation. The vapours of many substances, when they come in contact with cold surfaces pass at once to the state of crystalline solids, *e. g.* sulphur, iodine, benzoic acid, arsenious acid, camphor, &c. It is, however, in the transition from the liquid to the solid state that crystallisation most frequently takes place. If the body has been brought into the liquid state by the action of heat alone, it may be made to crystallise by cooling, *e. g.* bismuth, sulphur. To obtain definite crystals in this manner, the liquid mass is allowed to cool only till a certain portion near the surface and in contact with the sides of the vessel has become solid, a hole being then pierced in the crust,

and the vessel inverted, so that the portion which still remains liquid may run out (i. 590). A solid body dissolved to saturation in a hot liquid may also be made to crystallise by cooling; *e. g.* sulphur from solution in sulphide of carbon; nitre or alum from solution in water. The crystallisation of a solid from solution may likewise be effected by removing the solvent, either by evaporation, or by adding another substance with which the solvent has a greater tendency to unite than with the substance previously dissolved in it; in this manner, chloride of sodium crystallises from its aqueous solution on addition of chloride of calcium; nitre from its aqueous solution on addition of alcohol; iodine from solution in hydriodic acid on the introduction of a small quantity of chlorine.

The more slowly the liquefied body is brought back to the solid state, and the more the liquid is kept at rest, the smaller is the number and the greater the size and regularity of the crystals; but if the solvent be cooled or separated quickly, the crystals are numerous but small and ill defined. In the former case, the particles of the solidifying body have time to unite themselves regularly with those which separate first from the fluid and form nuclei of crystallisation; if, on the contrary, the crystallisation takes place rapidly, a great number of particles solidify at the same time, each forming a nucleus to which other portions may attach themselves, and thus we obtain a number of crystals irregularly formed and interlacing each other in all directions. In this consists the difference between sugar-candy and loaf-sugar; similarly, all granular and fibrous bodies, such as tufa and fibrous gypsum, must be regarded as collections of imperfectly formed crystals. To obtain crystals as large and regular as possible, Leblanc recommends (*J. Phys.* iv. 300) to allow a solution not quite saturated to cool slowly, so that none but distinct crystals may be formed, then to pick out the best formed of these and lay them, separate from one another, in a solution of the same salt, which by gentle warming in contact with the salt has been made to hold in solution a quantity of it just a little greater than that which it can contain at the ordinary temperature, so that it may deposit this excess on the crystals laid in it. This treatment is repeated till the crystals have obtained the desired magnitude, care being taken to turn them frequently, because the surfaces resting on the bottom are in a less favourable position than the others for taking up fresh particles. The trouble of repeatedly preparing a slightly supersaturated solution may be saved by suspending in the upper part of the liquid a quantity of the salt contained in a bag of muslin or in a funnel. Irregularly developed crystals may also be brought to regular shape by covering the fully developed surfaces with wax, so that only the faces which require further development may come in contact with the solution.

The formation of crystals takes place most readily in contact with bodies which abstract heat from the liquid, or to which the crystals can adhere. Hence they form on the surface of the liquid, in so far as evaporation and cooling by the influence of the air, or adhesion of the air to the crystals, can give rise to their production; also on the bottoms and sides of the containing vessels, and on solid bodies immersed in the liquid. For the most part, crystals deposit themselves more easily on wood and string than on porcelain, glass, and metal; more easily on porcelain than on glass, and generally more easily on rough than on smooth surfaces, because the former present a greater number of points of adhesion. When a glass tube containing a crystallisable liquid is scratched with a glass rod, the crystals deposit themselves in preference on the scratches. Crystallisation is also especially facilitated by introducing into the liquid a crystal of the substances previously formed. A solution saturated at a high temperature may, under certain circumstances, be cooled down several degrees without depositing crystals; but the introduction of a crystal of the substance, causes the whole to solidify instantly in a crystalline mass. This phenomenon is easily exhibited with Glauber's salt. (See SOLUTIONS, SUPERSATURATED.) In like manner, the introduction of a crystal of nitre into a solution of nitre and Glauber's salt, prepared hot and subsequently cooled, causes the nitre to separate alone; a crystal of Glauber's salt removes only the Glauber's salt; whereas, if the solution be left to itself, both salts crystallise out together, the crystals interlacing each other. (Lowitz.)

When a solution evaporates below its boiling-point, the first crystals are usually deposited on the sides of the vessel at the uppermost surface of the liquid: another portion of the liquid often rises through these, and yields by evaporation new crystals, which ultimately make their way over the edge of the vessel. This is efflorescence. When crystals form at the bottom of a liquid, a current is produced, because the individual crystals take, from that part of the solution with which they are immediately in contact, as much of the salt as is possible under the existing circumstances; consequently this part of the liquid becomes lighter and rises to the surface, its place being supplied by a more saturated portion of the liquid.

When a body crystallises from solution in a liquid, and the latter is not completely removed by evaporation, there remains a portion called the mother-liquor (*Eau*

mère, Mutterlauge). This liquid holds in solution as much of the crystallising body as is consistent with its quantity and temperature. It often happens, especially when crystallisation proceeds rapidly, and the crystalline laminae in the act of uniting leave small spaces between them, that small and (even with regard to the same substance) very variable quantities of the mother-liquid remain enclosed in the crystalline mass, forming the Water of Decrepitation. Crystals which contain liquids thus enclosed, and do not melt below the boiling-point of the mother-liquid, exhibit, when heated, the phenomena of Decrepitation, the vapour given off from the mother-liquid bursting the crystalline mass with violence. This water of decrepitation, which, as an accidental mechanical admixture, has no influence on the form of the crystal, is altogether different from the chemically-combined water which certain crystals contain in definite proportion, and which is essential to their crystalline form. Common salt, crystallised by slow evaporation from an aqueous solution does not decrepitate; but when crystallised by rapid boiling of the liquid, it decrepitates violently. Many forms of calespar decrepitate, others do not.

If a solution, in addition to the crystallising substance, likewise contains others which are less easily crystallisable, the latter will remain in the mother-liquid after the separation of the greater part of the former. This circumstance furnishes a method of purifying easily crystallisable substances by repeated solution, crystallisation, pouring off of the mother-liquid, washing with small quantities of the cold solvent, and pressing between blotting-paper. In this method of purification, the formation of large crystals by slow cooling or evaporation is usually preferred, because they present fewer surfaces, and are therefore more easily freed by washing from the adhering mother-liquid. Sometimes, on the contrary, as in the French method of purifying saltpetre, the smallest possible crystals are formed by constant stirring and rapid cooling of the hot solution, because large crystals of this salt contain a greater quantity of mechanically included mother-liquor, which cannot be removed by washing.

It has already been stated that the crystalline form of a body bears an essential relation to its nature and composition. Accordingly we find that every substance crystallises either in one single form or in a number of forms related to each other by simple laws and derivable one from the other; in other words belonging to the same crystalline system (see CRYSTALLOGRAPHY). Many bodies, however, both simple and compound, crystallise in two or more forms belonging to different crystalline systems, and not derivable one from the other; such bodies are said to be dimorphous, trimorphous, or generally polymorphous. (See DIMORPHISM.)

On the other hand, different substances often crystallise in forms either identical or exhibiting only small differences in the inclinations of the corresponding planes. When the forms are exactly similar, the substances are said to be isomorphous, when small differences in the angles exist, they are called homœomorphous. Isomorphous or homœomorphous compounds exhibit perfect similarity of chemical composition: thus, the alums, which crystallise in regular octahedrons and allied forms are all composed according to the general formula $\left\{ \begin{smallmatrix} M' \\ R^2 \end{smallmatrix} \right\} 2SO^4 + 12 \text{ aq.}$, where M denotes a monatomic metal, like potassium, and R a sesquiatomic metal, like aluminium; the magnesian double sulphates, which crystallise homœomorphously in the monoclinic system, are all composed analogously to sulphate of magnesium and potassium $(KMg)SO^4 + 3 \text{ aq.}$ Isomorphous salts are capable of crystallising together in any proportion; in other words, the isomorphous elements which enter into them are capable of replacing one another in any proportion; thus, common alum $\left\{ \begin{smallmatrix} K \\ (Al^2) \end{smallmatrix} \right\} 2SO^4 + 12 \text{ aq.}$ and iron-alum, $\left\{ \begin{smallmatrix} K \\ (Fe^2) \end{smallmatrix} \right\} 2SO^4 + 12 \text{ aq.}$, can crystallise together in all proportions; hence it is difficult to purify common alum from iron by crystallisation. (See ISOMORPHISM.)

CRYSTALLOGRAPHY is the science which treats of the external forms of crystals, and of the laws of symmetry according to which their faces are disposed.

Crystals are bounded by plane faces. The straight line in which two contiguous faces intersect is called an edge; the point in which three or more faces intersect is called an angle, solid angle, or summit of the crystal.

Similar and Dissimilar Boundaries. Similar faces of a crystal are those which resemble each other in form and in relative position; dissimilar, those which differ in either respect. Similar edges are those which are formed by similarly situated faces meeting at equal angles. Similar angles or summits are those which are formed by the concurrence of similar faces and edges; angles are also distinguished as three-faced, four-faced, &c., according to the number of faces by which they are formed. The regular octahedron (*fig. 149*), and the cube (*fig. 150*), have all their faces, edges and angles similar; the rhombic dodecahedron (*fig. 151*) has all its faces

Fig. 149.

Fig. 150.

and edges similar; but its solid angles are of two kinds, viz. eight 3-faced and six 4-faced angles. The square prism with pyramidal summits (fig. 152) has dissimilar

Fig. 151.

Fig. 152.

faces, triangular and rectangular; dissimilar edges, viz. 1, those formed by the intersection of two triangular faces; 2, those formed by two rectangular faces; and 3, those formed by a triangular and a rectangular face; and dissimilar angles or summits, viz. two at the extremities of the vertical axis, formed by the concurrence of four similar triangular faces; and eight others, also four-faced, but formed by the intersection of dissimilar faces and edges. Angles are also spoken of as equal- or unequal-edged, according as the edges which meet in them are similar or dissimilar. An unequal-edged angle may also be symmetrical or unsymmetrical, according as the dissimilar edges which form it follow one another in regular order or not. The four-edged angles of the double six-sided pyramid (fig. 153) are symmetrical, but those of the six-sided prism with pyramidal summits (fig. 154) are unsymmetrical.

Fig. 153.

Fig. 154.

Fig. 155.

Simple and Complex forms (Combinations). Simple forms are those which contain only similar faces, *e. g.* the regular octahedron, cube, and rhombic dodecahedron (figs. 149, 150, 151). Complex forms, or combinations, are those in

which dissimilar faces occur (*e. g.* *figs.* 152, 154). A combination is made up of those simple forms which would result from the extension of one set of similar faces till the others disappear; thus (*fig.* 155) is a combination of the octahedron O , and the rhombic dodecahedron ∞O . If we suppose the O -faces to be extended till they meet, the ∞O -faces will disappear and the octahedron (*fig.* 149) will result; conversely the extension of the faces ∞O to the obliteration of the others produces the dodecahedron (*fig.* 151).

The relation of a complex form to the simple forms of which it is made up may also be represented as follows:—Suppose two or more simple forms, as the cube and octahedron (*figs.* 156, 157), to be constructed round a common centre, and of such

Fig. 156.*Fig.* 157.

dimensions, that certain parts of each simple form shall project beyond the limits of the other, then the combination (represented by the shaded portion of the figures) occupies that portion of space which is common to both the simple forms; those portions of each being excluded, which project beyond the space enclosed by the other.

In any combination of simple forms, the one whose faces are most developed, and consequently determine the general aspect of the crystal is called the dominant form; thus in the combination above represented, the dominant form in *fig.* 156 is the octahedron and in *fig.* 157 the cube. The other (subordinate or secondary) faces are described according to the manner in which they are related to the dominant faces.

The secondary faces of a crystal may replace either the edges or the angles of the dominant form. If an edge is replaced by a face which makes equal angles with the two contiguous faces of the crystal, it is said to be symmetrically or perpendicularly truncated; if, on the other hand, the secondary face is unequally inclined to the two faces, which would form the edge of the crystal, the edge is said to be obliquely truncated. The cube in *fig.* 158 has its edges perpendicularly, that in *fig.* 159 has them obliquely truncated. If an edge of the dominant form is replaced by two similar faces, as in the cube (*fig.* 160) it is said to be bevelled. In like manner, a solid angle or summit of a crystal is said to be symmetrically or perpendicularly trun-

Fig. 158.*Fig.* 159.

cated when it is replaced by a face which is equally inclined to all the faces composing the solid angle; obliquely truncated when the truncating face is unequally inclined to those faces. *Fig.* 161 is an octahedron with the summits symmetrically truncated. *Fig.* 162 an oblique rhombic prism, in which the solid angle to the right above is obliquely truncated by the face $+P\infty$, which is unequally inclined to the faces ∞P and oP .

The face which replaces the solid angle is said to be set (or to rest) symmetrically or perpendicularly on an edge, when it is equally inclined to the two faces forming the edge; obliquely in the contrary case; in *fig.* 162 the truncating face $+P\infty$ is set

Fig. 160.

Fig. 161.

symmetrically or perpendicularly on the prismatic edge to the right, obliquely on the edge between oP and ∞P to the right in front. The face replacing the solid angle is said to be set (or to rest) symmetrically on a face of the crystal, when the plane angles which it makes with this face at the combination-edge are equal, obliquely if they are unequal; thus, in *fig. 162*, the face $+P\infty$ is set symmetrically on the face oP , but obliquely on the face ∞P to the right in front.

A solid angle replaced by a number of faces which together make a more obtuse solid angle, is said to be acuminated. The number of the acuminations-

Fig. 162.

Fig. 163.

Fig. 164.

faces may be equal to, or half, or double of that of the original faces of the summit. Thus the solid angles of the cube, which are three-faced, may be acuminated with three faces, as in *fig. 163*, or with six, as in *fig. 164*. The six-faced summits of *fig. 165*, which is a form of calc-spar (i. 722), are sometimes replaced by three-faced summits, as in *fig. 166*.

Fig. 165.

Fig. 166.

In prismatic crystals, *i.e.* such as are extended principally in one direction, the terms *bevelled* and *acuminated* are used to describe the conformation of the extremities. *Fig. 167* is a six-sided prism, acuminated at each end by six isosceles triangles, P , resting symmetrically on the prismatic faces. *Fig. 168* is a quadratic prism acuminated with rhombic faces, P , resting symmetrically on the prismatic edges. *Fig. 169* is a rhombic prism, whose extremities are bevelled by triangular faces $\tilde{P}\infty$, resting symmetrically on the acute prismatic edges.

Fig. 167.

Fig. 168.

Fig. 169.

Axes. In all perfectly developed crystals (with a few exceptions, to be afterwards considered as cases of hemihedry), every face, edge, or summit on one side or extremity, has an equal and similar face, edge, or summit opposite to it at the other side or extremity of the crystal, and if the opposite summits, or the middle points of opposite edges or faces * be joined by straight lines, all lines so drawn will cross one another in a single point called the centre of the crystal. Lines drawn through this point and in such directions that the faces of the crystal are symmetrically disposed with respect to them, are called **Axes**.

Similar axes are those which terminate in similar parts of the crystals; dissimilar axes, such as terminate in dissimilar parts. In the regular octahedron (fig. 170), in which all the summits are similar, the three axes xx' , yy' , zz , joining those summits, are likewise similar. In the double six-sided pyramid (fig. 171), the horizontal axes which join the opposite four-faced summits are similar to each other, but dissimilar to the vertical axis.

Fig. 170.

Fig. 171.

Poly-axial and Mono-axial Forms. Polyaxial forms are those in which no single axis can be drawn dissimilar to all the rest, *e. g.* in the cube and regular octahedron. Those forms, on the contrary, in which one or more axes can be drawn dissimilar to all the rest, are called **mono-axial**. If only one such singular axis can be drawn in the crystal, it is called the **principal axis**, the others being called **secondary**; and in describing the crystal, it is generally supposed to be placed so that the principal axis is directed from top to bottom (vertically, if it is perpendicular to the secondary axes). If two or more axes exist dissimilar to all the rest, neither can be regarded absolutely as the principal, but it is usual, for convenience, to consider one of them as such, generally the one in whose direction the crystal is most elongated. Such an axis is called a **relative principal axis**.

In mono-axial forms, the edges and summits through which the principal axis passes are called **terminal**, the others **lateral**; thus, in fig. 171, the summits **A A**, and the

* The middle point of a plane surface is the same as its centre of gravity; thus, in a triangle, it is the point of intersection of the straight lines drawn from the angles to the centres of the opposite sides.

edges A B, &c., are terminal; the summits B and the edges B B, which join them, are lateral. In polyaxial forms this distinction does not exist.

Mode of describing Simple Crystalline forms. The form of a crystal is determined by the position of its faces with regard to certain axes given in position. Suppose, for example, that the crystal is symmetrical with regard to three axes crossing one another at right angles, and passing through the same point, viz. the centre of the crystal (p. 120); then the position of each face of the crystals will be given by the distance from the centre at which it meets the three axes; and as all the faces of a simple form are similar, and similarly situated with regard to the axes, the position of this one face will determine the entire form. Thus, if each face of the crystal meets the three axes at equal distances from the centre, we shall have a figure bounded by eight equal equilateral triangles, viz. the regular octahedron (*fig. 170*); and if the distance at which the faces cut the axes be called a , such a figure may be denoted by the formula, $a : a : a$. A face which cuts two axes at equal distances from the centre, and the third at n times that distance, will in like manner be denoted by $a : a : n a$. If the number n be infinite, the face in question will be parallel to one of the axes (in other words, will not intersect it at any finite distance), and the formula will become $a : a : \infty a$. A face parallel to two axes is denoted by $a : \infty a : \infty a$.

Zones. A number of faces of a crystal parallel to either of the axes are said to form a zone, or to lie in the same zone; thus the cube (*fig. 150*) has four faces parallel to each of the axes passing through the middle points of its sides; so likewise each axis of the regular octahedron, joining the centres of the opposite edges, has a zone of four faces parallel to it; the six prismatic faces of the ordinary form of rock-crystal (*fig. 154*), form a zone parallel to the vertical axis. The faces of a zone cut one another in edges parallel to each other, and to the axis of the zone.

Holohedral and Hemihedral forms. A simple form, bounded by the greatest number of similar faces that can be arranged in different directions round the common centre, is called a holohedral (fully developed) form; thus, the greatest number of faces that can meet three rectangular axes at equal distances from the point of intersection is eight, the resulting figure being the regular octahedron (*fig. 170*), which is therefore a holohedral form; but four such faces are sufficient to form a closed figure, viz. the regular tetrahedron (*fig. 190*). Such a form, enclosed by only half the number of faces that might be drawn round the centre, according to the law which determines their position, is called a hemihedral form (half-developed). Simple forms also occur, containing only one-fourth of the number of faces that might exist according to the given law of symmetry; such forms are called tetartohedral.

Simple Crystals and Twin Crystals. Holohedral crystals, whose faces are all symmetrically disposed about a single system of axes are called simple crystals (an expression not to be confounded with *simple form*). Crystals are, however, frequently met with, the opposite sides of which are symmetrically disposed round different systems of axes. Such crystals are called twins (also *maclés*): they may be regarded as aggregates of two simple crystals, having their axes more or less inclined to each other.

Crystallographic Systems. The number of crystalline forms occurring in nature and produced by artificial processes, is so large, that some mode of classifying them is absolutely necessary. All systems of classification are founded on the symmetrical development of crystals with regard to certain axes.

The form of any solid whatever may be determined by referring it to three rectilinear axes intersecting one another in a single point: and with regard to crystals, observation shows that some are symmetrically developed about three axes intersecting one another at right angles; others, with respect to axes more or less obliquely inclined to each other: the former are called orthometric, the latter clinometric forms. Of the orthometric forms, some are equally developed in the direction of all three axes, others equally in two only, others unequally in all three. Some forms (the hexagonal) are more conveniently referred to a system of four axes. On these different modes of development are founded the following seven crystallographic systems:

I. The Monometric or Regular system, the forms of which are symmetrically disposed about three rectangular axes, all of equal length.

II. The Dimetric or Quadratic system, the forms of which are symmetric about three rectangular axes, two of equal, the third of different length.

III. The Hexagonal system, the forms of which are symmetric about four axes, three of which are of equal length, situated in the same plane, and inclined to one another at angles of 60° , while the fourth is of different length and at right angles to the plane of the other three.

IV. The Trimetric or Rhombic system, including the forms which are symmetric about three rectangular axes of unequal length.

V. The Monoclinic system, including the forms which are symmetric about three axes, two at right angles to each other, the third (the principal axis), perpendicular to one of them and oblique to the other.

VI. The Diclinic system, including forms which are symmetric about three axes, two of which are at right angles to each other, and the third oblique to both.

VII. The Triclinic system, including forms symmetric about three axes, all oblique to each other.

The first system comprises the polyaxial forms; the second and third, forms with absolute principal axis; the others, the mono-axial forms with relative principal axis.

Forms belonging to the same crystallographic system are related to each other by several natural affinities.

1. *It is only the simple forms of the same system that can combine into a complex form.*—For in all fully developed (holohedral) natural crystals, it is found that all the similar parts, if modified at all, are modified in an exactly similar manner (in hemihedral forms, half the similar edges and angles alternately situated are similarly modified). Now this can be the case only when the dominant form and the modifying form are developed according to the same law of symmetry. Thus, if a cube and a regular octahedron are developed round the same system of axes (as in *figs.* 156, 157), each summit of the cube is cut off to the same extent by a face of the octahedron, or *vice versâ*. But a cube could never combine in this manner with a rhombic octahedron, because it would be impossible to place the two forms in such a manner that similar parts of the one should throughout replace similar parts of the other.

2. *Crystals belonging to the same system are intimately related in their optical properties.*—Crystals belonging to the regular system (as the diamond, alum, rock-salt, &c.), refract light in the same manner as amorphous bodies; that is to say, they have but one refractive index, and a ray of light passing through them in any direction is refracted singly. But all other crystals refract doubly, that is to say, a ray of light passing through them (except in certain directions) is split into two rays, the one called the *ordinary* ray, being refracted as it would be by an amorphous body, the other, called the *extraordinary* ray, being refracted according to peculiar and more complex laws (see LIGHT). Now the crystals of the dimetric and hexagonal systems (those with an absolute principal axis) resemble each other in this respect, that in all of them there is *one* direction, called the optic axis, or axis of double refraction (coinciding with the principal crystallographic axis), along which a ray of light is refracted singly, while in all other directions it is refracted doubly; whereas in crystals belonging to the other systems, viz. the trimetric and the three clinometric systems, there are always *two* directions or axes, along which a ray is singly refracted.

3. *Crystals belonging to the same system resemble each other in their mode of conducting heat.*—Amorphous bodies and crystals of the regular system conduct heat equally in all directions, so that, supposing a centre of heat to exist within such a body, the isothermal surfaces will be spheres. But crystals of the dimetric and hexagonal systems conduct equally, only in directions perpendicular to the principal axis, so that in such crystals the isothermal surfaces are ellipsoids of revolution round that axis; and crystals belonging to either of the four other systems conduct unequally in all directions, so that in them the isothermal surfaces are ellipsoids with three unequal axes. (See HEAT.)

Monometric or Regular System.

Tessular, Isometric, or Cubic System.—All forms of this system are similarly and equally developed in three directions at right angles to each other; in other words, they are symmetrical about three rectangular axes meeting in a common centre. The position of each face is determined by the distances from the centre at which it meets the three axes (p. 121.) the following being all the cases that can occur:—

- A. 1. Each face (extended if necessary) meets all three axes at equal distances from the centre: the formula of such a face is $a : a : a$.
- B. 2. Each face meets two of the axes at equal distances from the centre, and the third at a different distance:
 2. Each face meets two of the axes at an infinite distance from the centre (*i. e.* it is parallel to these two axes), and the third at a finite distance. Formula $a : \infty : \infty$.
 3. Or two axes at equal and finite distances, the third at an infinite distance, $a : a : \infty$.
 4. Or two axes at equal and finite distances from the centre, the third also at a finite but less distance. Formula $a : ma : ma$ [$m > 1$].
 5. Or two axes at equal and finite distances, the third at a greater distance. Formula $a : a : ma$ [$m > 1$].
- C. Each face cuts the three axes at different distances from the centre:

6. Two axes at finite, the third at an infinite distance, $a : m a : \infty a$.

7. All three at finite distances, $a : m a : n a$.

We now proceed to determine the forms given by these several conditions.

1. The form in which each face meets all the three axes, xx, yy, zz , at equal distances, a , from the centre is evidently bounded by eight equilateral triangles. This form is the regular octahedron (*fig. 172*). It has twelve equal edges, in which the faces meet each other at angles of $109^{\circ} 28'$, and six equal four-faced solid angles or summits, through which the axes pass. A summit thus situated, in any form of the regular system, is called an octahedral summit; where such summits occur, they are always six in number.

The crystallographic formula of the regular octahedron is $a : a : a$, usually abbreviated into the symbol O .

The regular octahedron is the form of many crystals, both natural and artificial; *c.g.* red copper ore, magnetic iron ore, alum, chrome-alum, sal-ammoniac crystallised from its aqueous solution, chloride of sodium from a solution containing urea, &c.

Fig. 172.

Fig. 173.

2. The simple form $a : a : a$, or $\infty O \infty$, in which each face meets one axis at the finite distance a , and is parallel to the other two, is evidently the cube or hexahedron (*fig. 173*), bounded by six equal faces, intersecting one another at right angles, and each having the form of a square. It has twelve equal edges meeting one another at right angles, and eight three-faced, equal-edged, solid angles or summits, situated in each octant at equal distances from the three axes. Summits so situated are called hexahedral or cubic; in holohedral crystals they are always present to the number of eight, if at all.

Cubic forms are frequently exhibited by bismuth, chloride of sodium, iodide and chloride of potassium, sal-ammoniac crystallised from a solution containing urea; also by fluor-spar, galena, and other minerals.

The cube and octahedron are often found combined together; the one or the other form predominating, according to the relative length of their axes (*figs. 156, 157, p. 220*). If the axes of the cube are less than half as long as those of the octahedron, the combination is a modified cube, like that in *fig. 174*. If, on the contrary, the axes of the cube are more than half as long as those of the octahedron, the combination is a modified octahedron (*fig. 175*). If the axes of the cube are exactly half as long as those of the octahedron, the faces of the two forms meet only in points, and the combination is that shown in *fig. 176*, called the middle crystal. It has twelve summits, each of which is situated in the plane between two of the axes, and at equal distances from them. All summits thus situated in forms of the regular system are said to be situated, "like the summits of the middle crystal."

Fig. 174.

3. The formula $a : a : a$, or ∞O , represents a solid, each of whose faces meets two of the axes at equal distances, a , from the centre, and is parallel to the third; it must therefore have twelve faces, four parallel to each axis. To define its form more particularly, draw the system of rectangular axes xx', yy', zz' , meeting in C (*fig. 77*), and set off on them the points x, x', y, y', z, z' , all at equal distances from C . Now the face passing through z, y , and parallel to xx' , will intersect the face passing through $z' y'$, and parallel to xx' , in the line af , also parallel to xx' . Similarly the faces

Fig. 175.

Fig. 176.

parallel to yy' , and passing respectively through zx , $z'x$, will intersect in df parallel to yy' , and the lines zf , $z'f$, in which these pairs of faces intersect, form two edges of the crystal. Extending this construction all round the axes, we find that the four faces meeting in z , and the four meeting in z' , would, if extended till they intersect, form a double four-sided pyramid, represented in *fig. 177* and by the dotted lines in *fig. 178*. But there are still the faces parallel to zz' to be drawn. One of these faces passes through the line xy , and its position may be determined by drawing through the middle point of xy (*fig. 178*), a line ik , parallel to zz' , which will cut the edge zf of the pyramid in its middle point l ; and by joining this point with the points x , y ,

Fig. 177.

Fig. 178.

we obtain two edges of the required form, lx , ly . A similar construction carried out in the other parts of the figure finally gives the rhombic dodecahedron (also called granatohedron). It has twelve rhombic faces, with plane angles of $109^\circ 28'$ and $70^\circ 32'$, and diagonals in the ratio of $1 : \sqrt{2}$. The edges are all equal. The summits are fourteen in number, six 4-faced, octahedral summits, A (*fig. 151*), formed by the meeting of the acute angles of the rhombuses, and eight 3-faced cubic summits, B, formed by the meeting of the obtuse edges of the rhombuses. The dihedral angles formed by the meeting of the faces are all equal to 120° .

The dodecahedron sometimes occurs alone in artificial crystals, more frequently in combination; in minerals it is more common as a simple form, as in garnet.

The three forms above described, the regular octahedron, cube, and rhombic dodecahedron are unique in their kind; that is to say, all individuals of each species must be exactly similar to each other; there can be no variation either in the plane angles or in the inclination of the faces. This, indeed, is sufficiently evident from the formulæ, which admit of no variation, and from the mode of construction. But in the remaining four forms of the regular system, the formulæ of which contain numerical coefficients admitting of variations in magnitude, this constancy of shape no longer exists; and accordingly we shall find that the angles vary with the magnitude of the coefficients in the formula.

4. The formula $a : ma : ma$, or $m O m$, represents a solid, each of whose faces meets one axis at the distance a from the centre, and the other two at the greater distance ma . Draw a system of rectangular axes (*fig. 179*), and, taking for example $m = 2$, mark off single and double distances, x , $2x$, &c., on each of the three axes. It is then easy to see that the position of one face will be determined by a plane passing through the points y , $2z$, $2x$; a second through y , $2z$, $2x'$; a third through y , $2z'$, $2x''$ *; and a

* The points x' , y' , z' , &c. (not shown in the figure) are supposed to be on the prolongations of the lines xC , yC , zC , as in the preceding figure.

fourth through $y, 2z', 2x$; that is to say, there will be four faces meeting at the point y , and in like manner there will be four faces meeting in each of the points x, x', y', z, z' , or 24 in all, three in each octant. Further, the face $y, 2z, 2x$, will meet the face $y, 2z, 2x'$, in the line $y, 2z$, and the face $z, 2y, 2x$ will meet the face $z, 2y, 2x'$ in the $z, 2y$, meeting $y, 2z$ in the point c . Thus the edges, cy, cz , situated in the plane yz , are determined; and a similar construction gives the edges ax, ay , and bx, bz . Next, to find the intersections of the three faces included within the octant xyz . The face $z, 2x, 2y$, intersects $y, 2x, 2z$ in the line $c, 2x$, joining $2x$ with the intersection of $z, 2y$, and $y, 2z$; the face $x, 2y, 2z$, meets $y, 2x, 2z$ in the line drawn from $2z$ to a , the intersection of $x, 2y$, and $y, 2x$; and $x, 2y, 2z$ meets $z, 2x, 2y$ in the line drawn from $2y$ to b , the intersection of $x, 2z$, and $z, 2x$. This construction gives the intersections shown by the dark lines in the figure, and determines the form and position of the three faces in the octant xyz ; and the same construction repeated in the other octants gives the form shown in *figs. 180, 181*, which is called the *ikosi-tetra-*

Fig. 179.

Fig. 180.

Fig. 181.

hedron (also leucitohedron and trapezohedron). It is bounded by 24 deltoïds (quadrilaterals having two unequal pairs of equal sides), and has 26 summits, which are of three kinds; viz. six 4-faced, equal-edged, octahedral summits, A; eight 3-faced, equal-edged, cubic summits, B; and twelve 4-faced symmetric summits, C, situated like the summits of the middle-crystal (p. 123). It has also 48 edges, which are of two kinds, viz. 24 longer, A C, joining the octahedral with the symmetric summits, and 24 shorter, B C, joining the cubic with the symmetric summits.

The ikosi-tetrahedron is the intermediate form between the octahedron and the cube; for $m = 1$, it coincides with the octahedron; for $m = \infty$, with the cube. The nearer m is to 1, the more do the three faces in each octant fall into one plane, and the more nearly $m = \infty$, the more do the four faces round each octahedral summit, A, fall into one plane, the limit giving a cube. The inclination of the faces to one another in the longer and shorter edges is:—

	A C	B C
In 2 O 2	131° 43'	146° 27'
„ 3 O 3	144 54	129 31

The form 2 O 2 is found alone in leucite, analcime, and other minerals; 3 O 3 rarely, in native gold, silver, &c. In artificial crystals, the form 2 O 2 occurs combined in chrome-alum and common alum, when a crystal is immersed in a saturated solution mixed with a little hydrochloric acid slightly heated, so that the edges may be dissolved off, and then left to cool.

5. Formula $a : a : ma$, or m O, each face meeting two axes at the distance a from the centre, and the third at a greater distance, ma ; m being either a whole number or a fraction greater than 1. This form, like the preceding, has 24 faces, 3 in each octant. A construction similar to the preceding, and sufficiently indicated by the full and

Fig. 182.

Fig. 183.

dotted lines in *fig. 182*, shows that the solid is bounded by 24 isosceles triangular faces, and has the appearance of an octahedron with triangular pyramids erected on its faces. This form is called the triakis-octahedron (also pyramidal octahedron, galenoid). *Fig. 183* shows the form 20.

The triakis-octahedron has 14 summits, six of which, A, are 8-faced, symmetric, and octahedral, and eight 3-faced, equal edged, and cubic, B. The edges are also of two kinds; 12 A A, joining the octahedral summits and forming the bases of the isosceles triangles; and 24 A B, joining the octahedral and cubic summits, and forming the equal sides of the triangles.

The triakis-octahedron, $a : a : ma$, is the intermediate form between the octahedron, $a : a : a$, and the rhombic dodecahedron, $a : a : \infty a$.

The plane and dihedral angles vary with the value of m , as in the following examples:—

	$\frac{3}{2}0$	20
Plane angles at vertex of isosceles triangles	$119^{\circ} 14'$	$118^{\circ} 4'$
Plane angles at base of triangles	30 23	30 58
Dihedral angles A A	129 31	162 39
Dihedral angles A B	141 3	152 44

6. Formula $a : ma : \infty a$, or $m0 \infty$, each face meeting two of the axes at unequal distances and being parallel to the third. To determine the number of faces in this form, mark off, on the system of rectangular axes (*fig. 184*, supposing $m = 2$) single and double distances on each of the axes measured from C. Then there will be four faces passing through the point $1y$, two parallel to xx' , through the points $2z$ and $2z'$, and two parallel to zz' , through the points $2x$, $2x'$; and since the crystal is equally developed in the direction of all the three axes, there must be four similar faces meeting in

Fig. 184.

Fig. 185.

each of the points y', x', z, z' , that is to say, twenty-four faces in all; and by constructing each octant in the same manner as for the preceding formulæ, the form is

found to be a solid (*fig. 185*), bounded by 24 isosceles triangles, having 14 summits, viz. four 4-faced equal-edged octahedral summits, A, and eight 6-faced symmetric, cubic summits B. It has 36 edges, 12 longer, BB, uniting the cubic summits, and 24 shorter, AB, joining the octahedral with the cubic summits. This figure is the tetrakis-hexahedron. It is intermediate between the dodecahedron $a : a : \infty a$, and the cube $a : \infty a : \infty a$. In the more commonly occurring varieties, the plane and dihedral angles are :

	20 ∞	30 ∞
Plane angle, A, at vertex of isosceles triangles	83° 38'	86° 59'
Plane angles, B, at base of triangles	48 11	46 30
Dihedral angles, AB	143 8	154 9
Dihedral angles, BB	143 8	126 52

The form 20 ∞ occurs uncombined in native gold and silver; 30 ∞ in fluor-spar. In artificial crystals these forms occur but seldom, and then only subordinate to others, as for example in sulphantimonate of sodium (Schlippe's salt), and in rock-salt which has been exposed to moist air. Faces having the disposition of this form, but in only half the full number, are of more frequent occurrence.

7. Formula $a : ma : na$, or mOn . Each face meets the three axes at unequal but finite distances. Such a form must have 48 faces; for through each axial extremity 2 faces can be drawn in each of the four contiguous octants, *e. g.* from z above, one face passing through the point ma or x to the right, and na or y in front, and another through na or x to the right, and ma or y in front; therefore, $4 \times 2 = 8$ through each axial extremity, and $6 \times 8 = 48$ in all.

To determine the form of these faces, draw the system of axes as before, and taking as an example the form $1 : \frac{3}{2} : 3$, or $\frac{2}{3}O3$, mark off on each axis (*fig. 186*), both ways, the distances 1, $\frac{3}{2}$, and 3. The face $z : \frac{3}{2}y : 3x$, forms with the face $z : \frac{3}{2}y : 3x'$ (not drawn in the figure), an edge in the direction $z, \frac{3}{2}y$. The same face $z, \frac{3}{2}y : 3x$ intersects the face $z, 3y, \frac{3}{2}x$ in the direction za , drawn through z and the intersection of the lines $\frac{3}{2}y, 3x$, and $3y, \frac{3}{2}x$; and lastly, it intersects the face $y, \frac{3}{2}z, 3x$, in the direction $b, 3x$, where b is the point of intersection of the lines $z, \frac{3}{2}y$, and $y, \frac{3}{2}z$. The face thus determined is a triangle, and in like manner the position of the five other faces in the octant, $x y z$, may be determined. The result extended symmetrically to all the other octants, is the

Fig. 186.

Fig. 187.

form represented in *fig. 187*, bounded by 48 scalene triangles. This figure is called the Hexakis-octahedron (also *tetrakonta-octahedron*, *adamantoid*, &c.). It has 26 summits of three kinds, viz. eight 6-faced symmetrical octahedral summits A, through which the axes pass; six 8-faced, cubic summits B; and twelve 4-faced symmetric summits C, situated like those of the middle crystal (p. 123). Its edges are 72 in number, and likewise of three kinds, viz. 24 edges AC, uniting the octahedral with the four-faced summits; 24 edges BC, uniting the cubic with the four-faced summits, and 24 edges AB, uniting the octahedral with the cubic summits.

The plane and dihedral angles of the figure vary with the magnitudes of m and n : for the most commonly occurring forms they are as follows :

	30 $\frac{3}{2}$	204
Plane angles A of the scalene triangles	36° 49'	39° 48'
" B	56 15	54 22
" C	86 56	85 50
Dihedral angles A C	149 0	154 47
" B C	158 13	144 3
" A B	158 13	162 15

The form 204 often occurs very predominant in crystals of fluor-spar; $3O\frac{3}{2}$ in garnet. Diamonds are also found having the form of the hexakis-octahedron, but with curved faces, so that the angles cannot be accurately measured. This form occurs but very rarely in artificial crystals: it has, however, been observed, though very subordinate, in alum crystallised from a solution containing hydrochloric acid.

Hemihedral Forms of the Regular System.— Suppose four alternate faces of the octahedron (*fig. 188*), viz. the right front above, left front below, left back above, and right back below, to extend so as partially to obliterate the four remaining faces; a form will be produced like figure 189; and if the extension be continued till the alternate faces completely disappear, the four-sided pyramid (*fig. 190*) will be produced, called the regular tetrahedron, and denoted by the symbol $\frac{O}{2}$.

Fig. 188.

Fig. 189.

It is bounded by four equilateral triangles, has 4 three-faced summits, and 6 similar edges in which the faces are inclined at angles of $70^\circ 32'$. The axes pass through the middle points of each pair of opposite edges.

Fig. 190.

Fig. 191.

If the other four sides of the octahedron increase instead of those above-mentioned, the result will be the tetrahedron shown in figure 191, exactly similar to the former but oppositely situated. When both these tetrahedrons occur together in the same crystal, as in *fig. 189*, one of them is distinguished as $+\frac{O}{2}$ the other as $-\frac{O}{2}$; when either occurs alone the sign + or - may be omitted.

Tetrahedral faces occur in Schlippe's salt, chlorate of sodium, fahl-ore, blende, &c.

The cube and rhombic dodecahedron have no corresponding hemihedral forms. The icosi-tetrahedron, triakis-octahedron, tetrakis-hexahedron, and hexakis-octahedron all produce hemihedral forms by the growth of their alternate faces; but the only one of these forms that it is important to notice is the pentagonal dodecahedron (*fig. 192*) produced from the tetrakis-hexahedron (*fig. 185*, p. 126). This holohedral form may be regarded as a cube on each of whose six faces is erected a four-sided pyramid. Suppose now that on the top and bottom pyramids, the front and back faces grow, while the right and left disappear; that on the front and back pyramids, the right and left faces grow, while the upper and lower faces disappear; and that on the right and left pyramids, the upper and lower faces grow, while the right and left disappear; the result will be a dodecahedron whose general symbol is $\frac{mO\infty}{2}$. *Fig. 192* represents $\frac{2O\infty}{2}$.

If the other alternate faces of the holohedral form be supposed to increase, an exactly

Fig. 192.

Fig. 193.

similar dodecahedron (*fig.* 193) will be formed, but differently situated; these two forms may be distinguished by the symbols $+\frac{20\infty}{2}$ and $-\frac{20\infty}{2}$.

The pentagonal dodecahedron is bounded by 12 symmetric pentagons, each having four of its sides of equal length, and the fifth (the base) of different length. It has 30 edges, 6 of which, *E E*, are formed by the meeting of the faces at their bases, and 24, *B E*, forming the equal sides of the pentagons. The summits are 20 in number, 12 of which, *E*, formed by the meeting of a basal edge *E E*, and two equal edges *B E*, are situated in the planes of the axes, but at different distances therefrom, and 8 others, *B*, formed by the meeting of three equal edges of the pentagons and situated like the summits of the cube. The axes pass through the middle points of each pair of opposite basal edges.

The pentagonal dodecahedron has not yet been observed in its complete form in artificial crystals; among minerals it is especially exhibited by iron-pyrites and cobalt-glance.

Combinations of the Simple Forms of the Monometric system. These combinations are very numerous; we shall here notice some of the most important. In expressing a combination symbolically, the symbol of the dominant form is usually written first:

$0 . \infty 0 \infty . \infty 0 . 202 . + \frac{20 \infty}{2} . - \frac{20 \infty}{2}$ (fig. 212). Alum.

7. Combinations of the Hexakis-octahedron:

$0 . 30\frac{3}{2}$ (fig. 213). Alum (apparently).

$\infty 0 \infty . 204$ (fig. 214). Fluor-spar.

Dimetric or Quadratic System.

Square Prismatic, Pyramidal, Tetragonal, Monodimetric System (Zwei- und einaxiges, viergliedriges System).

Crystals belonging to this system are symmetric about three rectangular axes, two of equal, the third of different length; and may, therefore, be so placed as to appear equally developed in two horizontal directions at right angles to each other (right and left, and backwards and forwards), but differently in the vertical direction. The vertical or principal axis (p. 120) will be denoted by c , the horizontal or secondary axes by a . All sections perpendicular to the principal axis are squares or figures derived therefrom.

In this, as in the monometric system, the most general form is one, each of whose faces (produced if necessary) meets the three axes at different distances from the centre. Let these distances be a and na for the secondary axes (n being a multiplier either greater or less than unity), and c for the principal axis. To determine the form, draw two rectangular axes (fig. 215), and supposing, for example, $n = \frac{3}{2}$, set off from the centre the distances a and $\frac{3}{2}a$, and join each point a on the one axis with $\frac{3}{2}a$ on the other, as shown by the dotted lines in the left upper quadrant. The portions of these lines contained between the several points a and the intersections of these dotted lines will form an equilateral octagon; and if from each of the angles of this

Fig. 215.

Fig. 216.

octagon straight lines be drawn to the extremities c of the principal axis (perpendicular to the plane of the paper), the planes passing through these lines will enclose a double eight-sided pyramid (*fig. 216*), bounded by sixteen scalene triangles, $A B C$, the summits B being situated at the ends of the horizontal axes, and the summits C at angular distances of 45° therefrom. This figure evidently fulfils the condition essential to the forms of the dimetric system, of being equally developed in the direction of two rectangular axes, but differently in the direction of the third. It may be represented by the formula :

$$a : n a : c.$$

The inclinations of the edges $B C$ to each other (or the angles of the octagon, *fig. 215*), vary with the value of m . The more n approaches to unity, the more nearly do the points $n a$ (*fig. 215*) approach to a , and the more nearly do the lines joining these points ($B C$, $C B$ in *fig. 216*) approach to coincidence, the angles C of the base becoming greater; and when $n=1$, or the formula becomes $a : a : c$; the angles C become $= 180^\circ$; in other words, the lines $B C$, $C B$ coincide; the octagon becomes a square; and the double eight-sided pyramid is reduced to a double four-sided pyramid with a square base (*fig. 217*), having its angles B situated at the extremities of the horizontal axes.

Fig. 217.

Fig. 218.

If, on the other hand, n increases, the angles C (*fig. 216*) become less, and the angles B more and more obtuse; and finally, when $n = \infty$, or the formula becomes $a : \infty a : c$, the angles B become $= 180^\circ$, or the two horizontal lines $B C$, $C B$, drawn from the extremities of each axis, merge into single straight lines parallel to the other axis; and the base of the pyramid becomes a square, having the middle points of its sides at the extremities of the secondary axes, and its angles C equidistant from those points, as in *fig. 218*.

The symbols of the three forms just described are abbreviated as follows:—

$$\begin{aligned} a : a : c \text{ (fig. 217)} &= P \\ a : n a : c \text{ (fig. 216)} &= P n \\ a : \infty a : c \text{ (fig. 218)} &= P \infty. \end{aligned}$$

It appears then that a square pyramid may be represented by the formula $a : a : c = P$, or $a : \infty a : c = P \infty$ (the ratio $c : a$ being however different in the two cases), according as the secondary axes pass through the angles or the middle points of the sides of the base. When two pyramids so related to each other occur together in the same crystal, P is regarded as the primary form, and is called the square pyramid of the first order; $P \infty$ the pyramid of the second order.

A square pyramid is more or less acute, according to the ratio between the principal and secondary axes. When a is very nearly equal to c , the pyramid is scarcely distinguishable in outward form from the regular octahedron (*fig. 149*); the two forms may, however, always be distinguished by their modifications, the edges and summits of the regular octahedron being all modified alike, whereas in a square pyramid the terminal edges AB (*fig. 216*) may be modified differently from the lateral edges BB , and the summits A at the ends of the principal axis differently from the summits B at the ends of the secondary axes.

As the ratio of c to a becomes greater, the pyramid becomes more and more acute, and the angles of the planes meeting in the lateral edges BB (*fig. 217*), CC (*fig. 218*), or BC (*fig. 216*), approach more nearly to 180° ; and finally, when the ratio $c : a$ becomes infinitely great, this angle becomes $= 180^\circ$, and the pyramid is reduced to a prism of indefinite length, having its sides parallel to the principal axis.

When two quadratic pyramids, in which the ratio $c : a$ is different, occur together in the same crystal, one of them is regarded as the primary form, and denoted by one of the formulæ already given; the other in which the ratio of $\frac{c}{a}$ is m times that in the former ($m > 1$), is denoted by prefixing the symbol m to c in the full formula, or to P in the abbreviated formula; thus:—

Square pyramids of the first order	$a : a : mc = mP$
Octagonal pyramids	$a : na : mc = mPn$
Square pyramids of the second order	$a : \infty a : mc = mP\infty$

When in either of these formulæ m becomes infinite, the corresponding pyramid becomes a prism, as already explained.

When $m = 0$, the pyramid is reduced to a plane, called the terminal face, or end-face, oP , parallel to the plane of the secondary axes.

Among pyramids of the second order occurring together with a primary form P , it is usual to distinguish particularly the two following:

a. The next obtuser pyramid is that whose faces have the same position and inclination with respect to the principal axis, as the terminal edges of the primary form. For the primary form $a : a : c$, or P (*fig. 217*); the next obtuser pyramid is evidently $a : \infty a : c$, or $P\infty$ (*fig. 218*), having for its base the outer dotted square, $befd$ (*fig. 219*), whose sides are drawn parallel to the axes, through the angles of the base of the primary form; and generally, for every square pyramid of the first order, mP , the next obtuser pyramid is $mP\infty$. The terminal edges of P are symmetrically truncated by the faces of $mP\infty$.

b. The next acuter pyramid is that whose terminal edges have the same position and inclination with respect to the principal axis, as the faces of the primary form. The primary form having for its base the square represented by the continuous lines in *fig. 219*, the next acuter pyramid will have the same principal axis, and the base $ghki$, whose angles are at the middle points of the sides of the primary form. The formula of this pyramid is $\frac{1}{2}a : \infty a : c$, or $a : \infty a : 2c$, or $2P\infty$; and generally, for every square pyramid of the first order, mP , the corresponding next acuter pyramid is $2mP\infty$. The terminal edges of the latter are symmetrically truncated by the faces of mP .

Fig. 219.

Fig. 220.

Combinations of the Holohedral forms of the Dimetric system. The square and octagonal pyramids and prisms above described are the only simple holohedral forms of the dimetric system. The following are some of their principal com-

binations:—When two square pyramids of the same order occur together in a crystal, the more acute of the two is acuminated in the direction of the principal axis by the faces of the more obtuse, which rest on the faces of the former, as in *fig. 220*. In sulphate of nickel, which crystallises in this manner, the ratio $c : a = 1.888$ in the more acute, and 0.944 in the more obtuse pyramid, the length of c in the two pyramids referred to a secondary axis as unity, being in the ratio of $2 : 1$. In all such combinations, it is found that the principal axes of the two pyramids bear to one another a simple ratio, as $3 : 1$, $3 : 2$, &c.

When two square pyramids of different orders occur together, the faces of the one truncate the edges or the summits of the other. *Fig. 221* represents a form of tin-stone, in which the terminal edges of the primary form P are symmetrically truncated by the faces of the next obtuser pyramid $P\infty$. *Fig. 222* is a form of anatase, in which the terminal summits of P are acuminated by $\frac{1}{2}P$, and the lateral summits are bevelled by the faces of the next acuter pyramid, $2P\infty$. The terminal edges of this latter pyramid may also be regarded as very broadly truncated by the faces of P .

Fig. 221.

Fig. 222.

Fig. 223.

Fig. 224.

Combinations of prisms and pyramids of the different orders, with or without the terminal face oP , are of frequent occurrence. *Fig. 223* represents an octagonal prism formed by the prismatic faces of the first order, ∞P , truncated by the prismatic faces of the second order, $\infty P\infty$, and terminated above and below by oP . This form is seen in acetate of copper and calcium, $C^2H^2CuCaO^2$.

$\infty P.P$ (*fig. 224*) is a form of potassio-uranic acetate, a square prism with pyramidal summits resting on the prismatic faces.

Figs. 225, 226, 227 represent combinations of the forms $P.\infty P\infty$ in various proportions.

$P.\infty P\infty$ (*fig. 225*), with P predominant, is found in mellite or honeystone.

P and $\infty P\infty$ equally developed (*fig. 226*), which has very much the appearance of a rhombic dodecahedron, is exhibited by potassio-cupric chloride, $KCl.CuCl$.

$\infty P\infty.P$ (*fig. 227*) is a form of apophyllite.

Fig. 225.

Fig. 226.

Fig. 227.

The following figures (*figs. 228—231*) represent combinations of square pyramids with the terminal face oP ; they are all forms of sulphate of nickel, $Ni^2SO^4 + 3H^2O$. In all these combinations, it may be observed that pyramids similarly situated between the

Fig. 228.

Fig. 229.

Fig. 230.

Fig. 231.

axes form combination-edges parallel to the base, *e. g.*, oP , $\frac{1}{2}P$, P , and $P\infty$. $\infty P\infty$ (fig. 231), whereas pyramids and prisms differently situated with regard to the axes form combination-edges inclined to the base, *e. g.* P and $\infty P\infty$, in figs. 225, 226, 227, 230, 231; also P and $P\infty$ in figs. 230, 231. This rule is of great use in determining the relations of the faces in complicated combinations.

Hemihedral Forms. A square pyramid may become hemihedral in the same manner as a regular octahedron (p. 128), viz. by the extension of four alternate faces till the others are obliterated. The figure thus produced, called a quadratic sphe- noïd, is a four-sided pyramid distinguished from the regular tetrahedron by the form of its faces, which are not equilateral but isosceles triangles. The principal axis terminates in the middle points of two of the edges (terminal edges); the secondary axes in the middle points of the four other edges (lateral edges). A quadratic sphe- noïd is denoted by the symbol $\frac{mP}{2}$ or $\frac{mP\infty}{2}$, according to that of the pyramid from which it is formed. The signs + and - prefixed to these symbols have the same meanings as in the case of the regular tetrahedron (p. 128).

Sphenoids rarely occur alone; a solution of cyanide of mercury, however, sometimes yields by spontaneous evaporation perfectly developed sphenoids in which $\frac{c}{a} = 0.985$. More frequently sphenoids occur in combination, *e. g.* with their terminal edges truncated by the face oP , and their lateral edges by $\infty P\infty$. The summits of $\frac{P}{2}$ may also be replaced by the faces of the opposite sphenoid, in which case they are distinguished as $+\frac{P}{2}$ and $-\frac{P}{2}$. A combination of these two forms equally developed has the external form of a square pyramid, but may generally be distinguished therefrom by the different modifications of its edges and summits. Fig. 232 is a form of

Fig. 232.

copper-pyrites, consisting of a sphenoid $+\frac{P}{2}$ having its terminal edges replaced by oP , its summits by faces of $-\frac{P}{2}$, while those combination-edges of the two sphenoids which are situated like the terminal edges of P , are truncated by faces belonging to the pyramid $P\infty$. Modified sphenoids also occur in cyanide of mercury, formate of strontium, cholalic acid, &c.; but they are not common.

Another hemihedral form $\frac{mPn}{2}$ is produced by the growth of the alternate faces of the octagonal pyramid (fig. 216). It is a double pyramid with a square base,

but having the sides of the base obliquely inclined to the secondary axes, as may be seen by prolonging the alternate sides of the octagon (fig. 215) till they meet. Such a

form is called a square pyramid of the third order. In like manner are formed square prisms of the third order. Square pyramids of the third order never occur alone, and but rarely in combination. Examples are found in tungstate of lead, tungstate of calcium, and a few other minerals. In native tungstate of calcium (Scheelite) the primary form P occurs, modified by the faces $2P \infty$ and $\frac{4P^2}{2}$.

Hexagonal System.

Rhombohedral, Monotrimetric System (Drei- und einaxiges, sechsgliedriges, drei- und dreigliedriges System).—Crystals of this system have three equal secondary axes situated in the same plane and inclined to one another at 60° , and a principal axis at right angles to the plane of the secondary axes. If this axis be placed vertically, the crystal appears differently developed in the vertical and horizontal directions, but equally and similarly developed in the six directions lying in the horizontal plane, viz. at the six extremities of the three secondary axes.

The principal axis is sometimes longer, sometimes shorter than the secondary axes. Its length c is expressed by referring it to that of a secondary axis as unity.

As three points determine a plane, the position of any face of a crystal in this system is determined by the distances from the centre at which it cuts the principal axis and two of the secondary axes. The most general form is one in which each face cuts two of the secondary axes at unequal distances. Suppose, for example, these distances to be to one another as $1 : \frac{3}{2}$. Draw three horizontal axes cutting one another at 60° , as in *fig. 233*, and set off on two of them the distances $a, \frac{3}{2}a$. Then, by a construction similar to that described at p. 133, it is found that the horizontal section of the required form is an equilateral dodecagon; and by joining the angular points of this polygon with the extremities of the principal axis (supposed perpendicular to the plane

Fig. 233.

Fig. 234.

of the paper) we obtain the symmetrical double-twelve-sided pyramid (*fig. 234*), bounded by twenty-four scalene triangles ABC , six of the basal summits, B , being situated at the extremities of the secondary axes, and six others, C , half way between. Such forms occur in combination, but not singly.

The general formula of the solid thus determined is $a : na : pa : c$, in which when n is given, p is determined. In the preceding figure, where $n = \frac{3}{2}$, p is found to be equal to 3. There are two particular cases of special importance:—

1. When $n = 1$, or the formula becomes $a : a : pa : c$. In this case it is easy to see that the twelve sides of the base are reduced to six, and the base becomes a regular hexagon (*fig. 235*), having its angles at the extremities of the secondary axes. Each side meets two contiguous axes at equal distances, as at f, k , and is parallel to the third, so that $p = \infty$, and the formula becomes $a : a : \infty : c$. The form thus determined is a double six-sided pyramid (*fig. 236*) bounded by twelve isosceles triangles ABB , which

Fig. 235.

Fig. 236.

Fig. 237.

are acute- or obtuse-angled, according to the ratio of the principal to the secondary axes. Every section perpendicular to the vertical axis is a regular hexagon, like the base, and every vertical section passing through the principal axis is a rhombus.

2. When $n = 2$. Each face cuts one of the secondary axes at the distance a and another at $2a$. In this case the construction in *fig. 235* shows that the base of the figure is a regular hexagon, having its sides in the situation of the dotted lines of the figure, each side passing through one of the angles of the former hexagon, and cutting the third secondary axis also at the distance $2a$ from the centre, so that the formula becomes $a : 2a : 2a : c$. The solid figure obtained by joining the angular points of this hexagon with the ends of the principal axis is also a double six-sided pyramid, like *fig. 236*, but differently situated, the ends of the secondary axes passing through the middle points of the sides of the hexagon, and the basal summits C being situated half way between these axes (*fig. 237*).

When two or more hexagonal pyramids occur together in the same crystal, one replacing the edges or summits of the other, one of them is assumed as the primary form, the secondary axes being supposed to pass through the angles of its base; and of the rest, those which are similarly situated with regard to the axes are called acuter or obtuser pyramids of the first order, while those which are intermediately situated, that is to say, having the middle points of their basal edges at the extremities of the axes, are called pyramids of the second order. The relative lengths of the principal axes of these pyramids are denoted, as in the dimetric system, by placing a multiplier m before the sign of the principal axis. The abbreviated symbols of the several pyramids are also similar to those used in the dimetric system; thus:—

Primary form	$a : a : \infty a : c = P$
Pyramids of the first order	$a : a : \infty a : mc = mP$
Pyramids of the second order	$a : 2a : 2a : mc = mP2$
Dodecagonal pyramids	$a : na : pa : mc = mPn$

If in either of these formulæ $m = 0$, the pyramid is reduced to a terminal face of P parallel to the plane of the secondary axes.

If $m = \infty$, in either of the formulæ, the corresponding pyramid becomes a vertical prism, ∞P , $\infty P2$, or ∞Pn , of indefinite length.

These prisms and the terminal faces, being unclosed forms, can only occur in combination.

The terms, next obtuser and next acuter pyramid, are used in this system in the same sense as in the dimetric system (p. 134):— a . The next obtuser pyramid is that whose faces have the same situation and inclination relatively to the principal axis as the terminal edges of the primary form. For the primary form P , or $a : a : \infty a : c$ (*fig. 236*), the next obtuser pyramid is evidently $a : 2a : 2a : c$ or $P2$ (*fig. 236*); and generally, for every hexagonal pyramid mP , the next obtuser pyramid is $mP2$.

b . The next acuter pyramid for the primary form P , is that whose terminal edges have the same position and inclination relatively to the principal axis as the faces of the primary form. The base of the primary form being the full-lined hexagon (*fig. 235*), the next acuter pyramid is that whose faces meet the principal axis at the same distance c from the centre, and pass through b, d , the middle points of the sides ck, kf , and the corresponding points of the other sides of the same hexagon. Now the line bd cuts the axis gk in the point i , so situated that $gi = \frac{3}{4} gk$. Consequently, the formula of this pyramid is $\frac{3}{4} a : 2 : \frac{3}{4} a : 2 : \frac{3}{4} a : c$, or $a : 2a : 2a : \frac{4}{3} c = \frac{4}{3} P2$; and generally, for every pyramid of the first order mP , the corresponding next acuter pyramid is $\frac{4}{3} mP2$. The terminal edges of a pyramid of the first order mP are symmetrically truncated by the faces of a pyramid of the second order $mP2$.

The hexagonal and dodecagonal pyramids and prisms above described, are the only

holohedral forms of the hexagonal system. The closed forms (the pyramids) are rarely found alone; examples of simple hexagonal pyramids are found in the compound of grape-sugar and chloride of sodium, and occasionally in quartz. The unclosed forms, viz. the prisms and the terminal faces, occur only in combination.

Combinations of the Holohedral forms of the Hexagonal System.

Hexagonal pyramids and prisms combine together in the same manner as the corresponding figures of the dimetric system. When two pyramids of the same order occur together, the obtuser of the two acuminate the summits of the more acute, just as in *fig. 220* (p. 134). In like manner, the hexagonal prism occurs acuminate by the pyramid of the same order, the faces of the latter resting on those of the prism, and forming horizontal combination-edges, as in quartz (*fig. 238*). When hexagonal pyramids of different orders occur together, the faces of the one replace the edges and summits of the other, producing truncations, bevellings, or acuminations, according to their relative positions and inclinations. Examples of these combinations, together with the terminal face ∞P , are seen in *figs. 239, 241, 242*, which are forms of apatite, and *fig. 240*, which is a form of beryl.

Fig. 238.

Fig. 239.

Fig. 240.

The forms ∞P and ∞P combined together produce a vertical hexagonal prism with horizontal end-faces. When ∞P predominates, the prism is reduced to a hexagonal tablet. In *fig. 240* the combination-edges of this form are truncated by the faces P belonging to a pyramid of the same order as the prism; in *fig. 241* the combination-summits of the same form are truncated by the faces of a pyramid $2P_2$ of different order. *Fig. 242* affords a good example of the manner in which the different forms making up a complicated combination may be determined. The pyramid whose faces are

Fig. 241.

Fig. 242.

denoted by P is chosen as the primary form, because it is the one to which the other forms may be most conveniently referred. The relation of the faces ∞P , ∞P , ∞P_2 to this primary form is obvious. The faces of the next obtuser pyramid P_2 are known because they truncate symmetrically the terminal edges of P ; those of $2P_2$, because they truncate the combination-summits of ∞P and ∞P (as in *fig. 241*), forming combination-edges which are parallel to the terminal edges of P (or the combination-edges between P and P_2); and those of $2P$, because their terminal edges are symmetrically truncated by $2P_2$.

Symmetrical twelve-sided pyramids rarely occur in combination, with all their faces. An example of such a combination is, however, found in beryl (*fig. 243*), in which the twenty-four faces of $3P\frac{3}{2}$ (denoted in the figure by z) truncate the edges between $2P2$ and ∞P .

Fig. 243.

In all combinations of hexagonal (and likewise of quadratic forms, the following rule holds good: — *Forms which lie in the same direction between the secondary axes intersect one another in horizontal edges, or in such a manner that the upper and lower combination-edges are parallel to each other; but forms which are dissimilarly situated between the secondary axes, intersect one another in inclined edges, the upper and lower not being parallel.* Thus the combination-edges between oP , P , $2P$ and ∞P (*fig. 242*) are all parallel, as also are those between oP (which is the same as $oP2$), $P2$, $2P2$ and $\infty P2$; whereas the combination-edges between P and $2P2$, or $2P2$ and ∞P in the same figure, or between $3P$ and ∞P in *fig. 243* are not parallel to one another.

Hemihedral forms. The hemihedral forms of the hexagonal system occur more frequently than the holohedral forms, and among them there are two of especial importance, the Rhombohedron derived from the hexagonal pyramid, and the Scaenohedron derived from the dodecahedral pyramid.

1. *Rhombohedral forms.*—Suppose that in a hexagonal pyramid (of the first order, *fig. 236*) the front face above, the right and left faces below, and the three faces alternating with these, are extended till they obliterate the intermediate faces, viz. the front below, the right and left above, &c.; the result will be the rhombohedron (*fig. 244*), a figure bounded by six rhombuses. It has eight summits, which are of two kinds, viz. two terminal summits $A A$, formed by the meeting of three terminal edges, and six lateral summits $D D$, formed by the concurrence of two lateral edges and one terminal edge. Of the twelve edges, six are terminal, extending from the terminal to the lateral summits, and six lateral, extending in a zig-zag line between the lateral summits. The principal axis joins the terminal summits; the secondary axes unite the middle points of every two opposite lateral edges. The symbol of the rhombohedron would, according to general usage, be $\frac{P}{2}$, but it is usually replaced by the shorter symbol R .

In the rhombohedron formed as above described, one face extends from above forwards, and one edge from below forwards; if however the other alternate faces of the hexagonal prism (*fig. 235*) be supposed to grow, viz. the right and left above, the front below, &c., the result will be a rhombohedron in the opposite position, that is to say, having an edge extending from above forwards and a face from below forwards,

Fig. 244.

Fig. 245.

as in *fig. 245*. When these opposite rhombohedrons occur together in the same crystal, their faces are distinguished by the signs $+$ and $-$, the first described rhombohedron, which has a face extending from above forwards, being usually denoted by $+ R$, the opposite one by $- R$.

Rhombohedral forms are acute or obtuse, according as their terminal edges and faces intersect one another at acute or obtuse angles, these inclinations depending of course upon the ratio between the principal and secondary axes. For a particular value of this ratio, the faces and edges meet at right angles, and the rhombohedron has the form of a cube. It is not, however, identical with a cube in anything but external shape: for its edges and summits are of two kinds, and the terminal edges or summits may be modified, while the lateral edges or summits are not, and *vice versa*, whereas in the cube, if any modification occurs, all the corresponding parts must be similarly modified.

When a number of rhombohedrons of different degrees of acuteness occur together,

that one is selected as the primary form in the direction of whose faces the crystal cleaves most easily, and this rhombohedron being denoted by $+R$ (that is to say, being so placed that one face of the primary form extends from above forwards), the others are denoted by $\pm mR$, the number m denoting the ratio of the principal axis of each rhombohedron to that of the primary form. This ratio is always very simple. (See CALCSPAR, i. 721.)

When two rhombohedrons of the same order occur together, the more obtuse acuminate the terminal summits of the more acute, as in *fig. 246*, a form of calcspar in which the terminal summits of $+4R$ are acuminate by $+R$; but when rhombohedrons of different orders occur together, the edges or summits of the one are truncated by the faces of the other, as in *figs. 247—249*. A rhombohedron by which the terminal edges of the primary form are symmetrically truncated, is called the next

Fig. 246.

Fig. 247.

Fig. 248.

Fig. 249.

obtuser rhombohedron of that form; and the rhombohedron whose terminal edges are symmetrically truncated by the faces of the primary form is called the next acuter rhombohedron of that form. Of any rhombohedron $+mR$, the next obtuser is $\mp \frac{1}{2}mR$, and the next acuter is $\mp 2mR$. In *fig. 249*, $+R$ is the next obtuser rhombohedron of $-2R$. Examples of rhombohedrons thus related are found in calcspar (i. 721), also in chabasite (i. 843).

The two opposite rhombohedrons $+R$ and $-R$, formed from the same hexagonal pyramid, are often combined together, and when they are equally developed, produce a combination undistinguishable in form from the holohedral hexagonal pyramid. There are, however, essential differences between the two: sometimes the faces of the opposite rhombohedrons differ in lustre or in mode of striation; sometimes the crystal cleaves in directions parallel to one set of faces and not to the other; frequently also the manner in which the faces and edges are modified affords the means of distinction: thus the horizontal combination-edges of quartz, ∞P (*fig. 238*), are sometimes truncated by the faces $3P$; but this modification does not affect the whole of these edges, but only the alternate ones, *e. g.* the front combination-edge above, the right and left below, &c., whereas, if the crystal were holohedral, all these edges would be modified alike (*fig. 258*).

The terminal face oR truncates the terminal summits of a rhombohedron, as in corundum (*fig. 146*, p. 86); if the face oR predominates greatly, the crystal is reduced to a tablet like *fig. 147*.

The more the principal axis of a rhombohedron increases relatively to the secondary axes, the smaller do the angles at the terminal edges become, and the more nearly do those of the lateral edges approach to 120° , that is to say, to the inclination of the faces of a hexagonal prism (see TABLE, vol. i. p. 721). And finally, if the principal axis becomes infinite, the faces of the rhombohedron become parallel to it, and the figure becomes a hexagonal prism identical with ∞P ; in rhombohedral combinations it is however denoted by ∞R .

Rhombohedral combinations occur in combination with hexagonal prisms. With a predominant hexagonal prism of the first order, ∞P , or ∞R , a rhombohedron (of either order) combines in such a manner as to produce three-faced terminations, the acumination-faces resting symmetrically on the faces of the prism, and disposed alternately above and below, as in calcspar ∞R — $\frac{1}{2}R$ (*fig. 250*); on a prism of the second order, ∞P_2 , a rhombohedron likewise forms three-faced acuminations, with its faces likewise disposed alternately above and below, but resting symmetrically on the edges of the prism, as in *fig. 251*, which is a form of diopase.

2. *Scalenohedrons*.—This form, represented in *figs. 252, 253*, is produced by the extension of the alternate faces of the double twelve-sided pyramid, *fig. 234*, p. 137. It is bounded by twelve scalene triangles, has two six-faced terminal summits, six four-faced lateral summits, and eighteen edges of three different kinds, viz. six longer and six shorter edges between the terminal and lateral summits, and six lateral edges forming

Fig. 250.

Fig. 251.

a zigzag between the lateral summits. The middle points of these lateral edges are situated at the extremities of the secondary axes, so that these edges have the same relative situation as the lateral edges of a rhombohedron; and in fact, the easiest way of conceiving the generation of a scalenohedron is to suppose the principal axis of a rhombohedron to be elongated, and straight lines drawn from the extremities of this elongated axis to the lateral summits of the rhombohedron.

A scalenohedron is determined by the dimensions and position of the rhombohedron from which it may be conceived to be formed, and by the number of times that the axis of that rhombohedron must be multiplied to produce it; the latter is indicated by placing a superior figure to the right of the symbol of the rhombohedron; thus a scalenohedron whose vertical axis is n times that of its generating rhombohedron mR , is denoted by the symbol mR^n .

Fig. 252.

Fig. 253.

Scalenohedrons are further distinguished as + or -, according to the position or order of the generating rhombohedron, or according as they are produced by the extension of one or the other set of alternate faces of the primitive dodecahedral pyramid. The opposite forms are shown in *figs.* 252, 253. The form + R^3 occurs in calcspar, constituting the variety called *dog's-tooth spar* (*fig.* 123, vol. i. p. 722).

The terminal summits of a scalenohedron are often acuminate with three faces of the rhombohedron from which the scalenohedron may be supposed to be derived, the combination-edges being parallel to the lateral edges of the scalenohedron, as in *fig.* 254, which is also a form of calcspar. The lateral summits are also frequently truncated by the faces of the first hexagonal pyramid ∞P , and the lateral edges by those of the second hexagonal prism $\infty P2$.

3. *Other hemihedral forms.*—The double dodecahedral pyramid mPn (*fig.* 232) may become hemihedral in the same manner as the double eight-sided prism of the quadratic system (p. 133), viz. by the extension of each alternate pair of faces meeting in a lateral edge. The figure thus produced is a double six-sided prism of the third order. Every dodecahedral pyramid yields two such hexagonal pyramids of the third order, according as one or other set of alternate faces is supposed to grow. The base

Fig. 254.

Fig. 255.

of one of these pyramids is represented by the full lines in (*fig. 255*), that of the other by the dotted lines. The lateral summits of each of these pyramids are situated between the secondary axes, and at unequal distances from each pair of axes.

Hexagonal prisms of the third order, $\frac{\infty Pn}{2}$, are produced in like manner from the dodecagonal prism.

This kind of hemihedry is strikingly exhibited in apatite. In *fig. 241* (p. 139) the combination-edge, which each face of $2P2$ forms with the two contiguous faces of ∞P , may be truncated by a face of a dodecagonal pyramid, as in beryl (*fig. 243*, p. 140), where the twenty-four small faces denoted by z belong to the pyramid $3P\frac{3}{2}$. In apatite, however, only half of these combination-edges are thus truncated, viz. those which each face $2P2$ forms with the face ∞P to the left of it, while the one to the right remains unaltered (*fig. 256*). The truncation-faces, therefore (represented by m in *fig. 256*), belong to the hemihedral form $\frac{3P\frac{3}{2}}{2}$. In like manner, of the two combination-edges

Fig. 256.

Fig. 257.

Fig. 258.

which each face $\infty P2$ forms with the two contiguous faces ∞P (*fig. 242*), one only is truncated, the faces p (*fig. 256*) belonging to the hexagonal prism $\frac{\infty P\frac{3}{2}}{2}$.

The hexagonal pyramid of the second order (p. 138) may also become hemihedral by the obliteration of half of its faces in the manner just described, the resulting figure being a double triangular pyramid $\frac{mP2}{2}$, having an equilateral triangle for its base. It never occurs alone, but is found in quartz, replacing half of the summits formed by the faces of the two opposite and equally developed rhombohedrons $+R$ and $-R$ (p. 140) and the hexagonal prism ∞R . If the crystal were holohedral, the whole of these summits would be thus replaced, and the combination would be that represented in *fig. 257*, where the faces x belong to the second hexagonal pyramid $2P2$. In reality, however, only half these summits are thus replaced, as represented by the faces x or $\frac{2P2}{2}$ in *fig. 258*.

Hexagonal prisms of the second order likewise become hemihedral by the obliteration of half their faces alternately situated, producing triangular prisms.

Tetartohedry.—Quartz affords a remarkable example of a combination in which only one-fourth of the possible faces are present (p. 121). The combination-edges between the faces x and ∞R are often truncated by faces y , belonging to a dodecagonal pyramid, $6P_6^2$; but of the twenty-four faces belonging to this form, six only are present, as shown in *fig. 258*. Quartz likewise exhibits other forms of tetartohedral development.

Trimetric or Rhombic System.

Prismatic, Right prismatic, Orthotypic, Isoclinic, Holohedro-rhombo-trimetric System (Zwei- und zweigliedriges, ein- und einaxiges System).

Crystals belonging to this system have three rectangular axes, all of different lengths; in other words, they are unequally developed in three directions at right angles to each other. The axes are likewise dissimilar in this respect, that they terminate in dissimilar parts of the crystal.

The three axes of a trimetric crystal are therefore singular axes (p. 120), and there is no reason for considering either of them as a principal axis rather than the others.

Fig. 259.

$$a : b : c = 0.8 : 1 : 0.9.$$

It is, however, convenient to regard as the principal axis, that one of the three in the direction of which the crystal is to the greatest extent prismatically developed, or to which the greatest number of faces are parallel. This axis we shall suppose to be placed vertically, and denoted by the letter c . Of the two secondary axes, the shorter, called the brachydiagonal (a), will be supposed to extend from left to right; the longer, or macrodiagonal (b), from back to front (*fig. 259*). The relative lengths of the three axes vary greatly in different crystals belonging to this system; in sulphur, the proportion of $a : b : c$ is $0.81 : 1 : 1.90$; in neutral sulphate of potassium, it is $0.746 : 1 : 0.573$.

A plane passing through any two of the axes is called a principal section, and is further distinguished as basal when it passes through the two secondary axes, macrodiagonal when it passes through the principal and longer secondary axis, brachydiagonal when it passes through the principal and shorter secondary axis.

Fig. 260.

The most general, and at the same time the simplest form of a trimetric crystal, whose faces meet the axes at the distances a, b, c from the centre is a symmetric eight-sided pyramid* (*figs. 259, 260*), having its summits at the extremities of the axes. Its faces are all scalene triangles. Its twelve edges are of three kinds, viz. four lateral edges, BC , situated in the basal principal section, four terminal edges, AC , in the macrodiagonal, and four terminal edges, AB , in the brachydiagonal principal section. All the three principal sections are rhombuses, but with different angles. Hence this form is called a rhombic pyramid. The six summits are also of three kinds, viz. two terminal summits, A , two lateral summits, B , at the extremities of the brachydiagonal, and two lateral summits, C , dissimilar to the latter, at the extremities of the macrodiagonal.

The general symbol of a rhombic pyramid is :

$$a : b : c, \text{ or } P.$$

The particular form varies with the ratios between the axes. When two or more rhombic pyramids occur together in the same crystal, they are distinguished by symbols similar to those used in the preceding systems.

If the secondary axes remain the same and the principal axis varies, the formula becomes :

$$a : b : mc, \text{ or } mP,$$

* It is important to observe how the interpretation of a crystallographic formula varies according to the law of symmetry of the crystal, that is to say, according to the system to which it belongs. In the trimetric system, the formula $a : b : c$ represents a figure with only eight sides, one in each octant, because, the dimensions of the crystal being different in the directions of all three axes, each of the distances a, b, c , is measured along one axis only; but in the dimetric system, whose forms are equally developed in the directions of the two secondary axes, each of the distances a, b , must be set off on each of those axes, whence there results a figure having twice the preceding number of faces, that is to say, sixteen (p. 133); and in the monometric system, which includes the forms equally developed in the direction of all three axes, the process last described has to be repeated three times, regarding each axis in turn as a principal axis; hence results a figure having $3 \times 16 = 48$ sides (p. 127).

the pyramid becoming more acute or more obtuse in the vertical direction, according as m is greater or less than 1.

If the macrodiagonal varies, while the other two axes remain the same, the formula becomes :

$$a : nb : c, \text{ or } \bar{P}n.$$

and if the principal axis varies at the same time :

$$a : nb : mc, \text{ or } m\bar{P}n,$$

which represents pyramids more or less elongated in the direction of the axis b , according as n is greater or smaller. In like manner, the variation of the brachydiagonal gives the forms :

$$na : b : mc, \text{ or } m\bar{P}n.$$

When m or n becomes infinite, the faces become parallel to the principal or one of the secondary axes, and indefinitely elongated in the corresponding direction.

$$a : b : \infty c, \text{ or } \infty P$$

represents a rhombic prism, whose faces meet the secondary axes at the distances a , b from the centre (these axes forming its diagonals), and extend indefinitely in the direction of the vertical axes.

$$a : nb : \infty c, \text{ or } \infty \bar{P}n,$$

$$\text{and } na : b : \infty c, \text{ or } \infty \bar{P}n$$

likewise represent indefinite vertical prisms, but with different horizontal sections

$$a : \infty b : mc, \text{ or } m\bar{P}\infty$$

represents, in like manner, a series of prisms whose faces are parallel to the macrodiagonal, and whose sections perpendicular to that axis are rhombuses, having a and mc for their diagonals.

$$\infty a : b : mc, \text{ or } m\bar{P}\infty$$

represents a series of prisms whose faces extend indefinitely parallel to the brachydiagonal, and whose sections perpendicular to that axis are rhombuses, having b and mc for their diagonals.

The prisms $m\bar{P}\infty$ and $m\bar{P}\infty$, whose faces are parallel to one of the secondary axes, are called domes (from *domus*, a house), because they terminate the crystal in the vertical direction like pitched roofs (see *figs.* 266—268), and are further distinguished as macrodiagonal or brachydiagonal domes, according to the direction in which they extend. The formula

$$a : \infty b : \infty c, \text{ or } \infty \bar{P}\infty$$

represents a pair of indefinitely extended planes passing through the extremities of the brachydiagonal, and at right angles thereto, or parallel to the macrodiagonal section; and

$$\infty a : b : \infty c, \text{ or } \infty \bar{P}\infty$$

represents, in like manner, a pair of infinitely extended planes parallel to the brachydiagonal section, and passing through the extremities of the macrodiagonal.

When $c = 0$ (whatever may be the lengths of the secondary axes), the form is reduced to a single plane, the terminal face oP , parallel to the basal section.

The prisms and the terminal planes, being unclosed forms, occur only in combination.

The following table* exhibits a summary of all the forms of the trimetric system

Naumann.		Dana.
P	=	1
mP	=	m
∞P	=	1
$m\bar{P}n$	=	$m\bar{n}$
$m\bar{P}n$	=	$m\bar{n}$
$mP\infty$	=	$m\bar{i}$
$mP\infty$	=	$m\bar{i}$
$\infty P\infty$	=	$i\bar{i}$
$\infty P\infty$	=	$i\bar{i}$
oP	=	0

The expressions used in the monometric, dimetric, and hexagonal systems are of similar character. These formulæ are certainly shorter than those of Naumann, and the P in the latter (or the O in the monometric system) does not add much to the sense; but on the other hand, Naumann's formulæ strike the eye better, and are more distinct from anything else in the text than the shorter formulæ of Dana. [For the mode of representation adopted by Miller, see the new edition of *Phillips's Mineralogy*, by W. J. Brooke and W. H. Miller. London, 1852.]

[m denotes a multiplier varying in magnitude from 0 to ∞ ; n a multiplier varying from 1 to ∞]:—

	$m < 1$		$m > 1$	
$o\bar{P} \infty = oP$	$\bar{P} \infty$	$\bar{P} \infty$	$m\bar{P} \infty$	$\infty \bar{P} \infty$
$o\bar{P}n = oP$	$m\bar{P}n$	$\bar{P}n$	$m\bar{P}n$	$\infty \bar{P}n$
$o\check{P}n = o\check{P}$	$m\check{P}$	\check{P}	$m\check{P}$	$\infty \check{P}$
$o\bar{P} \infty = o\check{P}$	$m\bar{P}n$	$\bar{P}n$	$m\bar{P}n$	$\infty \bar{P}n$
	$m\bar{P} \infty$	$\bar{P} \infty$	$m\bar{P} \infty$	$\infty \bar{P} \infty$

Combinations. The pyramids, prisms, domes, and end-faces of the trimetric system form a large number of combinations, of which the following may be regarded as the most important.

The terminal edges of the primary form are acuminated by those of an obtuser pyramid of equal base, the combination-edges being parallel to the lateral edges of the primary form, as in *fig. 261*, which is a form of sulphur. The brachydiagonal dome $\bar{P} \infty$ truncates symmetrically the macrodiagonal terminal edges (*fig. 262*), and in like manner, the macrodiagonal dome $\bar{P} \infty$ produces symmetrical truncation of the brachydiagonal terminal edges, the combination-edges being in both cases parallel to each other. Acuter and obtuser domes ($m\bar{P} \infty$ or $m\check{P} \infty$, for which $m > 1$) would likewise replace the terminal edges wholly or partially, the combination-edges converging towards the terminal summits when the dome is more acute than the primary form ($m > 1$), and diverging in the contrary case.

The terminal summits of the primary form are truncated by the basal end-faces oP (*fig. 262*); the macrodiagonal summits by the brachydiagonal end-faces $\infty \bar{P} \infty$; and the brachydiagonal summits by the macrodiagonal end-faces $\infty \check{P} \infty$. If these two pairs of end-faces predominate together with the primary form, the result is a combination like *fig. 263*, a form of uranic nitrate.

Fig. 261.

Fig. 262.

Fig. 263.

The lateral edges of the primary form are symmetrically truncated by the prism ∞P having the same base or secondary axes; if the latter predominates, the pyramid P forms 4-faced summits to it, the combination-edges being parallel to the base and to each other, as in sulphate of zinc (*fig. 264*); but in the combination of a prism and a pyramid having different bases (*i. e.* having their secondary axes in different ratio to each other), the combination edges are inclined to one another, as in *fig. 271*, a form of sulphate of potassium, which exhibits the combination of P with $\infty \bar{P}2$.

The edges of a prism in which the macrodiagonal terminates (the acuter edges in ∞P) are truncated by the brachydiagonal end-faces $\infty \bar{P} \infty$, and the brachydiagonal edges by the macrodiagonal end-faces $\infty \check{P} \infty$ (*fig. 275*). The acuter edges of the prism ∞P are bevelled by the faces of a prism $\infty \bar{P}n$ of different transverse section (*e. g.* by $\infty \bar{P}2$, in *fig. 265*, a form of topaz), in which it may also be observed that the forms P and ∞P , which have the same base, form parallel combination-edges; whereas P and $\infty \bar{P}2$, which have different bases, form combination-edges inclined to each other. In like manner, the obtuse angles of ∞P are bevelled by a prism $\infty \bar{P}n$ of different horizontal section.

The prism ∞P is symmetrically truncated at the end by oP , and it is bevelled by a brachydiagonal or macrodiagonal dome; the bevelling faces formed by the macrodiagonal dome rest on the prismatic edges in which the brachydiagonal terminates, as in *fig. 266*, which represents formate of barium; and the bevelling faces formed by a brachydiagonal dome rest on the prismatic edges in which the macrodiagonal terminates, as in acid malate of calcium (*fig. 267*).

Fig. 264.

Fig. 265.

The edges of ∞P may also be replaced by end-faces, on which the bevelling-faces of the dome then rest. Several domes of the same kind may also occur together, as in *fig.* 268, a form of nitre, exhibiting the faces ∞P , $\infty \bar{P}$, $2\bar{P}$, \bar{P} , P .

In selecting the primary form and the principal axis of a complicated trimetric combination, the following considerations must be taken into account. When pyramidal and prismatic faces occur together, the pyramid is regarded as the primary form. When

Fig. 266.

Fig. 267.

Fig. 268.

several pyramids occur together, the most predominant is regarded as the primary form, unless the greater number of faces can be more conveniently referred to one of the other pyramids. When trimetric crystals are bounded only by prismatic and dome-faces, the predominant faces are regarded as belonging to the prism or the domes which have the simplest formula (∞P , \bar{P} , or \bar{P}), and the axes of the primary form are determined accordingly.

It has already been observed that the principal axis in a trimetric crystal is merely relative, not absolute, as in the dimetric and hexagonal systems, and that the axis in the direction of which the crystal is most developed, or to which the greater number of edges are parallel, is usually regarded as the principal. When crystals are partially imbedded in a matrix, or attached to its surface, the most completely developed extremity is usually regarded as the upper, and the axes are determined accordingly. When a crystal exhibits only one set of pyramidal faces, these are regarded as primary, and the two axes which are most nearly equal are regarded as the secondary axes. If a crystal exhibits only one pyramid and one kind of end-face, the axes are chosen so that these faces may be represented by ∞P ; if it has two kinds of end-face besides the pyramid, it will appear symmetrically placed if one kind of end-face is regarded as $\infty \bar{P}$, the other as ∞P .

When a trimetric crystal exhibits prismatic faces, the axis to which these faces are parallel is usually regarded as the principal; if it has prismatic faces parallel to several axes, that axis is chosen as the principal in the direction of which the faces are most developed. This rule may often appear of uncertain application, because different crystals of the same substance may be most developed in different directions; but when the choice of a principal axis has once been made, it must be maintained through-

out the description of the crystal, however much particular modifications may be developed in other directions.

The following are examples of the determination of somewhat complicated crystals belonging to the trimetric system.

Sulphate of potassium, K^2SO^4 , exhibits considerable variety of form. The crystals exhibit, for the most part, the most decided prismatic development in the direction which, in the following figures (269 to 275), is placed vertically. The primary form is a rhombic pyramid $c a b c' a'$ (fig. 269), whose axes, represented by the dotted lines, are in the proportion $a : b : c = 0.7464 : 1 : 0.5727$. This primary form is often modified by the faces of the vertical prism $\infty P2$. The horizontal axes of this prism are $2a$ and b , or, what comes to the same thing, a and $\frac{1}{2}b$. Two of its faces will therefore pass through the points a, a' and a line $d e$ drawn through the middle point of $O b$, parallel to the vertical axis,—or at least will be parallel to planes so drawn. If they pass exactly through the point a and $\frac{1}{2}b$, they will intersect the faces P in the lines $a d, a' d, a e, a' e$, and will produce a form ($\infty P \cdot \infty P2$ equally developed) scarcely distinguishable from a hexagonal pyramid. That its faces are really of two kinds may, however, be known from the fact that the faces $\infty P2$ appear sometimes less, sometimes more developed in crystals of the same salt, as in figs. 270, 271. Moreover, the faces $\infty P2$ in fig. 269 are isosceles, while the faces P are scalene triangles; and of the six edges $c d, d e, e c', \&c.$, lying in the macrodiagonal principal section (which might be taken for lateral edges of a hexagonal prism), two belong to the prism $\infty P2$, and the four others are terminal edges of the pyramid P . The former meet at an angle of $112^\circ 41'$, the latter at $112^\circ 22'$; the former may be replaced by cleavage-planes, the latter cannot. The twelve edges, $c a, c a', d a, d a', \&c.$, which might be taken for the ter-

Fig. 269.

Fig. 270.

minal edges of a hexagonal prism are also dissimilar, four, viz. $c a, c a', c' a, c' a'$, being terminal edges of P situated in the brachydiagonal principal section, and the rest combination-edges between P and $\infty P2$.

In fig. 272, the macrodiagonal terminal edges of P are truncated by the faces of a prism forming the macrodiagonal combination-edges, therefore $P \infty$; and the edges of $\infty P2$, through which the macrodiagonal passes, are truncated by $\infty P \infty$. The combination thus produced is very much like the hexagonal combination $\infty P \cdot P$ found in quartz (fig. 238, p. 139). Were this the only known form of sulphate of potassium, the axis which in fig. 272 appears as the brachydiagonal, would be taken for the principal axis, because it is the one in which the crystal exhibits the most decided prismatic develop-

Fig. 271.

Fig. 272.

Fig. 273.

ment. This axis is, however, not actually regarded as the principal, because a perfectly similar combination is known, viz. fig. 273 (the same as the preceding without

Fig. 274.

Fig. 275.

$\check{P}\infty$), in which the prismatic faces $\infty\check{P}\infty$, $\infty\check{P}2$, parallel to the vertical axis, are by far the most predominant. In *fig. 274* the faces $\infty\check{P}2$ and $\check{P}\infty$ predominate, so that the P -faces become very small, but are still large enough to show that the faces of the vertical prism do not form horizontal combination-edges with them, and consequently that this prism must have a different base (or its secondary axes in different proportions) from P ; also that the predominant brachydiagonal dome forms with P combination-edges parallel to the macrodiagonal section (and to each other), and therefore that this dome is $\check{P}\infty$ (not $m\check{P}\infty$, where m is greater or less than unity). The crystal has likewise small triangular faces belonging to a brachydiagonal dome more acute than $\check{P}\infty$; angular measurement shows them to be $3\check{P}\infty$.

Lastly in, *fig. 275*, the primary form P is combined with $\check{P}\infty$, $\infty\check{P}\infty$, $\infty\check{P}\infty$ which faces are easily determined, and two vertical prisms, one of which forms horizontal combination-edges with P , and is therefore ∞P , while the other evidently comes under the formula $\infty\check{P}n$, and is found by angular measurement to be $\infty\check{P}2$.

A remarkable example of the various directions in which crystals of the same substance may be prismatically developed, is afforded by native sulphate of barium, Ba^2SO_4 . One of its forms is shown in *fig. 276*, which exhibits several vertical prismatic faces; and as the same faces occur more or less developed in several other forms of the same substance, this axis is regarded as the principal. Regarding the pyramidal faces P as the primary form, two domes may be observed, which truncate symmetrically the acute and obtuse edges of P : these domes are therefore $\check{P}\infty$ and $\bar{P}\infty$; but the vertical prism whose faces form with P , combination-edges not parallel to each other, is a secondary prism of the general form $\infty\check{P}n$ (where $n > 1$), because the combination-edges which it forms with P diverge towards the macrodiagonal principal section [a prism $\infty\check{P}n$, in which $n < 1$ would form with P combination-edges converging towards that section]. Angular measurement shows that this prism is $\infty\check{P}2$. The end-face $\infty\check{P}\infty$ is known by the horizontality of its combination-edges with $\check{P}\infty$. The faces thus determined, $\infty\check{P}2$, $\infty\check{P}\infty$, $\check{P}\infty$, $\bar{P}\infty$, also occur alone and with various degrees of relative development, producing crystals of very different character. The face $\infty\check{P}2$ predominates in *fig. 277*; $\check{P}\infty$ in *fig. 278*; $\bar{P}\infty$ in *fig. 279*; and accordingly

Fig. 276.

Fig. 277.

Fig. 278.

the combination is prismatically elongated in the direction of the vertical axis in *fig. 277*, of the brachydiagonal in *fig. 278*, and of the macrodiagonal in *fig. 279*. In

short, whichever axis may be chosen as the principal, crystals of the mineral will be found which are prismatically elongated in the direction of one of the secondary axes. *Fig.* 280 is a combination similar to *fig.* 279, but without $\infty\bar{P}\infty$; the dominant face

Fig. 279.*Fig.* 280.

is $\check{P}\infty$, as in *fig.* 278; but $\bar{P}\infty$ is likewise more developed; $\infty\check{P}2$ is subordinate as in *fig.* 279.

The choice of a primary form and principal axis for any substance is binding, not only for all crystals of that particular substance, but likewise for all that are isomorphous with it; thus the crystals of *cælestine* (Sr^2SO^4) must be referred to the same primary form and principal axis as those of *heavy spar* (Ba^2SO^4), although *cælestine* generally exhibits a form like *fig.* 280, prismatically elongated in the direction of the macrodiagonal. The advantage of referring all isomorphous crystals to the same primary form and principal axis is, that the corresponding faces are then more easily made out and expressed by analogous symbols.

Hemihedral Forms. Rhombic pyramids, by the growth of their alternate faces

Fig. 281.*Fig.* 282.

till the others disappear, give rise to rhombic sphenoids, in the same manner as quadratic prisms produce quadratic sphenoids (p. 136). A rhombic sphenoid is bounded by four scalene triangles, and of its six edges, only the opposite pairs are similar to each other.

Rhombic sphenoids have hitherto been observed only in combination. A remarkable instance of such a combination is exhibited in *fig.* 281, the ordinary form of sulphate of magnesium ($\text{Mg}^2\text{SO}^4 + 7\text{H}^2\text{O}$), in which the vertical prism ∞P is terminated by dome-shaped summits placed in opposite directions above and below. In sulphate of zinc ($\text{Zn}^2\text{SO}^4 + 7\text{H}^2\text{O}$), which is isomorphous with sulphate of magnesium, both sets of alternate P -faces appear together, but developed in different degrees, as in *fig.* 282.

Monoclinic System.

Monoclinometric, Monoclinohedral, Oblique, Oblique prismatic, Clinorhombic, Augitic System (Zwei- und eingliedriges, hemidrisch-rhombisch-trimetrisches System).

The forms of this system have three unequal axes, like those of the rhombic system, but differ from the latter in having two of their axes obliquely inclined to one another, while the third is at right angles to the other two. Each of these axes is a singular

axis (p. 120), and therefore the choice of a principal axis is to a great extent arbitrary, as in the rhombic system; but it is usual to consider one of the oblique axes as the principal, because most crystals belonging to the system are prismatically developed in the direction of one of these oblique axes. Of the two secondary axes, that which is obliquely inclined to the principal axis is called the clinodiagonal, and that which is perpendicular to the other two, the orthodiagonal.

In representing monoclinic crystals, the secondary axes are supposed to be situated in a horizontal plane, the clinodiagonal $b\ b$ (*fig. 283*) extending from left to right, the orthodiagonal $a\ a$ from back to front, and the principal axis $c\ c$ from right above to left below. In this mode of representation, the principal axis and clinodiagonal appear of their true relative lengths, and at their true inclination ($= 75^\circ$ in the figure); but the orthodiagonal is fore-shortened and appears oblique to the other two axes, though really perpendicular. Sections passing through the planes of any two axes are called principal sections, as in the preceding system, and are distinguished as basal, clinodiagonal, and orthodiagonal, according to the axes through which they pass.

For every monoclinic crystal, the ratio of the three axes (the length of the clinodiagonal being taken as unity) and the inclination L of the principal axis to the clinodiagonal, have to be determined by angular measurement and calculation. The value of L varies considerably in different crystals; in some it is nearly 90° , while in others it differs considerably therefrom. For ferrous sulphate, $a : b : c = 0.848 : 1 : 1.267$; $L = 75^\circ 40'$; for felspar, $a : b : c = 1.519 : 1 : 0.844$; $L = 63^\circ 53'$.

The primary form in this system is the monoclinic pyramid (*fig. 283*) bounded by eight scalene triangular faces, which meet the axes at the distances a, b, c from the centre. This, however, is not a simple form, for its faces are of two kinds; four of them, which are opposite to the acute angles of the axial system and meet in the edges A above and below, are equal and similar to each other; and the four which are opposite to the obtuse angles of the axes and meet in the edges B , are also equal and similar to each other, but unequal and dissimilar to the former. These two sets of faces may occur in combinations quite independently of each other, and a monoclinic crystal may be cleavable in directions parallel to one set of faces but not to the other. Neither of them by itself constitutes a closed form; but the four faces of either set, if sufficiently extended, form an endless prism obliquely inclined to the principal axis and the clinodiagonal.

A complete monoclinic pyramid has two terminal summits $c\ c$, and four lateral summits, two at the ends of each secondary axis. It has four similar lateral edges D , joining the lateral summits, four similar terminal edges C , joining the extremities of the principal axis and orthodiagonal; and four other terminal edges joining the ends of the principal axis and clinodiagonal, the shorter ones, A , being opposite to the acute angles of the axes, and the longer, B , opposite to the obtuse angles.

The primary monoclinic pyramid is denoted by the symbol P ; but as its two sets of faces are dissimilar, and may occur independently of each other, the four faces meeting in the edges A are denoted by $+P$, and the four which meet in the edges B by $-P$; the closed pyramid containing all the eight faces is $\pm P$.

From this primary form, others may be derived, as in the rhombic system, by variation of the length of either of the three axes. The variation of the principal axis is denoted, as before, by placing before the P a multiplier m , which may have all values from 0 to ∞ . The variations of the secondary axes are denoted by placing after the sign P , a number n , which may have all values from 1 to ∞ , the formula being enclosed in brackets when the variation refers to the clinodiagonal, not enclosed when it refers to the orthodiagonal.

$m = 0$ gives the end-faces oP , which cut the principal axis and are parallel to the other two.

The pyramids mP , acuter or obtuser than the primary form, according as $m >$ or < 1 , have the same base as P ; and, like that form, have two sets of faces distinguished as $+mP$ and $-mP$. The oblique rhombic prism on the same base as P , has the symbol ∞P .

The pyramids mPn , $[mPn]$ and the oblique prisms ∞Pn , $[\infty Pn]$ have rhombic bases differing in form from that of P .

The symbol $[mP\infty]$ represents a series of clinodiagonal domes, that is to say, prisms whose faces and edges are parallel to the clinodiagonal. $[P\infty]$ is the clino-

Fig. 283.

diagonal dome of the primary form: its four faces are similar, and its transverse sections are rhombuses similar to the orthodiagonal principal section, *caca* (fig. 283).

$mP\infty$ is the symbol of a series of orthodiagonal domes, acute or obtuse, according to the value of m . The four faces of such a dome are not all similar; two of them, which are opposite to the acute angles of the axial system, are distinguished as $+mP\infty$; the other two, which are opposite to the obtuse angles of the axial system, as $-mP\infty$. Either of them may be present without the other. $\pm P\infty$ is the orthodiagonal dome of the primary form; its transverse sections are similar to the clinodiagonal principal section.

$[\infty P\infty]$ represents the clinodiagonal end-faces, which cut the orthodiagonal and are parallel to the principal axis and clinodiagonal; $\infty P\infty$, the orthodiagonal end-faces, which cut the clinodiagonal and are parallel to the principal axis and orthodiagonal.

The following is a tabular view of the forms of the monoclinic system:

	($m < 1$)		($m > 1$)	
$oP\infty = oP$	$\pm mP\infty$	$\pm P\infty$	$\pm mP\infty$	$\infty P\infty$
$oPn = oP$	$\pm mPn$	$\pm Pn$	$\pm mPn$	∞Pn
oP	$\pm mP$	$\pm P$	$\pm mP$	∞P
$[oPn] = oP$	$\pm [mPn]$	$\pm [Pn]$	$\pm [mPn]$	$[\infty Pn]^*$
$[oP\infty] = oP$	$[mP\infty]$	$[P\infty]$	$[mP\infty]$	$[\infty P\infty]^*$

Combinations. The monoclinic system does not include any closed simple forms, every completely developed crystal belonging to it being a combination of dissimilar faces. Even the monoclinic pyramid, P , is a combination of two hemipyramids, each consisting of four faces similar to each other, but dissimilar to those of the other half.

In monoclinic, as in rhombic crystals, the following rule is of great use in determining the relative positions of the faces: *Any two faces which cut two of the axes at proportional distances from the centre, form a combination-edge parallel to the plane of those axes*; thus, two faces (such as $a : 2b : 3c$, or $3P2$ and $a : 2b : 5c$, or $5P2$) which cut the ortho- and clinodiagonal proportionally, intersect in an edge parallel to the basal section.

The combination of the basal end-face oP with the prism ∞P (fig. 284), so fre-

Fig. 284.

Fig. 285.

quently predominates in monoclinic crystals, that it may be conveniently taken as the starting point for the description of the rest. This combination is an oblique rhombic prism. The end-face oP is set symmetrically on the edges b situated in the clinodiagonal section, obliquely on the edges a in the orthodiagonal section. This combination may sometimes be easily mistaken for a rhombohedron, namely when the prismatic edges b are nearly equal to the combination-edges between oP and ∞P . Ferrous sulphate ($FeSO_4 + 7H_2O$), when part of the iron is replaced by another metal, as by copper, often takes the form represented in fig. 285, which, if the face $+P\infty$ be removed, and the form of the crystal completed in the manner shown by the dotted lines, has very much the appearance of an acute rhombohedron, and has in fact actually been mistaken for one. In the rhombohedron, however, all the faces are similar, and the crystals cleave with equal facility parallel to either of them; but ferrous sulphate exhibits very distinct cleavage parallel to oP , and much less distinct parallel to ∞P . Moreover, the face oP makes with ∞P to the right in front, an angle of $80^\circ 37'$, and ∞P to the right in front makes with ∞P to the right behind, an angle of $82^\circ 21'$, whereas if the crystal were rhombohedral, these angles would be

* Dana's symbols for the forms of the monoclinic system are the same as those for the rhombic system (see note page 145), excepting that an accent is placed over all numerals or letters referring to the clinodiagonal; thus $mPn = mn$; $[mPn] = m\acute{n}$; $[mP\infty] = m\acute{i}$; $[\infty P\infty] = i\acute{i}$.

equal; and the face $+P\infty$ is an isosceles triangle resting symmetrically on oP and obliquely on the two faces ∞P , whereas, in a rhombohedral crystal, the corresponding face oP of the hexagonal system would be an equilateral triangle resting symmetrically on all three faces.

The clinodiagonal edges b of the prism ∞P are symmetrically truncated by the orthodiagonal end-faces $\infty P\infty$, as in sugar (*fig. 286*). When this combination is developed at one end only of the orthodiagonal, it is not easily distinguished from the hemihedral combination $\infty P. \frac{P}{2}$ of the trimetric system, exhibited by sulphate of magnesium (*fig. 281*, p. 150), supposing this latter to be developed at one extremity only of the principal axis. The two faces $\frac{P}{2}$ of *fig. 281* may then exhibit much the same character as the faces ∞P of the oblique rhombic prism (*fig. 286*), two faces ∞P of *fig. 281* being likewise situated like the basal end-faces oP of the oblique prism, and the other two like the orthodiagonal end-faces $\infty P\infty$. The two forms differ however in this respect, that the four faces ∞P of the rhombic prism are similar, whereas the faces oP of the monoclinic crystal are dissimilar to the faces $\infty P\infty$.

The orthodiagonal edges a of the prism ∞P are symmetrically truncated by the clinodiagonal end-faces $[\infty P\infty]$, as in ferrous sulphate (*fig. 287*), and in acetate of sodium (*fig. 291*).

Fig. 286.

Fig. 287.

Fig. 288.

Fig. 289.

The combination-edges between oP and $\infty P\infty$ (*fig. 286*) are of two kinds, two acute (the right above and left below) and two obtuse (the left above and right below). The former are truncated by the $+$ faces, the latter by the $-$ faces of the orthodiagonal dome $+P\infty$. *Fig. 288*, shows the acute edges truncated by $+P\infty$, a modification often occurring in sugar. The four combination-edges between oP and $[\infty P\infty]$ are similar, and are truncated by a clinodiagonal dome $[P\infty]$, as in ferrous sulphate (*fig. 289*).

The combination-edges between oP and ∞P (*fig. 284*) are of two kinds, four acute w (the two right above and the two left below) and four obtuse v (two left above and two right below). The former are truncated by the $+$ faces, the latter by the $-$ faces of a pyramid $\pm P$, having the same base as the prism. *Fig. 290* shows the former in the combination $\infty P. oP. +P$ of formate of copper; *fig. 291*, the latter in the combination $\infty P. oP. [\infty P\infty]$. $-P$ of acetate of sodium. The $+$ and $-$ faces of P may likewise occur together, as in the form of ferrous sulphate shown in *fig. 292*; but this is accidental, the occurrence of either set of faces being quite independent of that of the other.

The combination-summits between oP and ∞P (*fig. 284*) are of three kinds. Four of them, x , situated in the orthodiagonal principal section, are similar, and are truncated by the faces of a clinodiagonal dome $[P\infty]$, or more generally $[mP\infty]$, as in sugar (*fig. 288*), and in ferrous sulphate (*figs. 289, 292*). Of the other four combination-summits, y, z , (situated in the clinodiagonal section), the two, z , which are opposite to the acute angles of the axes, are acute, and truncated by the $+$ faces of an orthodiagonal dome $+P\infty$.

Fig. 290.

Fig. 291.

or $+mP\infty$, while the other two, y , opposite to the obtuse angles of the axes, are obtuse, and are truncated by the $-$ faces of an orthodiagonal dome. Fig. 293 exhibits the former of these modifications, fig. 294 the latter, and fig. 292 both together. All these are forms of ferrous sulphate. When the $+$ and $-$ faces of the primary form P occur together, the terminal edges, C (fig. 283), between the principal axis and the orthodiagonal may be truncated by the clinodiagonal dome $[P\infty]$, with formation of parallel combination-edges, as in fig. 292. The terminal edges of P opposite the acute angles of the axes (the edges A , fig. 283) are truncated by $+P\infty$, with formation of parallel combination-edges; and those opposite to the obtuse angles of the axes (B , fig. 283) are replaced in like manner by $-P\infty$. Both these modifications are seen in fig. 292. The $+$ and $-$ faces of an acuter macrodiagonal dome replace these summits, with

Fig. 292.

Fig. 293.

Fig. 294.

Fig. 295.

Fig. 296.

Fig. 297.

Fig. 298.

Fig. 299.

formation of combination-edges converging towards the extremities of the principal axis, as in acetate of copper (fig. 295) and in sulphate of nickel and potassium (figs. 296, 297). In figs. 298, 299, which represent the same combination of ferrous sulphate, ∞P . $[\infty P\infty]$. ∞P . $+P\infty$. $-P\infty$. $-P$. $-\frac{1}{3}P\infty$ in two different positions, the face $-P\infty$ is recognised by truncating the terminal edge between each pair of

— P faces, with parallel combination-edges. In the same figures, the faces of an obtuser dome — $\frac{1}{3}P\infty$ included in the general formula — $mP\infty$ (where $m < 1$) may be recognised by forming with two contiguous — P faces, combination-edges which diverge towards the ends of the principal axis.

The orthodiagonal edges of ∞P are bevelled by the faces of a prism of different base [∞Pn] with longer clinodiagonal, as seen in *fig. 296*, where the beveling faces are [$\infty P2$]; on the other hand, the clinodiagonal edges of ∞P are beveled by the faces of a prism ∞Pn , with longer orthodiagonal.

The ends of the prism ∞P are acuminated by the + and — faces of the pyramid P with equal base, as in gypsum (*fig. 300*). As the faces + P and — P are quite inde-

Fig. 300.

Fig. 301.

Fig. 302.

Fig. 303.

Fig. 304.

Fig. 305.

Fig. 306.

pendent of each other, one set may be quite subordinate or even absent, in which case the opposite set of faces form oblique bevelings at the ends of the prism, as in gypsum, $\infty P \cdot -P \cdot [\infty P\infty]$ (*fig. 302*), and augite, $\infty P \cdot +P \cdot [\infty P\infty]$. $\infty P\infty$ (*fig. 303*).

Faces of other pyramids likewise occur in monoclinic combinations, but generally of such as have the same base as the primary form, with a different principal axis; those, in short, which are included in the formula $\pm mP$; thus borax exhibits the combination $\infty P \cdot \infty P\infty \cdot \infty P + P \cdot + 2P$ (*fig. 304*).

The preceding details show that monoclinic combinations generally exhibit considerable analogy to those of the trimetric system; the chief difference between the two

is that in the former, hemipyramids and hemidomes occur, whereas in the latter the pyramids and domes are generally present with all their faces. A trimetric crystal properly placed, exhibits the same development in front as behind, and the same to the right as to the left; but a monoclinic crystal placed as described at page 151, though it exhibits the same development above backwards as above forwards, is differently developed to the right above and to the left above.

The choice of a principal axis is subject to the same uncertainty as in the trimetric system, arising from the circumstance that different crystals of the same substance may exhibit the greatest prismatic development in different directions. An instance of this is afforded by the two forms of felspar represented in *figs.* 305, 306, the former being most elongated in the direction of the principal axis, the latter in that of the clinodiagonal.

The determination of monoclinic crystals is affected with a further source of uncertainty. In the case of a trimetric crystal, doubt may exist as to the choice of the principal axis, and as to the dimensions of the primary form, but not as to the quality of the several faces, *i.e.* whether they are pyramidal, prismatic, or terminal. But in a monoclinic crystal, any two similar faces may be regarded as terminal, or as forming a hemi-dome; any four similar faces as forming either a prism, or a clinodiagonal dome, or a hemipyramid; and in fact the same faces of a monoclinic crystal are often regarded in different lights by different observers, according to the particular varieties which have come under their notice. If gypsum occurred only in the form shown in *fig.* 302, the faces there marked —P might just as well be regarded as belonging to a clinodiagonal dome; but the occurrence of the variety of the same substance represented in *fig.* 301, renders the former view of these faces preferable. The only rule that can be given for these determinations is to choose the axes and assign the relations of the faces in the simplest possible manner, having regard to all the varieties of form that a substance presents.

Fig. 307.

Fig. 308.

Fig. 310.

Fig. 309.

Monoclinic crystals present a prismatic, tabular, rhombohedral, or pyramidal character, according to the predominance of particular faces. The prismatic is the prevailing character, as may be seen from the instances already adduced. When the three conterminous edges of an oblique rhombic prism, $\infty P \cdot oP \cdot \infty P$, are nearly equal, the combination, as already observed, has very much the aspect of a rhombohedron, but may be distinguished therefrom by the inclinations of the faces, and by the character of its modifications (pp. 141, 152). The tabular character arises from the predominance of the terminal faces, as in acetate of zinc, $oP \cdot \infty P \cdot +P \cdot 2P\infty \cdot \infty P\infty$ (*fig.* 307), where the predominant faces are oP , and in ferrous sulphate, *fig.* 308, where the tabular form arises from the predominance of $+P\infty$, as may be seen by comparing this form with *fig.* 309, which contains the same faces, but in different proportion.

A pyramidal character is often given to monoclinic crystals by the occurrence of one or more hemipyramids, as in gypsum (*fig.* 300). Another example is afforded by ferrous sulphate, which sometimes crystallises in the form shown in *fig.* 310, the same as *fig.* 285, but with the faces $+P\infty$ more developed. Sulphate of nickel and potassium (*fig.* 296) also assumes the pyramidal form, *fig.* 297, by the enlargement of the faces $+2P\infty$ and $+P$.

Hemihedral Forms. As the simple forms of the monoclinic system have at most but four faces, hemihedral forms are not of frequent occurrence. The most ordinary case is that in which the clinodiagonal dome [$P\infty$] is present with only half its faces. Thus, in sugar (*fig.* 288), the two front faces of this dome, are often present without the hinder ones. In ordinary tartaric acid also, two faces of [$P\infty$] (the front ones in a given position of the crystal) are present without the others, whereas in antitartaric acid

(i. 348), which differs from the ordinary acid only in possessing equal but opposite optical rotatory power, the *other* two faces of the same dome are present. Two crystals exhibiting this opposite hemihedral development are related to one another like an object and its reflected image, or, like the two hands, or the two halves of the face; they are similar but not superposable. This hemihedral relation is frequent in substances possessing the power of circular polarisation.

Diclinic System.

Diclinometric, Diclinohedral, Hemianorthic System.—In this system, two of the axes are at right angles to each other, while the third (which may be regarded as the principal axis) is oblique to the other two. The occurrence of diclinic crystals has not yet been demonstrated with certainty, and as their simple forms and modes of combination are very similar to those of the following system, it is unnecessary to dwell upon them. The primary form is a symmetrical eight-sided pyramid, the basal section of which is a rhombus, and the other two principal sections rhomboids.

Triclinic System.

Triclinometric, Triclinohedral, Anorthic, Anorthotypic, Doubly oblique prismatic, Clinorhomboidal System (*Ein- und eingliedriges, Tetratoedrisch-rhombisch-trimetrisches System*).

Crystals of this system have three axes, all obliquely inclined to each other, and (in all actually observed forms) of unequal length. The axis in the direction of which the crystal is for the most part prismatically developed, is regarded as the principal axis (*c*), the other two as secondary axes, the longer being called the macrodiagonal (*b*), and the shorter the brachydiagonal (*a*). In representing triclinic crystals, the secondary axes are supposed to lie in a horizontal plane, one or the other being drawn from left to right, according to the peculiarities of the crystal may be most conveniently exhibited.

For the complete determination of a triclinic axial system, five magnitudes must be given, viz. the lengths of two of the axes referred to the third as unity, and the three acute angles which they form with each other; and for this determination, five independent measurements of the inclinations of planes are required.

The primary form in this system is a pyramid whose faces cut the three axes at the distances *a b c* from the centre. *Fig. 311* exhibits such a pyramid, which may be regarded as the primary form of sulphate of copper ($\text{Cu}^2\text{SO}_4 + 5\text{H}_2\text{O}$). *a a* is the brachydiagonal, *b b* the macrodiagonal, *c c* the principal axis; *a : b : c* = 1.027 : 1.816 : 1. The acute angles of the axes are *a : b* = $77^\circ 37'$; *b : c* = $82^\circ 21'$; *a : c* = $73^\circ 10'$.

The eight faces of this pyramid are of four kinds, only each pair of parallel faces being similar to each other, and each pair may occur in combinations quite independently of the rest. The six summits are of three kinds. The three principal sections, and indeed all sections parallel to any two of the axes are rhomboids. Of the twelve edges, only the parallel pairs are similar.

Of the four front faces of the pyramid, the right above is designated by *P'*, the right below by *P*, the left above by *P*, the left below by *P'*; each of the back faces is designated by the same symbol as the front face to which it is parallel.

Other pyramids having the same base as the primary form are denoted by the general symbol *mP*, and those having different bases by *mPn* and *mP̄n*, just as in the trimetric system. Each of these pyramids has faces of four kinds, each pair of parallel faces being independent of the rest, and capable of occurring without them. The several faces of any individual pyramid are distinguished as to their position in the manner described for the primary form.

There are also triclinic prisms, ∞P , of the same base as the primary form; also prisms with different bases, ∞Pn and $\infty P̄n$. Of the four faces of these prisms, only the parallel pairs are similar, and either pair may occur without the other. In the prism ∞P (for a position once determined), the right front face and the one behind parallel to it are denoted by $\infty P'$, the other two by ∞P , and similarly for the other prisms.

Domes parallel to either of the secondary axes are denoted by the general symbols $m\bar{P}\infty$ and $mP\infty$; in these also only the opposite faces are similar to each other; a pair of such faces occurring (for a given position of the crystal) in front above and at

Fig. 311.

the back below are denoted by the symbol $m\bar{P}\infty$, or $m\bar{P}'\infty$; in front below, and behind above, by $mP\infty$, or $mP'\infty$; to the right above and left below by $mP'\infty$, or $m\bar{P}\infty$; to the left above and right below by $m\bar{P}'\infty$, or $mP\infty$.

Lastly, there are the basal end-faces oP , the macrodiagonal end-faces $\infty\bar{P}\infty$, and the brachydiagonal end-faces $\infty P\infty$, each pair of which cuts one of the axes and is parallel to the other two, as in the trimetric system.

All triclinic crystals are combinations made up of pairs of opposite faces of the simple forms. Each pair of parallel faces may be designated in various ways, either as end-faces, or as parallel faces of a prism, or of a pyramid. If, as frequently happens, three pairs of faces are predominant, as in *fig. 312*, the upper and under faces may be regarded as oP , the others as ∞P and $\infty P'$, or as $\infty\bar{P}\infty$ and $\infty P'\infty$.

Figs. 313, 314, 315 represent three forms of sulphate of copper, referred to the primary form represented in *fig. 311*.

Fig. 313 consists of the primary form modified by the end-faces $\infty P\infty$ and $\infty\bar{P}\infty$, and the hemiprisms ∞P and $\infty P'$. If, however, only the P' faces of the primary pyramid are present (the top and bottom faces in the figure), and these faces, together with the faces parallel to the principal axis, are extended till they meet, the result is *fig. 314*, the most common form of sulphate of copper. Other faces likewise occur, though less developed. In determining the relations of these, and of tri-

Fig. 312.

Fig. 313.

Fig. 314.

Fig. 315.

clinic combinations in general, the same rule holds good, as in the other systems, viz. that faces whose combination-edges are parallel to a principal section, cut the two axes contained in that section at proportional distances from the centre. In *fig. 315* the hemidomes $2P'\infty$, $P'\infty$, $P\infty$, $2P\infty$, and the basic end-face oP , which are all parallel to the brachydiagonal, form with one another and with $\infty\bar{P}\infty$ combination-edges parallel to the basal principal section; oP forms with P' an edge parallel to that between P' and $\infty P'$. In *fig. 314*, the edges between P' and $\infty P\infty$ are parallel to the macrodiagonal principal section; the faces which (in *fig. 315*) truncate these edges cut the principal axis and macrodiagonal in the same proportion as P' ; that is to say, if they are also parallel to the brachydiagonal, they belong to the dome $P'\infty$. The face $P'\infty$ is recognised by this character. $2P'\infty$ truncates the (acute) edges between P' and ∞P . The edges between P' and $\infty\bar{P}\infty$ are parallel to the brachydiagonal principal section; in *fig. 315* they are partly truncated by the faces of a pyramid, $2P^2$, which cuts the principal axis and brachydiagonal in the same proportion as the primary form; instead of these faces, or together with them, are sometimes found the faces $3P^3$.

The edges between the end-faces parallel to the principal axis and the adjacent prismatic faces are dissimilar, and either may be modified without the other. Thus, in sulphate of copper (*fig. 314*) the edges between $\infty\bar{P}\infty$ and ∞P are often truncated by ∞P^2 , while those between $\infty\bar{P}\infty$ and $\infty P'$ remain unaltered; similarly, two faces of ∞P^2 are often present alone, as truncations of the edges between $\infty\bar{P}\infty$ and $\infty P'$.

Aggregations of Crystals.

Crystals of the same substance are frequently united in groups, sometimes regularly, sometimes irregularly. Alum often forms groups of crystals regularly combined in the manner shown in *figs.* 316, 317, the octahedrons being united with their edges parallel to each other.

Aggregations of cubes end to end, so as to form elongated prisms, are also of frequent occurrence, as in chloride of potassium, which, under peculiar circumstances, has been seen to form thin silky threads, like tufts of cotton grass, made up of microscopic cubes (Warington, Chem. Soc. Qu. J. viii. 31). Chloride of sodium sometimes crystallises in such a manner that four such prismatic aggregates of cubes unite

Fig. 316.*Fig. 317.*

together by their extremities, forming a hollow frame, and on this frame smaller ones similarly constituted are successively built up, till a four-sided pyramid is produced, composed wholly of little cubes; sometimes again it assumes the inverted position, like a funnel.

Groups of crystals (excepting when formed of cubes or prisms laid end to end) may always be distinguished from single crystals by presenting re-entering angles (*figs.* 316, 317). Sometimes, however, the re-entering angles are so shallow as not to be perceptible without the use of highly magnifying powers; the crystal then appears striated. Suppose, for example, the number of octahedrons united as in *fig.* 316, to be so much increased, and the distance between the horizontal parallel edges proportionately diminished, that the individual crystals can no longer be distinguished. The mass would then present the appearance of an octahedron having its horizontal edges replaced by prismatic faces, and these faces horizontally striated. Such striations, which are frequently observed on the faces of natural crystals, afford good indications of the internal structure of the crystal, and of the manner in which it has been formed by the juxtaposition of successive layers.

Twin Crystals.

When two crystals are regularly aggregated, but not according to the parallel mode of arrangement just described, they are called *twins* or *maclés*; twins by contact, if the two individuals extend only to the plane of junction; twins by intersection, if each of them is continued beyond this plane and through the substance of the other. The plane of junction is always parallel to a face of the crystal either actual or possible, and one of the crystals is turned from its original position through an angle of 180° , round an axis perpendicular to the plane of junction.

The two crystals thus united are seldom fully developed, but for the most part only fragments of an ideal crystal; in many cases, each of them is the half of a completely developed crystal, and then the combination is called a *hemitrope*; such aggregates may be supposed to be produced by cutting a perfectly developed crystal in halves parallel to one of its faces, and turning one of the halves through an angle of 180° .

In the regular system, twin crystals of this kind are found bearing this relation to the regular octahedron, as shown in the annexed figures, where, if we suppose the octahedron (*fig.* 318) to be cut in two by the horizontal plane indicated by the dotted lines, and the upper fragment turned half round, the twin crystal (*fig.* 319) will be produced; examples of this arrangement are found in nitrate of lead, alum, magnetic iron ore, spinel, &c. Hemitropes also occur formed in like manner from the cube, regular dodecahedron, and tetrakis-hexahedron; an example of the last is found in native copper.

In most cases, twin-crystals thus formed may be distinguished from simple crystals

by the occurrence of re-entering angles; under peculiar circumstances, however, twins may be formed without reentering angles, as in some cases when each individual is smaller than the half of the ideally perfect crystal, or when the plane of junction is at right angles to the faces through which it passes, as in some cases of twin-formation from the regular dodecahedron. (See *Kopp's Krystallographie*, p. 87.)

Fig. 318.

Fig. 319.

Intersecting twins are often formed from the cube (as in fluor-spar, galena, sal-ammoniac, chloride of potassium, &c.), the plane of junction (passing through the six reentering angles situated in one plane) being situated like the face of an octahedron (*fig. 320*). In these twins, and in all those which are derived from the holohedral forms of the regular system, the individual crystals are intergrown in such a manner that their axial systems are not parallel to one another; indeed, two holohedral

Fig. 320.

Fig. 321.

forms, so long as their axes remain parallel, can only unite so as to form aggregates like those represented in *figs. 316, 317*; as soon as they are brought together in such a manner as to have a common centre and parallel axes, they coincide altogether. But hemihedral crystals often form intersecting twins, with parallel system of axes, like the two tetrahedrons in *fig. 321*, because, though the axes are parallel, the faces may lie in opposite directions.

Fig. 322.

Fig. 323.

In the dimetric or quadratic system, twin-crystals occur both with parallel and non-parallel systems of axes. The former occur but rarely, and, as already explained, only in hemihedral forms. Intersecting twins, like *fig. 321*, are sometimes formed from quadratic spheroids, $\pm \frac{P}{2}$, as in copper pyrites. The same mineral also forms hemi-

tropic crystals, like *fig. 319*, derived from the quadratic pyramid $+\frac{P}{2}$, and $-\frac{P}{2}$ equally developed, which has the same shape as the regular octahedron.

But the most frequent twin-formation in the quadratic system is that formed by two crystals united by a face parallel to $P\infty$, one of them being turned half round. *Fig. 322* is a form of tin-stone, $\infty P . P . \infty P \infty . P \infty$. If this crystal be divided in the middle by a plane parallel to $P\infty$, and the lower half turned through an angle of 180° , the form represented in *fig. 323* will be produced.

Fig. 324.

Fig. 325.

In the hexagonal system, intersecting twins are formed by two rhombohedrons penetrating each other like the cubes in *fig. 320*, and having the face ∞P in common; this form is exhibited by chabasite. Contact twins are exhibited by several forms of calespar; thus, if we suppose the crystal represented in *fig. 324* to be cut through the middle by a horizontal plane, and the lower half turned half round, a hemitropic form will result, like that in *fig. 325*, which has the peculiarity of not exhibiting any re-entering angles. The scalenohedron (*fig. 326*), cut through the middle and turned half round, yields the form shown in *fig. 327*, which is often very regularly developed in calespar.

Fig. 326.

Fig. 327.

In the trimetric or rhombic system, twin crystals with parallel axial systems are of very rare occurrence. In those with non-parallel axes, the crystals are generally united by a face of the prism ∞P , or of the macrodiagonal dome $\check{P}\infty$, or of the brachydiagonal dome $\check{P}\infty$. *Fig. 328* shows the combination $\infty P . \infty \check{P}\infty . \check{P}\infty$ occurring in arragonite. If we suppose this form cut in halves by a plane parallel to the left front face ∞P , and the left hand fragment turned through 180° , the hemitrope (*fig. 329*), which often occurs in arragonite, will be produced. The re-entering angle between the two front faces $\infty \check{P}\infty$ is, however, frequently overgrown by the enlargement of the adjacent faces ∞P . If we suppose the combination $P . \check{P}\infty . \infty \check{P}2$, occurring in sulphate of potassium (*fig. 330* without the face $3\check{P}\infty$), to be halved parallel to the face $\check{P}\infty$ in front below, and the lower half turned round 180° , the hemitrope, *fig. 331*, will result, which is a common form of sulphate of potassium.

In the monoclinic system, as hemihedral forms are very rare, nearly all the twin crystals which occur are such as have their axial systems not parallel. The contact face is almost always parallel to the orthodiagonal and one of the obliquely inclined axes, that is to say, either to the orthodiagonal end-faces $\infty P\infty$, or to the basic end-face ∞P . The twins are for the most part contact twins.

Fig. 328.

Fig. 330.

Fig. 331.

Fig. 332.

Fig. 333.

Fig. 334.

Fig. 335.

Fig. 336.

Fig. 337.

The twins whose contact-face is parallel to $\infty P\infty$ are often composed of individuals which appear like the halves of very regular crystals. If we imagine the forms represented by *fig. 332* (gypsum), *fig. 334* (ferricyanide of potassium), and *fig. 336* (augite),

to be cut in halves by planes passing through the orthodiagonal and principal axis, and one half of the crystal turned through an angle of 180° , the first will produce *fig. 333*, the second, *fig. 335*, and the third, *fig. 337*, twin formations of frequent occurrence in the substances above mentioned.

In many instances, the two half-crystals composing a hemitrope formed in this manner, are not such as can be derived from the same, but belong to different crystals. An example of this mode of formation is presented by felspar (orthoclase).

*Fig. 338.**Fig. 339.**Fig. 340.**Fig. 341.*

If the combination, $\infty P. [\infty P\infty]. oP. + 2P\infty$ (*fig. 338*), exhibited by this mineral be supposed to revolve through 180° round a line ab , perpendicular to the orthodiagonal section, it will be brought into the position shown in *fig. 339*. These two crystals (which we will denote by p and q) are, therefore, in the relative positions required for the formation of a twin crystal, according to the manner under consideration. But the mode in which they actually unite is this: Supposing each crystal to be cut in halves through the clinodiagonal section (as indicated by the dotted lines), the front half of p unites with the back half of q , producing *fig. 340*, and the back half of p with the front half of q , producing *fig. 341*. The two twin crystals thus produced are related to one another in form just like an object and its image reflected in a mirror.

In all the preceding twin formations of the monoclinic system, the principal axes of the individual crystal remain parallel, though the secondary axes do not. When, however, the contact-faces are parallel to the basal end-face oP , the principal axes of the two halves do not remain parallel; such a mode of union is exhibited by acetate of copper (*fig. 342*). If this crystal be cut in halves parallel to oP , and the lower

*Fig. 342.**Fig. 343.*

half turned round through 180° , the result is the hemitropic crystal shown in *fig. 343*. If the development of each crystalline fragment be continued beyond the contact plane, an intersection twin will result; such a mode of formation is exhibited by sphene.

In the triclinic system, twin crystals are of somewhat rare occurrence; an example is, however, afforded by triclinic felspar (albite). The contact-face is in many cases parallel to $\infty P\infty$ (corresponding to $\infty P\infty$ in monoclinic felspar), and then twins are produced resembling *figs. 340, 341*. In other cases, it is parallel to $\infty P\infty$ (corresponding to $[\infty P\infty]$ in monoclinic felspar), and these last-mentioned twins exhibit the triclinic character very clearly. If a crystal of monoclinic felspar be cut in halves through the clinodiagonal principal section, and one half turned round through 180° , the crystal still exhibits the same form as before; for the portions of the oP faces thus brought together fall into one plane, as also do the contiguous portions of the faces $2P\infty$. But if a crystal of triclinic felspar (*fig. 344*), in which oP is oblique to $\infty P\infty$, be thus divided through the brachydiagonal section (as indicated by the dotted lines), and one half turned round through 180° , a hemitropic crystal (*fig. 345*) will be formed, in which one end (the upper end in the figure), oP , of the one half forms with oP of the other half, a re-entering angle of $172^\circ 48'$; and $P'\infty$ forms with $P'\infty$ a re-

Fig. 344.

Fig. 345.

entering angle of $175^{\circ} 12'$, whilst at the other end, the corresponding faces are inclined to one another in projecting angles of the same magnitude.

Twins also occur in the triclinic system, in which the individuals are united by a face parallel to oP .

Imperfect and Distorted Crystals.

Crystals are often imperfectly developed, or not bounded all round by crystalline faces, in consequence of being attached on the side to a matrix or to the surface of a vessel; and in very many cases they are distorted, that is to say, some of their similar faces are more developed than others, and may thus acquire even a different form. In all cases, however, their inclination to each other and to the axes remains unaltered. Every distorted crystal may be referred to a regular form, by supposing certain faces of the latter to approach nearer to the centre than the rest, or slices to be cut from the crystal parallel to certain faces.

Octahedral crystals of the regular system, such as alum, often exhibit only one complete octahedral face, the crystal having grown to the surface of the vessel by the

Fig. 346.

Fig. 347.

Fig. 348.

Fig. 349.

face $a b c d e f$ (fig. 346), so that the portion below that plane has not been developed; sometimes only the middle of the crystal, shown in fig. 347, is developed, as if the octahedron (fig. 346) had been sliced parallel to the right front face O , as indicated by the

dotted lines. Nitrate of lead, which crystallises in the middle form between the cube and octahedron (*fig. 176*), often exhibits only portions of this form, like that bounded by the thick lines in *fig. 348*, the crystal having grown to the surface of the vessel by the plane $a b c d e f$ parallel to O .

Cubic crystals are often reduced to square plates by being less developed in the direction of one axis than of the other two; sometimes again they are more or less elongated in the direction of one axis, as if a number of cubes had grown together by their faces, and thus acquire the appearance of elongated square prisms (*p. 159*).

Octahedral crystals also are sometimes elongated in the direction of a line joining the middle points of two of their opposite faces, as shown in *fig. 349*, where the thin lines represent the ideal octahedron and the thick lines the distorted form. This distortion, which is seen in chrome-alum and nitrate of lead, gives the crystal the appearance of a rhombic prism bevelled at its extremities by the triangular faces resting perpendicularly on the acute edges of the prism, like *fig. 267*, *p. 147*.

Similar imperfections and distortions occur in crystals belonging to the other systems. A quadratic pyramid (*fig. 217*, *p. 133*) may be shortened or elongated in the same

Fig. 350.*Fig. 351.*

manner as the regular octahedron, exhibiting forms like *figs. 347* and *349*. The combination of P and $\infty P \infty$ equally developed (*fig. 350*), which is the normal form of potassio-cupric chloride, often appears distorted in the manner shown in *fig. 351*, by elongation in the direction of a terminal edge of the pyramid, thereby acquiring the appearance of a hexagonal prism with trihedral summits.

Quartz, the normal form of which is a hexagonal prism with pyramidal summits $P \cdot \infty P$ (*fig. 154*, *p. 117*), seldom or never exhibits this form in perfect regularity, some of the faces being more developed than others, as shown in *fig. 352*. Rhombohedrons also are often reduced to plates by shortening in one direction between two parallel faces, or elongated to prisms by abnormal development in the direction of one of the edges.

Fig. 352.*Fig. 353.**Fig. 354.*

In the trimetric or rhombic system, the most common distortion arises from the unequal development of the four faces of a prism ∞P , two of them being larger and nearer to the centre than the rest, so that the transverse section, and the end-face in the combination $\infty P \cdot \infty P$, is altered from a rhombus to a rhomboid. The true character of the crystal, may, however, be recognised in such cases by the cleavage

and by the modifications. The crystal, if cleavable parallel to the prismatic faces, splits as easily in the direction of the smaller as of the larger of these faces. If an edge of the distorted prism is truncated, the truncation-face is equally inclined to the two adjacent faces, ∞P , and if its ends are beveled by domes, the faces of the domes are likewise equally inclined to the two prismatic faces.

Monoclinic crystals exhibit similar distortions; indeed the faces of an oblique rhombic prism are almost always unequally distant from the centre, so that the transverse section becomes a rhomboid instead of a rhombus. Crystals of ferrous sulphate of the normal form shown in *fig. 353* are often distorted in such a manner that two parallel faces ∞P and the basic end-faces oP are very much developed in one direction, producing the form shown in *fig. 354*; if the crystal is developed on one side only and attached on the other, the difficulty of recognising it is of course considerably increased.

Curvature of Crystals.—The surfaces of crystals are sometimes curved, in consequence of curvature in the laminae of which the crystal is made up. Crystals of diamond often have their faces curved to such an extent, as to make them appear almost like spheres. More frequently, a convex surface is opposite and parallel to a concave surface. This kind of distortion is seen in spathic iron, the crystals of which are sometimes saddle-shaped, in consequence of several curvatures occurring in the same face.

Fig. 355.

Fig. 356.

Another kind of curvature is seen in prismatic and aggregated crystals, and is especially frequent in such as are implanted or imbedded. *Fig. 355* exhibits this kind of distortion as seen in quartz. Six-sided prisms of calcite and prismatic crystals of gypsum are sometimes curved in a somewhat similar manner.

In many species, the crystals appear as if they had been broken transversely into several pieces, a slight displacement of which has given a curved form to the prism. This is common in tourmalin and beryl. The beryls of Monroe County, Connecticut, often present interrupted curvatures, as shown in *fig. 356*. (Dana.)

Most of the distortions above described occasion no change in the inclinations of the faces of crystals. But those imperfections which produce curved or striated faces necessarily lead to variations in the angles. The surfaces of large crystals often have a composite character, appearing, when examined by a magnifying glass, as if there had been a tendency to the formation of smaller crystals while the crystal was growing. Octahedrons of fluor-spar sometimes have their faces made up of little cubes. Such a cause produces more or less irregularity in the planes and their inclinations. Variations of form and angular magnitude also arise from the presence of foreign particles entangled in the crystallising mineral. Even the presence of foreign ingredients in solution when the crystallisation is going on, seems often to affect the angles, and such ingredients may be included in the crystal without being at all apparent, except on analysis. According to Baudrimont's measurements of calcspar, the rhombs of this mineral seldom have the three angles at their summits exactly equal.

The imperfections and distortions of crystals often present great obstacles to the determinations of crystalline forms, and even, as already observed, of the system to which a crystal belongs. In most cases, angular measurement may be safely relied on; but even this method, in consequence of the disturbing causes just noticed, may sometimes lead to erroneous results. In all cases, however, excepting in some of the grosser distortions, the character of the modifications affords an unerring guide to the system to which a crystal belongs, the general law which governs them being, that like parts of a crystal are similarly, unlike parts dissimilarly modified. This principle, already developed at some length in the descriptions of the several systems, may be further elucidated and facilitated in application by the following table taken from *Dana's Mineralogy*, i. 123.

Table of Modifications of Crystals.

<p>1. All edges modified alike.</p> <p>2. Angles truncated or replaced by 3 or 6 similar planes.</p>	<p>} MONOMETRIC System.</p>	
<p>1. All edges <i>not</i> modified alike.</p> <p>2. Two* or <i>none</i> of the angles truncated or replaced by three or six similar planes.</p>	<p>Number of similar planes at extremities of crystal, 3 or some multiple of 3.</p> 	

Important aids in the determination of the system to which a crystal belongs are also afforded:

a. By *cleavage*, which is similar parallel to like faces, dissimilar parallel to unlike faces.

b. By the *characters of surfaces*. Similar planes are alike in lustre, hardness, colour, striation, &c. If, for example, a cubic crystal has similar striæ on all its six sides, it is monometric, but if the surfaces of one pair of its opposite sides differ from the rest, it belongs to some other system. Similar cleavage-faces also exhibit similar lustre, &c.

c. By the *optical* relations of the crystal. Monometric crystals refract light singly, but crystals of the dimetric and hexagonal systems have one axis of double refraction, and those belonging to the other systems have two axes of double refraction (p. 122). These characters are often of great use in determining the system to which a crystal belongs.

d. The *thermic* relations of crystals likewise differ according to the system to which they belong, as explained at page 122; so likewise do their relative elasticities in different directions; but the methods of observation on these points are too difficult of execution to be of much practical utility in the determination of crystals. (See *HEAT*.)

Cleavage of Crystals.

Most crystals exhibit less coherence in some directions than in others, and consequently may be cloven or split in certain directions with more or less facility. Some crystals, as mica, may be split into laminæ by the fingers; in others, a slight blow with a hammer is sufficient; others require the application of a sharp cutting instrument, and often considerable skill in its use. When other means fail, cleavage may sometimes be effected by heating the mineral and plunging it into cold water; this method sometimes succeeds with quartz. Many crystals cannot be cloven by any means: in these cases, however, the direction of cleavage is sometimes indicated by lines on the surface, or by cracks in the mass of the crystal. It is often important to observe these lines or cracks, even when cleavage is possible, in order to determine its direction before applying the knife.

The general laws with respect to cleavage are as follows:

1. Cleavage in crystals of the same species yields the same form and angles.
2. Cleavage takes place parallel either to one or more of the faces of a fundamental form, or to its diagonals, or to some of the secondary planes.

* The rhombohedron is the only solid included in this division, any of whose angles admit of a truncation or replacement by three or six planes.

† The terminal edges of the octahedrons are here termed lateral, in order that the statements may be generally applicable to both prisms and octahedrons.

3. Cleavage is obtained with equal ease or difficulty parallel to *similar* faces, and with unequal ease or difficulty parallel to *dissimilar* faces.

4. Cleavage parallel to similar faces affords planes of similar lustre and appearance; in the contrary case, of dissimilar lustre and appearance.

Thus, cleavage is obtained with equal ease or difficulty parallel to all the faces of a cube, regular octahedron, rhombic dodecahedron, or rhombohedron, which are bounded by similar planes. The right square prism, right rhombic prism, and oblique rhombic prism ($\infty P \cdot \infty P$ of the dimetric, trimetric, and monoclinic systems respectively) cleave with equal ease or difficulty parallel to their lateral planes, since these also are similar. Frequently, however, these prisms cleave only parallel to their bases, and sometimes not even in this direction. In some cases, also, the cleavage is diagonal, in the square prism alike in both vertical planes, but unlike in the rhombic prisms. The right rectangular prism ($\infty P \infty \cdot \infty P \infty \cdot \infty P$, of the trimetric system), the right rhomboidal prism ($\infty P \infty \cdot [\infty P \infty]$, ∞P of the monoclinic system) and the oblique rhomboidal prism ($\infty P' \cdot \infty P \cdot \infty P$, or $\infty P \cdot \infty P \infty \cdot \infty P$, of the triclinic system), have the cleavage unequal parallel to their faces, if attainable at all in these directions; moreover, cleavages in these two directions and parallel to the base yield faces of unlike lustre and general aspect. This is exemplified in gypsum, which in one direction cleaves with great facility into thin laminae of perfect transparency and highly polished surface; whilst in a second direction, the laminae first bend and then break, exhibiting a surface which is not smooth or possessed of much lustre; and in a third direction, the laminae are brittle, break immediately on attempting to bend them, and exhibit a surface smoother than the second, but not polished. In thick masses, the second and third cleavages are scarcely attainable. Two of these cleavages incline at an oblique angle, but one is at right angles to the third, showing that the crystal is monoclinic.

Measurement of Crystals.

A crystal is determined when we know the relative lengths of the axes for each of the primary forms which compose it, and their inclination, in case they are not at right angles to each other. These magnitudes cannot however be measured directly; the only element of the form admitting of direct measurement is the inclination of the faces one to another; and as these inclinations are connected with the ratios and inclinations of the axes by fixed geometrical relations, the latter may be determined by calculation, when a sufficient number of the dihedral angles of the crystal have been measured. The number of angular measurements absolutely required for each form is of course equal to the number of unknown quantities to be determined; thus for a square pyramid $a : a : c$ (p. 133), the only magnitude to be determined is the

ratio $\frac{a}{c}$; and for this, one angular measurement will suffice, viz. the angle either in the

terminal or in the lateral edges. For a rhombic pyramid $a : b : c$, two quantities have to be determined, viz. the lengths of two of the axes referred to the third as unity, and for this, two independent measurements are required. For a monoclinic pyramid, in which, in addition to the two ratios just mentioned, the inclination of the principal axis to the clinodiagonal has to be determined, three independent angular measurements are required. In all cases, however, it is advisable to take as many angular measurements as possible, in order to check the values first determined.

For the formulæ which express the relations between the inclinations of faces and the ratios and inclinations of the axes in the several systems, we must refer to more detailed works*, and confine ourselves here to the description of the instruments used for measuring the angles of crystals. These instruments are called **GONIOMETERS**, and are of two kinds, the *Application- or Hand-goniometer*, and the *Reflecting Goniometer*.

The hand-goniometer is a divided semicircle $a b d$ (fig. 357), to which are adapted two metal rules, one $k m$ being fixed, the other $g h$ movable round a pin c at the centre of the semicircle. Both these rules have slits, so that they may be moved backwards and forwards, making the sides of the angle $k n h$ longer or shorter as may be required. A straight line drawn through the point c and the middle of the rule $k m$ passes through the points 0° and 180° of the divided semicircle. The other rule, $g h$, is narrower in the part which moves round the semicircle (and likewise bevelled), so that the edge $g i$ produced would pass through the centre c . The angle which the edge $g i$ marks on the graduated arc, is therefore equal to the angle n contained between the edges $k n, n h$.

The crystal to be measured is placed between the rules $k n, n h$ in such a manner

* Dana, *System of Mineralogy*, vol. i. 8vo. New York, 1858. Miller, *Treatise on Crystallography*, vol. i. 8vo. Cambridge, 1839. Brooke and Miller, new edition of Phillips's *Mineralogy*, 12mo. London, 1852. Kopp, *Einleitung in die Krystallographie*, 8vo. Braunschweig, 1849.

that the edges of these rules may both be at right angles to the line of intersection of the two faces whose inclination is to be measured. The edge kn is applied close to one face of the crystal, and the other rule gh is moved round c , till the edge nh coincides exactly with the other face. The inclination is then indicated by the number of degrees in the arc $d e g$.

Fig. 357.

If one of the faces of the crystal presents irregularities arising from small crystals being implanted on it, the edge kn must be laid closely on the smooth face, and the other edge nh , brought as close as possible to the other face and parallel to it.

In measuring crystals implanted on a surface, the parts kn , hn of the rules must be moved along the slits into the required positions. In such cases, the part ab of the graduated arc is often in the way. To obviate this inconvenience, the semicircle is in some instruments cut through at b and the two parts joined by a hinge: there is then also a strip of metal fi movable about c , which, when placed in the position shown in the figure, serves to keep the two halves of the semicircle in the same plane, but when moved towards e , allows the half ab to be turned round to the back of $b d$.

This instrument is very convenient, and indeed indispensable, for measuring the angles of large crystals; on the other hand, it is evidently inapplicable to small crystals or to such as are very soft or friable; and as small crystals are of much more frequent occurrence than larger ones, and generally exhibit the best defined forms and flattest surfaces, the use of the hand-goniometer is necessarily somewhat limited. For these reasons, the reflecting goniometer of Wollaston, which also gives greater accuracy of measurement, is much more frequently used.

The reflecting goniometer depends upon the following principle. Let bac (fig. 358) be a section of a crystal, the angle c of which is to be measured. The crystal is supposed to be fixed so that its edge

is exactly in the prolongation of the axis of a divided circle $m n p$. Let a mark y (a black line drawn on paper for example), be so fixed that the eye of the observer placed at E may see this mark y directly, in the same direction as the image of an object x above the crystal, reflected from the bright surface bc . Now suppose the crystal to be turned round the edge c till the face ca comes into the position ca' , in the prolongation of bc ; the eye placed at E will still see the image of x in the same direction $E y$, by reflection from ca' . But it is evident that the angle aca' (measured by the arc $m n$) through which the crystal has been turned, is the supplement of bca , the angle to be measured: hence the following rule: The

angle α , contained between two faces of a crystal, is the supplement of the angle through which the crystal must be turned, in order that these two faces may reflect the image of a given object in the same direction; or if this latter angle is $= \alpha$, the angle between the two faces of the crystal will be $180^\circ - \alpha$.

The instrument by which this principle is applied to the measurement of crystals is represented in fig. 359. It consists of a vertical circle $E E$, divided on the edge, and turning upon a horizontal axis passing through the socket C , which is fixed upon the pillar B , supported on a heavy foot A . This axis likewise carries a smooth-edged disc

Fig. 358.

F, and a mill-edged disc G, both immovably fixed to it. The disc G is for turning the graduated circle round; the use of the disc F is to assist in clamping it, which is effected by compressing the lower edge of F between two plates of metal S, T, the former attached to the socket C, by means of the screw U. A vernier R, attached by the metal strap Q to the socket C, serves to read off the degrees on the circle E E. The axis which carries this circle and the discs F, G, is hollow, and encloses a thinner

Fig. 359.

axis which turns within it somewhat stiffly, and carries at one end the mill-edged disc I, and at the other a bent brass rod K. This rod carries a socket L in which another bent rod M turns, and in this is another socket N, through which passes a rod O O, which can be moved backwards and forwards, and turned round by the disc P; at the other end of this rod the crystal to be measured is fastened with wax.

To use the instrument, it is placed in front of a window with the plane of the circle E vertical, and at right angles to the plane of the window, the axes being then parallel to the horizontal bars of the window, one of which—or better, a slit in a piece of black paper fastened to one of the panes, may serve for the object *x*—to be reflected from the planes of the crystal. The observer, standing in front of the instrument, may bring his eye into such a position above the crystal, as to see a horizontal black line *y* drawn below the window, just along the edge of the crystal; and by turning the crystal round by the disc P, he may bring one face of it into such a position that the reflected image of the window-bar *x* may just coincide with the line *y* seen directly. It is, however, absolutely necessary that the edge of the crystal be brought exactly into a line with the axis of the instrument. This must first be done as nearly as possible by the unassisted eye: but to obtain a more exact adjustment, the crystal must be turned, by means of the movements at L and N, till the reflected image of the window-bar seen from each face of the crystal, is parallel to the line *y*, that is to say, horizontal. The crystal is then properly placed. To measure the angle, the disc G is turned round till 180° on the divided circle E E coincides with the zero of the vernier; the screw U is tightened so as to clamp the circle E E; and the crystal is turned round by the disc I, till the image of *x* from one face coincides with the line *y*. The circle is then unclamped, and turned round by the disc G, till the other face of the crystal is brought into the same position. The division of the circle which is thus brought opposite to the zero of the vernier, gives directly the number of degrees in the angle contained between the two faces of the crystal. (For other forms of the reflecting goniometer, see *Dana's Mineralogy*, i. 127.)

When the faces of a crystal are bright and reflect well, a comparatively distant object, such as the edge of the roof of an opposite house, may be viewed in them, and the angles may then be measured within a few minutes; the greater the distance of this object, the more exact, *cæteris paribus*, will be the measurement. With crystals of less reflecting power, nearer objects, such as the window-bars, must be chosen; sometimes indeed it is necessary to use the flame of a candle placed behind a screen having a horizontal slit. Crystals whose surfaces have little or no reflecting power may sometimes be measured with the reflecting goniometer, by attaching to their faces very thin

plates of mica, by means of water or oil of turpentine, according to the nature of the crystal.

Artificial crystals generally lose their lustre when touched with the hand, and will not bear cleaning. The best way of manipulating with them, is to fasten them with wax by their dullest surface to a little piece of wood, which may then be used as a handle, and for attaching them to the goniometer.

It is important to observe that the angles of crystals often change to a certain extent with change of temperature; hence, for accurate measurements, the temperature should always be noted.

CUBAN. A native sulphide of iron and copper, $\text{Cu}^2\text{Fe}^4\text{S}^3$ (see page 79).

CUBE ORE. *Pharmacosiderite*, *Siderite*, *Würfelerz*. A variety of native arsenate of copper occurring in crystals of the regular system, viz. cubes, sometimes perfect, sometimes having their edges or angles truncated, e.g. $\infty\infty \cdot \infty 0$ (fig. 195), $\infty\infty \cdot \frac{0}{2}$ (fig. 198), and others. Cleavage cubic, imperfect. The cube-faces are sometimes striated parallel to their intersections with the octahedral faces. Planes often curved. Rarely granular. Specific gravity = 2.9 to 3. Hardness = 2.5. Lustre adamantine, not very distinct. Colour olive-green to blackish-brown, also passing into grass-green and emerald-green. Streak olive-green to brown, yellow, pale. Subtranslucent. Rather sectile. Pyroelectric. (Dana, ii. 422.)

When heated, it gives off water and turns red. Before the blowpipe on charcoal, it gives off arsenic vapours, and melts in the reducing flame to a grey shining slag, which gives with fluxes the reactions of iron and arsenic. Soluble in hydrochloric acid. Caustic potash quickly turns it reddish-brown, and decomposes it for the most part.

An analysis by Berzelius gave 40.92 per cent. As_2O_5 , 2.57 P_2O_5 , 39.90 Fe^4O_3 , 0.66 Cu_2O , and 18.94 water (= 102.99; after deduction of 1.76 per cent. matrix). If the small quantity of copper be regarded as Cu^2AsO_4 and deducted, the remainder may be regarded as a tetrabasic ferric arsenate with 15 at. water, in which $\frac{1}{10}$ of the arsenic is replaced by phosphorus, giving the formula —

in which the first member has the form of Scorodite. (Ramm. Mineralch. p. 372.)

Cube-ore was formerly obtained from certain mines in Cornwall, where it occurred coating cavities in quartz, with ores of copper. It is now found in small shining crystals at Bundle Gill, Cumberland; also in Australia; at St. Leonard in France, and at Schneeberg and Schwarzenberg, in Saxony.

CUBERA CLUSII MIQ. The fruit of the black pepper of West Africa, called *Piper caudatum*. According to Stenhouse (Ann. Ch. Pharm. xcv. 106), it contains piperin and not cubebin, so that it must be regarded as pepper, not as cubebs.

CUBEENE. An isomeric modification of oil of cubebs (p. 172).

CUBEIN. $\text{C}^{17}\text{H}^{16}\text{O}^5$? (Soubeiran and Capitaine, Ann. Ch. Pharm. xxxi. 190. Riegel, N. Jahrb. Pharm. viii. 96. Schuck, N. Repert. Pharm. i. 213.) A crystalline substance existing in cubebs. It is obtained by exhausting with alcohol the pulpy residue left after the preparation of the essential oil of cubebs, treating the alcoholic solution with potash, washing the resulting precipitate with water, and crystallising from alcohol (Soubeiran and Capitaine).—Schuck prepares cubebin by mixing cubebene with $\frac{1}{6}$ of its weight of quicklime, exhausting with alcohol, treating the evaporated extract with dilute potash, dissolving the residue in alcohol, decolorising with animal charcoal, and leaving the solution to crystallise. 17 oz. of cubebene thus treated yielded 15 grains of cubebin.

Cubebin crystallises in groups of small white needles. It is tasteless, inodorous, melts at 120°C . (Schuck), but cannot be volatilised without decomposition. It is very slightly soluble in water and in cold alcohol, more soluble in boiling alcohol, the solution solidifying to a pulp on cooling. Ether dissolves 3.75 per cent. cubebin at 12°C ., and more when heated. Cubebin also dissolves in acetic acid, and in oils both fixed and volatile. Strong sulphuric acid first colours it of a fine bright red, very much like that which it imparts to salicin, but afterwards changing to crimson.

CUBEBS. The fruit of *Piper Cubeba*, L., a native of Java. When dry, it forms roundish blackish-grey berries of the size of pepper, enclosing a hard white oily seed. It has an aromatic peppery odour, and a sharp bitter taste. According to Monheim (J. Chim. méd. xi. 352), it contains 2.5 per cent. green volatile oil, 1.1 yellow liquid

172 CUBEBS, CAMPHOR OF—CULILABAN, OIL OF.

oil, 6·0 cubebin, 1·5 balsamic resin, 3·0 waxy matter, 6·0 extractive matter, 1·5 chloride of sodium, and 64·0 woody fibre.

CUBEBS, CAMPHOR OF. (Blanchet and Sell, Ann. Ch. Pharm. vi. 294.) *Stearoptene of Oil of Cubebs.* The volatile oil of cubebs, after rectification with water, deposits this compound in rhombic crystals P. oP. ∞ P, in which P : P in the terminal edges = $115^{\circ} 40'$ and $75^{\circ} 24'$, and in the lateral edges = 145° . Cleavage perfect, parallel to oP. It melts at 68° C., boils at 150° , and distils without alteration. It is insoluble in water, soluble in alcohol, ether, and volatile oils. The alcoholic solution possesses optical rotatory power.

According to Blanchet and Sell's analyses, the camphor contains from 80·1 to 81·1 per cent. carbon, and 11·1 to 11·7 hydrogen, agreeing approximately with the formula $C^{15}H^{26}O$ or $C^{15}H^{24}.H^2O$, whence it appears to be a *hydrate* of oil of cubebs or of cubebene.

The camphor dissolves in strong sulphuric acid, forming apparently a conjugated acid. It is partially soluble in boiling potash. By nitric acid it is converted into a brown resin; by chlorine into a viscid substance.

CUBEBS, OIL OF. $C^{15}H^{24}$. (Müller, Ann. Ch. Pharm. ii. 90. Blanchet and Sell, *ibid.* vi. 294. Winckler, *ibid.* viii. 203. Soubeiran and Capitaine, *ibid.* xxxiv. 311. Aubergier, Rev. scient. iv. 220. Brooke, Annals of Philosophy, new series, v. 450. Gerh. iii. 634.) This oil is obtained by distilling cubebs with water. It is colourless, viscid, of specific gravity 0·929, has an aromatic odour, and a camphor-like spicy taste. It boils between 250° and 260° C., always, however, with partial decomposition. Exposed to the air, it becomes thicker and resinous. It turns the plane of polarisation of a luminous ray to the left.

Hydrochlorate of oil of cubebs, $C^{15}H^{24}.2HCl$, is produced by passing hydrochloric acid gas into the rectified oil. It forms oblique prisms, colourless, tasteless, inodorous, melting at 131° C., very soluble in alcohol. They turn the plane of polarisation to the left.

Cubebene.—Oil of cubebs distilled with sulphuric acid is converted into an isomeric oil, cubebene, possessing much less optical rotatory power than the original oil.

CUBICITE. Syn. with ANALCIME (i. 210).

CUBILOSE. A constituent of the edible birds' nests of India, exhibiting the general properties of the neutral albuminoids. (Payen, Compt. rend. xlix. 528.)

CUBOICITE. Syn. with CHABASITE.

CUBOITE. Syn. with ANALCIME, also with SODALITE.

CUCUMIS. A genus of cucurbitaceous plants, including the cucumber, melon, and some kinds of gourd.

The fruit of *Cucumis colocynthis*, the bitter apple, or colocynth gourd, contains a pulp or pith which, when separated from the seeds, constitutes the purgative drug colocynth. (See COLOCYNTHIN, p. 78.)

C. melo, the melon, has been examined by Payen (Buchn. Repert. lxvi. 104): it contains the usual vegetable constituents. The root contains, according to Torosiewicz (*ibid.* xlv. 1), an emetic principle, melonemetin; and yields 6·4 per cent. of ash, of which 5 per cent. consists of salts soluble in water, and 95 per cent. insoluble matter.

The fruit of *C. prophetarum* contains, according to Winckler, a bitter principle, which, according to Walz, is essentially a resin (*Prophetinharz*), containing $C^{23}H^{46}O^7$, separable into *propheterin* or *prophetein*, $C^{20}H^{30}O^4$, and a carbohydrate (glucose).

CUCURBITA. Another genus of cucurbitaceous plants, including the common gourd, *C. maxima*, with its numerous varieties, the vegetable marrow, *C. ovifera*, the orange gourd, *C. aurantia*, the squash or bush gourd, *C. melopepo*, the bottle gourd, *C. lagenaria*, &c. &c. Most of them are eatable; but the orange gourd is bitter, and the bottle gourd is a dangerous poison. The fruit of this last-mentioned species, however, contains, according to Marquardt (J. pr. Chem. xi. 500), about 6 per cent. of sugar, and is used in Hungary for the extraction of sugar. The seeds contain a mild fixed oil.—The water-melon, *C. citrullus*, has been examined by Landerer (Buchn. Repert. lxvi. 104). Lenoble (J. Pharm. [3] xx. 356) found in it 3 per cent. sugar, 30 per cent. residue, and 67 water.

CUDBEAR. See ARCHIL (i. 355).

CULEBRITE. A name sometimes given to a mineral from Culebras in Mexico, resembling Riolite, and said to consist of selenide of zinc and sulphide of mercury. (Handw. d. Chem. ii. [3] 235.)

CULILABAN or CULILAWAN, OIL OF. A volatile oil obtained from the bark of *Laurus Culilaban* or *Culilawan*, or *Cinnamomum Culilawan* (Nees), a native of the Moluccas, by distillation with water. It is colourless; smells like oil of cajeput

and oil of cloves; is heavier than water; dissolves, with red colour, in nitric acid, forming a solution from which water throws down a brick-red resin (Schloss). Heated with 5 parts of fuming nitric acid, it swells up strongly, gives off nitrous gas, and, when repeatedly distilled, yields oxalic acid, amounting to $\frac{1}{6}$ of the oil. (Gm. xvi. 364.)

CUMENE. *Cumol. Hydride of Cumenyl.* $C^9H^{12} = C^9H^{11}.H$. (Pelletier and Walter [1837], Ann. Ch. Phys. [2] lxxvii. 99. Gerhardt and Cahours, Ann. Ch. Phys. [3] i. 87, 372; Ann. Ch. Pharm. xxxviii. 88. Gerhardt, Ann. Ch. Phys. [3] xiv. 107. Abel, Ann. Ch. Pharm. lxxiii. 308; Mem. Chem. Soc. iii. 441; Phil. Mag. xxxii. 63. Cahours, Compt. rend. xxiv. 557, xxx. 321. Mansfield, Chem. Soc. Qu. J. i. 244; Ann. Ch. Pharm. lxxix. 179. Gerhardt and Liès-Bodart, Compt. rend. xxix. 506; Compt. chim. 1849, 385; Ann. Ch. Pharm. lxxii. 293. Ritthausen, J. pr. Chem. lxi. 79. Church, Phil. Mag. [4] ix. 256. Liès-Bodart, Compt. rend. xliii. 394; Ann. Ch. Pharm. 100, 352. Warren de la Rue and H. Müller, Chem. Gaz. 1856, 375; J. pr. Chem. lxx. 30.

This body, discovered by Gerhardt and Cahours in 1840, is probably identical with the resin-oil or retinyl obtained by Pelletier and Walter from the resin of *Pinus maritima* (see PINE-RESINS), and probably also with the hydrocarbon produced by the action of phosphoric anhydride on phorone. It is isomeric with mesitylene, with methol, and with a hydrocarbon discovered by Church among the products of the distillation of eugenate of barium.

Cumene exists ready formed in Burmese naphtha, that substance, when aqueous vapour at 200° C. is passed through it, yielding hydrocarbons from which sulpho-cumenic acid is produced by the action of oil of vitriol (Warren de la Rue and H. Müller). It is produced: 1. In the distillation of cuminic acid with excess of baryta (Gerhardt and Cahours).—2. In the dry distillation of the resin of *Pinus maritima* (Pelletier and Walter); of the wood of that tree, passing over into the crude spirit (Cahours); and of coal, being found in coal-tar naphtha (Mansfield, Ritthausen, Church).—3. In the distillation of phorone with anhydrous phosphoric acid. (Gerhardt and Liès; Liès.)

Preparation.—1. *From Cuminic Acid.*—1 pt. of cuminic acid is gradually heated in a retort with 4 pts. of baryta. When the heat is carefully applied, and not more than 6 grammes of cuminic acid are used, nothing but colourless cumene passes over, while carbonate of barium remains behind. The use of larger quantities at once is not to be recommended (Gerhardt and Cahours). Abel mixes cuminic acid with 4 pts. of lime, and heats the mixture nearly to redness in a copper retort placed in a deep sand-bath. The colourless distillate has an unpleasant empyreumatic odour, which it retains even after rectification over hydrate of potassium. Abel therefore distils it with concentrated chromic acid (which does not alter the cumene), distils (whereby the bad smell is completely destroyed, and the pleasant odour of cumene becomes perceptible), and dries over chloride of calcium.

2. *From the Resin of Pinus maritima.*—When the brown oil obtained in the preparation of illuminating gas by the dry distillation of this resin, is subjected to fractional distillation, benzylene passes over between 130° and 160° C., and then cumene. The latter is several times distilled, with separation of the first portion of the distillate, which contains toluene, then treated alternately with oil of vitriol and caustic potash, and each time distilled, and finally rectified two or three times over potassium. (Pelletier and Walter.)

3. *From Light Coal-tar Naphtha*, passing over between 140° and 145° C. (Mansfield); between 139° and 140°. (Ritthausen).—It exists in the naphtha in considerable quantity, and may be advantageously prepared therefrom.

4. *From crude Wood-spirit.*—When the oil separated from this liquid by water is shaken up with oil of vitriol, washed with potash-ley and water, dried over chloride of calcium, and distilled over phosphoric anhydride, and the portion which distils between 140° and 150° C. is subjected to fractional distillation, cumene passes over between 145° and 148°. (Cahours.)

Properties.—Cumene is a colourless strongly refracting oil, having an agreeable odour like that of benzene, and a pungent, somewhat bitter taste. Specific gravity 0·87 (Pelletier and Walter). Boils at 144° C. (Gerhardt and Cahours); at 148° (Abel and Cahours). Vapour density = 4·0 to 4·3 (obs.); 4·16 (calc. 2 vols.). Its composition is shown in the following table:

	Calculation.		Pelletier and Walter.	Gerhardt and Cahours.	Abel.	Liès.
C^9	108	90	89·48	89·81	90·34	88·57
H^{12}	12	10	10·08	9·97	9·88	10·28
C^9H^{12}	120	100	99·56	99·78	100·22	98·85

Cumene is insoluble in water, but dissolves readily in *wood-spirit, alcohol, ether, and volatile oils*. It combines with *fixed oils, fats, and most resins*. With the aid of heat it dissolves *sulphur*, which crystallises out on cooling; it also dissolves *iodine*.

Decompositions.—1. Cumene is converted by fuming *sulphuric acid* into sulphocumenic acid (Gerhardt and Cahours).—2. When *chlorine* is passed into boiling cumene, and the volatilised portion is cohobated, a thick faint-smelling oil is obtained, which burns slowly with a smoky green-edged flame; its vapour does not attack the eyes (Pelletier and Walter).—3. By fuming *nitric acid*, it is converted into nitrocumene (Cahours, Nicholson), also by boiling with strong nitric acid, but by continued boiling it forms a peculiar acid (Gerhardt and Cahours). If the boiling be continued, the nitrocumene disappears again, and is gradually converted into a yellowish crystalline mass, which dissolves in ammonia, with the exception of a small pulverulent residue. Hydrochloric acid added to the solution precipitates nitrobenzoic acid (Abel, Cahours). Dilute nitric acid converts cumene, after four or five days' boiling, into benzoic acid (Abel).—4. A mixture of *fuming nitric and fuming sulphuric acid* slowly converts cumene into dinitrocumene (Cahours).—5. *Potassium* kept for some time in contact with cumene, blackens and becomes covered with a black crust, which appears to be carbide of potassium (Pelletier and Walter). Cumene is not altered by potash-ley or by fused potash.

Nitrocumene. $C^9H^{11}(NO^2)$. (Cahours, Compt. rend. xxv. 552, xxvi. 315. Nicholson, Chem. Soc. Qu. J. i. 2. Ritthausen, J. pr. Chem. lxi. 79.)—When cumene is dissolved in fuming nitric acid, the mixture becomes hot and gives off abundance of red vapours, and on adding water to the liquid, nitrocumene is precipitated as a heavy oil. It is yellowish, and has a fainter and less agreeable odour than nitrobenzene. By sulphuretted hydrogen in presence of alcohol and ammonia, it is converted into cumenylamine.

Dinitrocumene. $C^9H^{10}(NO^2)^2$.—Obtained by treating cumene with a mixture of fuming nitric and fuming sulphuric acid. The action takes place with difficulty, and requires frequent renewal of the acid to complete it.

Dinitrocumene crystallises from alcohol in white laminæ. It is insoluble in caustic alkaline leys, but dissolves in alcoholic potash and is converted thereby into nitrobenzylene; hydrochloric acid added to the solution throws down brown flakes. (Cahours, Ritthausen, *loc. cit.*)

CUMENE-SULPHURIC ACID. See CUMENYL-SULPHUROUS ACID.

CUMENGITE. A crystallised mineral from the province of Constantine in Africa, containing, according to Cumenge (Ann. Min. [4] xx. 81), 20 at. antimony, 21 at. oxygen, and 16 at. water. Rammelsberg (*Mineralchemie*, p. 156) suggests that it may be a hydrate of antimonious acid, $Sb^2O^3 \cdot 4H^2O$ (or $2H^3SbO^4 \cdot H^2O$).

CUMENYL. C^9H^{11} .—A monobasic radicle which may be supposed to exist in cumene, cuminic acid, and many allied compounds. Thus:

Cumene (Hydrate of Cumenyl)	=	$C^9H^{11}.H$
Cumidine (Cumenylamine)	=	$C^9H^{11}.H^2.N$
Cumonitrile (Cyanide of Cumenyl)	=	$C^9H^{11}.CN$
Cumene-sulphuric or Sulphocumenic acid (Cumenyl- sulphurous acid)	=	$C^9H^{11}.H \left\{ \begin{array}{l} O^2 \\ (SO^2) \end{array} \right.$
Cuminic or Cymylic Alcohol	=	$CH^2.C^9H^{11} \left\{ \begin{array}{l} H \\ O \end{array} \right.$
Cumyl	=	$CO.C^9H^{11}$
Cuminic Aldehyde or Cuminol	=	$CO.C^9H^{11} \left\{ \begin{array}{l} H \\ H \end{array} \right.$
Cuminic Acid	=	$CO.C^9H^{11} \left\{ \begin{array}{l} H \\ O \end{array} \right.$

It will be seen from these formulæ, that cumene, cuminic alcohol, cuminol, and cuminic acid are related to one another in the same manner as marsh-gas, ethylic alcohol, acetic aldehyde, and acetic acid.

The name *cumenyl* has also been applied to $C^{10}H^{13}$, the radicle which is to cymylic alcohol as ethyl to common alcohol; but this creates confusion.

CUMENYLAMINE. *Cumidine.* $C^9H^{13}N = N.H^2.C^9H^{11}$. Cahours [1847], Compt. rend. xxiv. 557; xxvi. 315; xxx. 321. Ed. Chambers Nicholson, Ann. Ch. Pharm. lxx. 58; Chem. Soc. Qu. J. i. 2. A. W. Hofmann, Ann. Ch. Pharm. lxxi. 145; lxxiv. 15. Ritthausen, J. pr. Chem. lxi. 79. Church, Phil. Mag. [4] ix. 454.)

Formation.—By the action of sulphydric acid on nitrocumene, $C^9H^{11}(NO^2)$, in presence of alcohol and ammonia.

Preparation.—Nitrocumene is dissolved in alcohol, and the solution is saturated, first with ammonia, then with sulphydric acid. After a few days, when a large quantity of sulphur has been deposited and the odour of sulphydric acid is no longer perceptible, the gas is again passed through the solution and the liquid is distilled, whereby the decomposition of the sulphydric acid is accelerated; and this treatment is repeated till the whole of the nitrocumene has disappeared. The alcohol and sulphide of ammonium are then removed by distillation; the residue is dissolved in hydrochloric acid; the liquid filtered from the sulphur is evaporated till it solidifies in a crystalline mass on cooling; and the boiling solution of hydrochlorate of cumenylamine is treated with potash to separate the base, which rises to the top of the liquid as an oily layer. This oil is rectified and supersaturated with a concentrated solution of oxalic acid; the liquid is evaporated to dryness; the residue dissolved in boiling alcohol; and the solution treated with blood-charcoal; the filtrate, on cooling, deposits perfectly pure colourless prisms of oxalate of cumenylamine. This salt is dissolved in water; the solution decomposed by potash; and the layer of oil which rises to the surface is removed with a pipette, dried over chloride of calcium, and rectified. (Nicholson.)

Properties.—Pale yellow, or, when recently distilled, nearly colourless oil, of specific gravity 0.9526. Refracts and disperses light strongly. When cooled by a mixture of ice and salt, it solidifies in a mass of square plates, which quickly melt again as the temperature rises. Dropped upon paper, it forms a grease-spot, which gradually disappears. In contact with platinum-wire, it boils constantly at 225°C. , when the barometer stands at 0.761 met. It has a peculiar odour and burning taste. Neutral to turmeric and red litmus paper. Colours fir-wood intensely yellow (like phenylamine and benzylamine), but does not exhibit the reaction of phenylamine with chloride of lime. It dissolves very sparingly in water; very easily in sulphide of carbon, wood-spirit, alcohol, ether, and fat oils. (Nicholson.)

Decompositions.—1. Cumenylamine exposed to the *air*, even for a few minutes only, turns yellow and then dark red, especially if warmed.—2. The vapour burns with a yellow, very fuliginous flame.—3. It is violently attacked by *chlorate of potassium* and *hydrochloric acid*, and converted into a brown viscid mass, which smells strongly like trichlororophenic acid, and is dissolved by alcohol, leaving a residue of chloranil.—4. By *bromine* it is converted, with rise of temperature and evolution of hydrobromic acid, into a solid mass, which is insoluble in water, but soluble in alcohol and ether, crystallises in white needles, and is perhaps tribromocumenylamine ($\text{C}^6\text{H}^9\text{Br}_3\text{N}$).—5. Strong *nitric acid* dissolves cumenylamine with splendid purple colour, and water added to the liquid throws down flakes which appear to be an acid.—6. Dry *chromic acid* becomes very hot in contact with cumenylamine, but does not set it on fire.—7. In phosgene-gas, cumenylamine is immediately converted into a crystalline mass, which separates from alcohol in long crystals like nitre; probably *dicumenylcarbamide* $\text{N}^2\text{H}^2(\text{C}^6\text{H}^{11})^2(\text{CO})$, homologous with diphenylcarbamide or carbanilide.—8. Cumenylamine dissolves in *sulphide of carbon*, and then gives off a large quantity of sulphuretted hydrogen; water added to the solution throws down, after a long time, a quickly solidifying oil, which crystallises from alcohol in long needles; probably *dicumenylsulphocarbamide*, $\text{N}^2\text{H}^2(\text{C}^6\text{H}^{11})^2(\text{CS})$ (Nicholson).—9. When dissolved in water, it is converted by *cyanogen gas* into cyanocumenylamine (Hofmann).—10. With *cyanate of phenyl*, it immediately solidifies to a solid crystalline mass. (Hofmann.)

Salts of Cumenylamine. Cumenylamine is a very weak base. It precipitates sesquioxide of iron from ferric salts. It does not precipitate alumina or zinc-salts. Its salts crystallise very easily, and, with the exception of a few double salts containing chlorides of the heavy metals, they are colourless, but turn reddish on exposure to the air, or when dried at a very high temperature. They have an acid reaction and are anhydrous, like the salts of phenylamine. From concentrated solutions of cumenylamine-salts, alkalis separate the cumenylamine in dark oil-drops, and from dilute solutions in the form of a curd. All the salts of cumenylamine dissolve in water, but better in alcohol. (Nicholson.)

Acetate of Cumenylamine crystallises readily.

Hydrobromate of Cumenylamine crystallises readily.

Hydrochlorate of Cumenylamine, $\text{C}^6\text{H}^9\text{N.HCl}$.—The combination of cumenylamine with hydrochloric acid is attended with evolution of heat. The salt crystallises from water or alcohol in large, colourless, inodorous prisms, which turn red in the air when moist. It does not undergo any alteration at 100°C. , but melts and sublimes when strongly heated.

Chloroplatinate of Cumenylamine, $\text{C}^6\text{H}^9\text{N.HCl.PtCl}_2$.—When a warm aqueous solution of hydrochlorate of cumenylamine is mixed with excess of dichloride of platinum,

the liquid, on cooling, deposits long yellow needles, which may be obtained pure by washing with cold water. The salt is decomposed by boiling water. When heated *per se* to 100°C ., it becomes darker, without further alteration, and at a stronger heat, gives off hydrochlorate of cumenylamine, and leaves platinum. Alcohol dissolves it in large quantity; and the solution yields, after a while, dark red oil-drops, which solidify, after the alcohol has evaporated, in a crystalline mass of a splendid orange-yellow colour.

With *Protochloride of Palladium*, hydrochlorate of cumenylamine forms a double salt, resembling the chloroplatinate in appearance.

Sulphate of Copper forms, with alcoholic cumenylamine, a precipitate of a fine green colour.

Protochloride and *Cyanide of Mercury* form, with alcoholic cumenylamine, white crystalline precipitates which are decomposed by boiling water.

With *Trichloride of Gold*, alcoholic cumenylamine forms a violet precipitate, which dissolves with violet colour in a larger quantity of alcohol.

*Hydrofluat*e of *Cumenylamine* crystallises.

Hydriodate of Cumenylamine crystallises readily: it appears to be the most soluble of the cumenylamine salts.

Nitrate of Cumenylamine, $\text{C}^9\text{H}^{13}\text{N}.\text{HNO}^3$.—When cumenylamine is dissolved in dilute nitric acid, the liquid becomes filled, on cooling, with long needles, which are colourless if the acid used was not too strong. The salt remains unaltered at 100°C . It is soluble in water and in alcohol.

With *oxalic acid*, cumenylamine forms a neutral and an acid salt, which are both crystallisable, but cannot be separated. By dry distillation, they yield a slightly crystalline mass, which dissolves sparingly in alcohol, and exhibits the relations of oxy-cumenylamine. (Nicholson.)

Phosphate of Cumenylamine crystallises readily.

Sulphate of Cumenylamine, $2\text{C}^9\text{H}^{13}\text{N}.\text{H}^2\text{SO}^4$.—When cumenylamine is dissolved in boiling dilute sulphuric acid, the solution, solidifies, on cooling, in a crystalline mass, which may be obtained perfectly pure by recrystallising with animal charcoal. Inodorous; has an unpleasantly bitter taste. At 100°C . it gives off the odour of cumenylamine, and assumes a reddish colour, without further alteration. Dissolves sparingly in cold water, much more readily in alcohol.

Cyanocumenylamine. $\text{C}^9\text{H}^{13}\text{N}.\text{CN}$, or $2\text{C}^9\text{H}^{13}\text{N}.\text{Cy}^2$.—An alcoholic solution of cumenylamine saturated with cyanogen quickly deposits long needles of cyanocumenylamine, which are easily purified by crystallisation from alcohol. This substance forms, with hydrochloric acid, a salt nearly insoluble in water. (Hofmann, Ann. Ch. Pharm. lxvi. 145.)

Nitrocumenylamine. $\text{C}^9\text{H}^{12}(\text{NO}^2)\text{N}$. (Cahours, Compt. rend. xxiv. 557; xxvi. 315).—Prepared by treating an alcoholic solution of dinitrocumene with sulphide of ammonium. It forms yellow crystalline scales, which melt below 100°C ., and solidify in a radiating mass on cooling. The compound exerts a slight but distinct alkaline reaction on test-paper. It is insoluble in water, but dissolves readily in alcohol and ether.

It is partially decomposed by distillation; nevertheless the greater part passes over unaltered.—*Bromine* acts violently upon it, converting it into a crystalline product, which is no longer basic.—It is not altered by *chloride of benzoyl* at ordinary temperatures; but between 50° and 60°C . it is converted, with violent action, into a crystalline product, which, when dissolved in alcohol, after being washed with acid, alkaline, and pure water, crystallises in snow-white needles, containing $\text{C}^{16}\text{H}^{16}\text{N}^2\text{O}^3 = \text{N}.\text{C}^8\text{H}^5\text{O}.\text{NO}^2.\text{C}^9\text{H}^{11}$), *nitride of benzoyl, cumenyl and nitril*, corresponding therefore to benzamide and benzanilide.—With *chloride of cumyl* and *chloride of cinnamyl*, it forms products similar to that with chloride of benzoyl.

Nitrocumenylamine neutralises acids completely, even the strongest, forming salts which crystallise well. These salts, if exposed to air in the moist state or in solution, decompose quickly, assuming a greenish-blue colour.

The *sulphate*, $2\text{C}^9\text{H}^{12}(\text{NO}^2)\text{N}.\text{H}^2\text{SO}^4 + \text{aq.}$, is obtained by dissolving nitrocumenylamine in hot dilute sulphuric acid, and leaving the solution to cool slowly. Long needles having a strong lustre. May be pulverised.

Hydrochlorate.—The saturated solution yields, by slow cooling, white silky needles, which, in the dry state, are composed of $\text{C}^9\text{H}^{12}(\text{NO}^2)\text{N}.\text{HCl} + \text{aq.}$

The *oxalate* forms slender needles.

CUMENYL-SULPHUROUS ACID. *Cumene-sulphuric, Sulphocumenic, Sulphocumolic, or Sulphocumenylic acid.* $\text{C}^9\text{H}^{12}\text{SO}^3 = \left. \begin{matrix} (\text{SO})'' \\ \text{C}^9\text{H}^{11}.\text{H} \end{matrix} \right\} \text{O}^2$. (Gerhardt and

Cahours, Ann. Ch. Phys. [3] i. 90.)—This acid is produced by the action of fuming sulphuric acid on cumene. It is not known in the free state, but the barium-salt may be prepared as follows:—2 pts. of fuming oil of vitriol are poured upon 1 pt. of cumene in a glass cylinder, and the liquid is stirred till the whole of the cumene is dissolved. When large quantities are used, the whole may be left to stand in a closed vessel, the cumene then dissolving gradually. The dark-brown solution is diluted with 4 volumes of water, whereupon, if the cumene and the acid have been long enough in contact, a colourless solution is formed, without separation of cumene; and the liquid, saturated with pulverised carbonate of barium, then filtered and evaporated, yields, on cooling, cumenylsulphite of barium. The colourless mother-liquor yields, to the last drop, the same salt, which may be obtained pure by pressure between paper.

Cumenyl-sulphite of Barium, $C^9H^{11}BaSO_3$, forms very beautiful scales, having a strong pearly lustre. It dissolves very easily in water, especially when hot. It is soluble in alcohol, even in anhydrous alcohol, and likewise in ether.

The aqueous solution does not precipitate chloride of cadmium, neutral acetate of lead, or the salts of bismuth, nickel, copper, or mercury.

CUMICYL. A name sometimes applied to the radicle of cymylic alcohol, $C^{10}H^{13}.H.O$.

CUMIN, OIL OF. A volatile oil obtained from the seeds of *Cuminum Cyminum* by extraction with absolute alcohol and precipitation by water. It is a mixture of cuminol (p. 182) and cymene.

CUMINAMIC ACID. See OXYCUMINAMIC ACID (p. 179).

CUMINAMIDE or CUMYLAMIDE. $C^{10}H^{13}NO = N.H^2.C^{10}H^{11}O$. (Field, Ann. Ch. Pharm. lxx. 45.)—This compound is obtained by the action of heat on cuminate of ammonium:

or by the action of ammonia on cuminate of ethyl, chloride of cumyl, or cuminic anhydride. Like benzamide, it crystallises in two different forms, according to the manner in which it is deposited. By rapid crystallisation from a strong solution, it is obtained in highly lustrous tables, whereas a dilute solution deposits it in long opaque needles. It dissolves sparingly in cold water, easily in alcohol and in ether. It offers considerable resistance to the action of strong alkalis, and requires long boiling with an acid or an alkali to convert it into ammonia and cuminic acid.

Cumophenamide or *Cumanilide*, $C^{16}H^{17}NO = N.C^{10}H^{11}O.C^6H^5.H$, is produced by the action of chloride of cumyl on phenylamine. The mixture becomes very hot, and cumophenamide is formed, which, when purified by washing with water and crystallisation from alcohol, in which it dissolves but sparingly, forms long satiny needles, resembling benzoic acid. (Cahours, Ann. Ch. Phys. [3] xxiii. 349.)

Cumo-sulphophenamide, $C^{16}H^{17}NSO^3 = N.C^{10}H^{11}O.C^6H^5SO^2.H$. (Gerhardt and Chiozza, Ann. Ch. Phys. [3] xlvi. 151.)—Sulphophenamide treated with chloride of cumyl in the oil-bath at a moderate heat is rapidly attacked, and on cooling solidifies to an amorphous glassy mass, which may be crystallised from alcohol. If the temperature were allowed to rise too high, cumonitrile and sulphophenic acid would be produced.

The compound forms rectangular prisms with shining, well-developed terminal faces. It is insoluble in boiling water, but dissolves easily in cold and still more in hot alcohol, easily also in aqueous ammonia. It melts at $161^\circ C$. When quickly heated in a test-tube, it gives off cumonitrile.

Cumo-sulphophenargentamide, $N.C^{10}H^{11}O.C^6H^5SO^2.Ag$, is obtained by adding nitrate of silver to a solution of cumo-sulphophenamide in boiling water containing a few drops of ammonia. It forms very light slender needles nearly insoluble in boiling water, easily soluble in ammonia. Decomposes quietly when heated, giving off cumonitrile. (Gerhardt and Chiozza, *loc. cit.*)

Cumo-sulphophen-argento-diamide, $N^2.H^3.Ag.C^6H^5SO^2.C^{10}H^{11}O$, is obtained by dissolving the preceding compound in ammonia, and leaving the solution to evaporate. Crystallises in nacreous needles, grouped like a fan. Soluble in alcohol, very slightly soluble in water. When boiled for some time with water, it gives off a little ammonia.

Cumo-benzo-sulphophenamide, $C^{23}H^{21}NSO^4 = N.C^{10}H^{11}O.C^7H^5O.C^6H^5SO^2$. Formed by the action of chloride of cumyl on benzosulphophenargentamide (i. 540), and obtained in confused prisms by dissolving the product in boiling ether and evaporating. It is nearly insoluble in water, more soluble in alcohol, sparingly in ether. Ammonia dissolves it with difficulty, the solution being precipitated by acids and by the salts of lead and silver. (Gerhardt and Chiozza, *loc. cit.*)

Cumo-salicylamide, $C^{17}H^{17}NO^3 = N.C^{10}H^{11}O.C^7H^5O^2.H?$ — Obtained by the action of chloride of cumyl on salicylamide. Crystallises in very light shining needles, melting at $200^{\circ} C.$, becoming pasty at a stronger heat, and remaining so on cooling.

CUMINIC ACID. $C^{10}H^{12}O^3 = C^{10}H^{11}O.H.O$, or $C^{10}H^{12}O^4$. (Gerhardt and Cahours [1840], Ann. Ch. Phys. [3] i. 70. Gm. xiv. 148.)—This acid is produced by the oxidation of the oxygenated oil (hydrate of cumyl) contained in essence of cumin.

Preparation.—Hydride of cumyl is added drop by drop to potash in the state of fusion, whereupon hydrogen is evolved and cuminate of potassium is formed; and this salt, dissolved in water and decomposed by nitric acid, deposits cuminic acid, which may be purified by crystallisation from alcohol.

The formation of cuminate of potassium in this process is represented by the equation:

Properties.—Colourless prismatic tables, having a pure acid taste and an odour somewhat like that of bugs. It melts at $92^{\circ} C.$, and volatilises at about 250° . It is nearly insoluble in cold water, but soluble in alcohol and ether. When pure, it dissolves without colour in strong sulphuric acid.

Decompositions.—1. *Fuming nitric acid* converts cuminic acid into nitrocuminic acid; with a mixture of *nitric and sulphuric acids*, it yields dinitrocuminic acid. 2. By dry distillation with *baryta or lime*, it is resolved into cumene, C^9H^{12} , and carbonic acid:

3. With *pentachloride of phosphorus*, at a temperature not exceeding 50° or $60^{\circ} C.$, it yields oxychloride of phosphorus, chloride of cumyl, and hydrochloric acid:

4. *Oxychloride of phosphorus* converts cuminate of sodium into cumini canhydride (Gerhardt).—5. Cuminic acid boiled with *acid chromate of potassium* and *sulphuric acid* is converted into insolinic acid, $C^9H^8O^4$ (Hofmann, Ann. Ch. Pharm. xlvii. 197).—6. Cuminic acid heated with *bromide of cyanogen* yields cumonitrile and bromide of potassium.—7. The sodium-salt heated with *chloride of cumyl, acetyl, or benzoyl*, yields cuminic, acetocuminic, or benzocuminic anhydride (Gerhardt).—8. Cuminic acid does not undergo any transformation in passing through the animal organism, but is found in the urine unaltered.

CUMINATES.—Cuminic acid is monobasic, the formula of its salts being $C^{10}H^{11}MO^2$.

Cuminate of ammonium forms delicate tufts which lose their lustre when exposed to the air. When heated, it gives up the elements of water and yields cuminamide and cumonitrile. The *potassium-salt* is deliquescent, and cannot be obtained in regular form.

Cuminate of barium, $C^{10}H^{11}BaO^2$, is obtained in dazzling white nacreous scales by decomposing carbonate of barium with a solution of cuminic acid. With a hot concentrated solution, the salt is precipitated immediately on passing through the filter; and each crystal, at the moment of its formation, reflects the light with great vividness, exhibiting all the tints of the spectrum.—*Cuminate of calcium* forms small needles moderately soluble in water.—*Cuminate of copper* is light blue and insoluble in water.—*Cuminate of lead*. White precipitate, insoluble in water.

Cuminate of silver, $C^{10}H^{11}AgO^2$, is obtained by adding nitrate of silver to cuminate of ammonium. It is white, curdy, and blackens rapidly when exposed to the light. When calcined, it leaves a residue of carburet of silver, CAg^4 , of a dull yellow colour. By dry distillation, it yields carbonic anhydride, cuminic acid, and cumene.

Derivatives of Cuminic Acid.

Nitrocuminic Acid. $C^{10}H^{11}(NO^2)O^2$. (Gerhardt and Cahours, Ann. Ch. Phys. [3] i. 73; Cahours, *ibid.* xxv. 36.)—Produced by the action of fuming nitric acid on cuminic acid. On boiling the mixture, and then adding water, the nitrocuminic acid separates as a heavy yellow oil, which soon solidifies. It is triturated, washed with distilled water, and crystallised from alcohol.

Nitrocuminic acid forms yellowish-white scales, insoluble in water, easily soluble in alcohol and ether. It dissolves in ammonia, potash, and soda, forming crystallisable salts. The *calcium-salt*, $C^{10}H^{10}Ca(NO^2)O$, crystallises in stellate groups of yellow needles, which become darker when exposed to light. The *silver-salt*, $C^{10}H^{10}(NO^2)AgO^2$, is a white precipitate insoluble in water.

Dinitrocuminic Acid. $C^{10}H^{10}(NO^2)^2O^2$. (Cahours, Ann. Ch. Phys. [3] xxv. 37.)—When cuminic acid is added by small portions to a gently heated mixture of fuming nitric and sulphuric acid, it disappears without evolution of gas. On boiling the liquid,

red vapours are evolved, and nitrocuminic acid is deposited in shining yellow scales, which may be recrystallised from boiling alcohol. It dissolves also readily in ether. It is not acted upon by fuming nitric acid, even after long boiling. It does not dissolve in caustic ammonia, potash, or soda, or appear to combine with them by long boiling. *Hydrogen* in the nascent state (from acetic acid and iron) converts it into dioxycuminamic acid (p. 180).

According to Cahours, dinitrocuminic acid does not combine with bases, and is insoluble in aqueous potash, soda, or ammonia, even at the boiling heat; according to Kraut, on the other hand (Chem. Centr. 1859, p. 85), it unites with bases, forming yellowish-red salts which become darker on exposure to light. The *barium-salt* $C^{10}H^9Ba(NO_2)_2O^2$, is obtained by dissolving the acid in baryta water, precipitating the excess of baryta with carbonic acid, then boiling, filtering, and evaporating: it separates in films which become crystalline on standing. The *calcium-salt*, $C^{10}H^9Ca(NO_2)_2O^2$, prepared in like manner, forms yellow-red needles, which dissolve easily and with deep wine-red colour in boiling water. The *silver-salt*, $C^{10}H^9Ag(NO_2)_2O^2 + aq.$, obtained by precipitating the calcium-salt with nitrate of silver, and recrystallising the precipitate from boiling water, forms light yellow needles, which are scarcely altered by light, but when heated to $100^\circ C.$ give off 5 per cent. (= 1 at.) water. (Kraut.)

Oxycuminic Acid. $C^{10}H^{12}O^4$. (Cahours, Ann. Ch. Phys. [3] liii. 338.)—This acid, regarded by Kolbe as $C^{10}H^{11}(HO)O^2$, that is, as derived from cuminic acid by the substitution of HO for 1 at. hydrogen, is produced by the action of nitric oxide or nitrous acid on oxycuminamic acid dissolved in a moderate excess of nitric acid:

It separates in small brownish prisms, sparingly soluble in cold water, more soluble in boiling water, still more in alcohol. It unites with bases, and some of its salts crystallise well. The silver-salt has the composition $C^{10}H^{11}AgO^3$.

Oxycuminamic acid, $C^{10}H^{13}NO^2 = N.H^2.(C^{10}H^{10}O^0)'' .H.O$, or *Amidocuminic acid*, $C^{10}H^{11}(NH^2)O^2$, also called *Cuminamic acid*.—This acid, the homologue of oxybenzamic acid, was discovered by Cahours (Ann. Ch. Phys. [3] liii. 822.) It is produced by the reduction of nitrocuminic acid, either with sulphydric acid, or with ferrous acetate.

Preparation.—1. Nitrocuminic acid is reduced by excess of sulphydric acid; the liquid is evaporated at a gentle heat till all the ammonia is expelled and the excess of sulphur is separated; the concentrated solution is precipitated by a slight excess of acetic acid; and the resulting precipitate is collected, washed, dried, and recrystallised from alcohol (Cahours).—2. It is also obtained by treating nitrocuminic acid with iron filings and acetic acid (a brisk action then taking place, attended with rise of temperature, after which the mixture must be heated for a while in the water-bath), digesting the mixture with aqueous carbonate of sodium, filtering, neutralising the excess of soda with acetic acid, precipitating with acetate of lead, and decomposing the precipitate with sulphydric acid. (Bouillet, Compt. rend. xliii. 399.)

The acid forms colourless or light-yellow crystals, sparingly soluble in cold, more soluble in hot water; also in alcohol and in ether.

Decompositions.—1. In solution in *nitric acid*, it is converted by *nitric oxide gas* into oxycuminic acid.—2. By treating *aleoholic* oxycuminamic acid with *nitrous acid*, light yellow needles are obtained, consisting of a new dibasic acid = $C^{20}N^3H^{23}O^4$ (P. Griess, Compt. rend. xlix. 80):

This acid, regarded by Griess as diazocumin-amidocuminic acid, = $C^{10}H^{10}N^2O^2$. $C^{10}H^{11}(NH^2)O^2$, forms yellow crystals, insoluble in water, and nearly insoluble in alcohol and ether.—3. Oxycuminamic acid distilled with *caustic baryta* or *lumps of potash*, yields an alkaline carbonate together with cumenylamine.

Combinations.—Oxycuminamic acid unites with bases, but its metallic salts have not been examined. The ethyl-compound, $C^{10}H^{12}(C^2H^3)NO^2$, is obtained by reducing nitrocuminic acid of ethyl with sulphide of ammonium, or with iron filings and acetic acid. It is a heavy oil, which dissolves in hydrochloric, nitric, and sulphuric acid, forming crystallisable compounds. Ammonia decomposes it slowly, forming a substance probably analogous to phenyl-urea.

Oxycuminamic acid likewise unites with other acids, forming crystalline salts.

Hydrochlorate, $C^{10}H^{13}NO^2.HCl$.—Oxycuminamic acid dissolves slightly in boiling hydrochloric acid, and the solution on cooling deposits thin needles. The compound may also be prepared by adding alcohol to a mixture of oxycuminamic acid and hydrochloric acid, whereby a considerable quantity of oxycuminamic acid is dissolved,

and evaporating. Delicate shining prisms, which dissolve in water, and are partly precipitated on addition of hydrochloric acid.

The *chloroplatinate*, $C^{10}H^{13}NO_2 \cdot HCl \cdot PtCl_2$, is obtained by adding alcohol to the mixed solutions of concentrated dichloride of platinum and hydrochlorate of oxycuminamic acid, warming the mixture till it dissolves, then filtering and leaving the solution to evaporate. It forms long reddish needles.

The *nitrate* forms beautiful prisms.

Sulphate, $2C^{10}H^{13}NO_2 \cdot H_2SO_4$.—Oxycuminamic acid is mixed in slight excess with oil of vitriol diluted with an equal bulk of water, and the mixture is dissolved in warm alcohol. On cooling, thin, white, silky needles are deposited. The compound has a slightly sweet taste, dissolves sparingly in cold, easily in hot water.

Dioxycuminamic acid, $C^{10}H^{11}N^2O^2 = N^2 \cdot \overbrace{H^4 \cdot (C^{10}H^9O)^{''''}}^{\text{''''}} \cdot H \cdot O$, or *Diamidocuminic acid*, $C^{10}H^{10}(NH^2)^2 \cdot O^2$: also called *Dicuminamic acid*.—This acid, the homologue of dioxybenzamic acid, is obtained by reducing dinitrocuminic acid with iron filings and acetic acid, the mode of preparation being similar to that of oxycuminamic acid. It is crystallisable, and unites with bases (Bouillet, Compt. rend. xliii. 399). The first of the above rational formulæ represents the compound as a diamic acid derived from a hypothetical dioxybenzoic acid, $C^{10}H^{12}O^4$, containing the triatomic radicle $C^{10}H^9O$.

CUMINIC ALCOHOL. Syn. with CUMYLIC ALCOHOL (*q. v.*)

CUMINIC ALDEHYDE. Syn. with HYDRIDE OF CUMYL (p. 182).

CUMINIC ANHYDRIDE. *Anhydrous Cuminic acid. Cuminic acid of Cumyl*, $C^{20}H^{22}O^3 = (C^{10}H^{11}O)^2 \cdot O$.—[Gerhardt (1852), Ann. Ch. Phys. [3] xxxvii. 304].—Produced by the action of chloride of cumyl on cuminate of sodium. The two substances, perfectly dry, are heated together in a flask, till the odour of chloride of cumyl completely disappears. A syrupy mass is then left, which, when treated with hot water, yields the anhydride. The product may be purified by recrystallising it several times from pure ether.

Cuminic anhydride, recently prepared, is oily, tasteless, nearly colourless, and inodorous, but soon experiences a molecular change, by which it is converted into a mass of very brilliant rhomboidal crystals. In moist air, it is rapidly converted into cuminic acid. With ammonia it forms cuminamide.

CUMINACETIC ANHYDRIDE. See ACETO-CUMINIC ANHYDRIDE. (i. 21.)

CUMINO-BENZOIC ANHYDRIDE. See BENZO-CUMINIC ANHYDRIDE. (i. 558.)

CUMINO-EUGENIC ANHYDRIDE. *Cuminic acid of Eugenyl*, $C^{20}H^{22}O^3 = C^{10}H^{11}O \cdot C^{10}H^{11}O \cdot O$.—Isomeric with cuminic anhydride; obtained by heating eugenic acid with chloride of cumyl. Crystallises in colourless, very brilliant plates, which melt very easily, but do not volatilise below $400^\circ C$. It is not decomposed by boiling potash-ley, but when fused with hydrate of potassium, it is resolved into cuminate and eugenate of potassium. Sulphuric acid decomposes it in a similar manner. Fuming nitric acid decomposes it readily, producing a reddish-yellow tenacious mass, in which crystals may be observed. Hydrochloric acid does not act upon it, even at boiling heat. (Cahours, Ann. Ch. Phys. [3] xli. 491.)

CUMIN-ÆNANTHYLIC ANHYDRIDE. *Cuminic acid of Ænanthyl*, $C^{17}H^{24}O^3 = C^{10}H^{11}O \cdot C^7H^{13}O \cdot O$.—Produced by the action of chloride of cumyl on ænanthylate of potassium. It is an oily liquid, heavier than water, and smelling like apples. Its vapour excites coughing. (Chiozza and Malerba, Gerh. Traité, iii. 601.)

CUMO-SALICYLOUS ANHYDRIDE. *Cuminic acid of Salicyl, Cumosalicyl*, $C^{17}H^{16}O^4 = C^{10}H^{11}O \cdot C^7H^5O^2 \cdot O$. (Cahours, Ann. Ch. Phys. [3] lii. 107).—Obtained by heating salicylous acid with chloride of cumyl. Crystallises in colourless, shining, friable prisms, which melt to a clear oil at a gentle heat, and solidify on cooling. Insoluble in cold water, slightly soluble in boiling water; soluble in alcohol, especially when warm; insoluble in ether. With *chlorine*, *bromine*, and *fuming nitric acid*, it yields crystallisable products. It is not attacked by solid caustic potash or by aqueous potash, even at the boiling heat.

CUMO-METHYL-SALICYLIC ANHYDRIDE. *Cuminic acid of Methyl-salicyl*, $C^{18}H^{18}O^4 = C^{10}H^{11}O \cdot C^7H^4(CH^3)O^2 \cdot O$. (Gerhardt, Traité, iii. 317).—Produced by heating chloride of cumyl with salicylate of methyl (oil of wintergreen). The product is a viscid oil which remains fluid for a long time, but if a small quantity of ether is poured into it, it solidifies in a radiated mass as the ether evaporates. It crystallises from boiling alcohol in very brilliant rhombic scales, insoluble in cold water, sparingly soluble in cold alcohol, very soluble in ether, which, as it evaporates, deposits the compound in rhomboidal prisms, often of considerable size. From a hot saturated alcoholic solution, it is deposited as an oil which remains liquid for a considerable time.

CUMINIC ETHERS. *Cuminate of Ethyl.* $C^{12}H^{16}O^2 = C^{10}H^{11}O^2.C^2H^5$. — Obtained by passing hydrochloric acid gas into a solution of cuminic acid in absolute alcohol, till it is no longer absorbed, then heating the liquid over the water-bath to expel the excess of alcohol, distilling the residue over the naked fire, washing the distillate with carbonate of sodium, and rectifying over massicot. It is a colourless liquid, lighter than water, and having an agreeable odour of apples. It boils at $240^\circ C.$, giving off a vapour which easily takes fire and burns with a bluish flame. Index of refraction of the liquid, 1.504. Vapour-density, 6.65. When heated with solution of potash, it yields alcohol and cuminate of potassium.

Cuminate of Phenyl. $C^{16}H^{16}O^2 = C^{10}H^{11}O.C^6H^5.O$. (Williamson and Scrugham, Proc. Roy. Soc. vii. 18.—Kraut, *Dissertation über Cuminol und Cymen*, 1854.)—Produced: 1. By the action of chloride of cumyl on phenate of potassium (W. and Scr.).—2. By the dry distillation of cumo-salicylic acid, or of a mixture of equivalent quantities of chloride of cumyl and salicylate of sodium (Kraut). Crystallises in long white needles, melting between 57° and $58^\circ C.$ and distilling without decomposition. It has an agreeable odour, resembling that of benzoate of phenyl, especially when heated. Insoluble in water, easily soluble in alcohol and ether.

A mixture of this ether with *nitrate of sodium*, heated with strong sulphuric acid, yields dinitrocuminic (and probably also nitrocuminic) acid. By *sulphuric acid* alone, it is resolved into cuminic and sulphophenyl acids. It is decomposed by *alcoholic* (not by aqueous) *potash*, yielding cuminate and phenate of potassium. (Kraut.)

CUMINOL. Syn. of HYDRIDE OF CUMYL (p. 183).

CUMINURIC ACID. *Glycol-cuminic acid, Cumyl-oxyacetamic acid*, $C^{12}H^{15}NO^3$

$= N.H.C^{10}H^{11}O.(C^2H^3O).H.O$.—This acid, homologous with hippuric (benzoyl-oxy-acetamic) acid, is produced by the action of the silver-compound of glycol (oxy-acetamate of silver) on chloride of cumyl:

The cuminuric acid is extracted from the product by warm alcohol, and remains on evaporation as a brown mass, which may be purified by pressure and recrystallisation. Its silver-salt is $C^{12}H^{14}AgNO^3$. The acid heated with aqueous hydrochloric acid is resolved into glycol and cuminic acid. (Cahours, Ann. Ch. Phys. [3] liii. 356.)

CUMINYL. $C^{10}H^{11}$. A monatomic radicle, of which cuminol, $C^{10}H^{12}O$, may be regarded as the hydrate $= C^{10}H^{11}.H.O$.

CUMMINGTONITE. See HORNBLÉNDE.

CUMO-GLYCOL. Syn. with HYDRATE OF CUMYLENE (hyp.) $= C^{10}H^{12}.H^2.O^2$. (See page 184.)

CUMOL. Syn. of CUMENE (p. 173).

CUMONITRILE. $C^{10}NH^{11}$, or *Cyanide of Cumenyl*, $C^9H^{11}.CN$. (Fr. Field. Ann. Ch. Pharm. lxx. 51; Mem. Chem. Soc. iii. 408.)

Formation.—1. By the dry distillation of cuminate of ammonium, cuminamide being formed at the same time.—2. By the action of bromide of cyanogen on cuminate of potassium, carbonic anhydride being likewise evolved (Cahours, Ann. Ch. Phys. [3] lii. 201):

—3. By the action of heat on cumosulphophenamide and on cumosulphophenargenta-mide. (Gerhardt and Chiozza, Ann. Ch. Phys. [3] xlvi. 157.)

Preparation.—Cuminate of ammonium is heated in a retort to complete fusion, and then maintained in violent ebullition, whereupon large drops of cumonitrile pass over together with water. As soon as the oil has completely passed over, it is separated with a pipette from the distillate, and the watery liquid is poured back into the cooled retort, and redistilled five or six times. The whole of the oil thus obtained is freed by washing with ammonia from traces of dissolved cuminic acid; it is then washed successively with hydrochloric acid and water, dried by leaving it for some days over chloride of calcium, and rectified. The portion which goes over last may contain water.

Properties.—Transparent, colourless oil, of specific gravity 0.765 at $14^\circ C.$ Refracts light strongly. Boils constantly from platinum wire at $239^\circ C.$, under pressure of 0.7585 met. Has a very strong but agreeable odour, and a burning taste. It dissolves but slightly in water, and renders it milky. Alcohol and ether dissolve it in all proportions.

Decompositions.—1. The vapour of cumonitrile is inflammable, and burns with a brilliant flame.—2. Cumonitrile is but slightly altered by strong *nitric acid* in the cold, but on boiling, cuminic or nitrocuminic acid is produced.—3. Heated with *potassium*, it becomes darker and forms a larger quantity of cyanide of potassium.—4. *Alcoholic potash* does not alter it immediately, but converts it, after a few days, into a crystalline pulp, consisting of the oil turned yellow and cuminamide.

CUMOPHENAMIDE. See CUMINAMIDE (p. 177).

CUMOSALICYL. Syn. with CUMOSALICYLOUS ANHYDRIDE (p. 180).

CUMOBENZOSULPHOPHENAMIDE.

CUMOSALICYLAMIDE.

CUMOSULPHOPHENAMIDE.

} See CUMINAMIDE (p. 177).

CUMOKYL. Syn. with CUMYL.

CUMOYL. Weltzien's name for the radicle $C^{10}H^{11}$, of which cuminol (*vid. inf.*) may be regarded as the hydrate.

CUMYL. *Cumoxyl*, $C^{10}H^{11}O$.—An acid organic radicle homologous with benzoyl, and forming a series of compounds corresponding to the benzoyl-compounds, viz. *hydride of cumyl* or *cuminol*, $C^{10}H^{11}O.H$; *hydrate of cumyl*, or *cuminic acid*, $C^{10}H^{11}O.H.O$; *nitride of cumyl* and *hydrogen*, or *cuminamide*, $N.H^2.C^{10}H^{11}O$, &c.

Cumyl in the free state, or *Cumylide of Cumyl*, $C^{10}H^{22}O^2$, is obtained by the action of chloride of cumyl on an equivalent quantity of cumylide of potassium:

The mixture is gently heated to facilitate the separation of the chloride of potassium, and the resulting mass is treated with a weak solution of potash to decompose the last traces of chloride of cumyl. It is then digested with ether to dissolve out the cumyl, and the ethereal solution is left to evaporate.

Cumyl is an oily liquid, heavier than water; its odour is scarcely perceptible at ordinary temperatures, but becomes very strong under the influence of heat, and resembles that of the geranium. It boils at $300^{\circ}C$., decomposing at the same time, and yielding cuminic acid, several substances less highly oxidised than that acid, and carbonaceous matter. It is combustible, and burns with a smoky flame. Heated with potash, it is converted into cuminic acid and hydride of cumyl:

Cumyl dissolves sparingly in cold alcohol, but boiling alcohol dissolves it in considerable quantity. (Chiozza, *Ann. Ch. Phys.* [3] xxxix. 246.)

CUMYL, HYDRIDE OF. *Cuminic Aldehyde*. *Cuminol*, $C^{10}H^{12}O = C^{10}H^{11}O.H$. (Gerhardt and Cahours, *Ann. Ch. Phys.* [3] i. 60.—Bertagnini *Ann. Ch. Pharm.* lxxxvi. 275.—Kraut, *Dissertation über Cuminol und Cymen*, 1854; *Ann. Ch. Pharm.* xviii. 366.—G m. xiv. 148.)—This compound exists in the essential oil of cumin, which is in fact a mixture of cuminol with a hydrocarbon named *Cymene* ($C^{10}H^{14}$). On distilling this essence, the cymene passes over first at about $200^{\circ}C$., and afterwards the hydride of cumyl. To obtain this latter in the pure state, it should be distilled as rapidly as possible in an atmosphere of carbonic anhydride. Another mode of separation is to agitate the cumin-oil with a moderately concentrated solution of acid sulphite of potassium or sodium, which takes up the hydride of cumyl, but not the cymene, forming a crystalline compound from which the hydride of cumyl may be separated by potash. Hydride of cumyl also occurs, together with cymene, in the volatile oil obtained from the seeds of the water-hemlock (*Cicuta virosa*), and may be separated by acid sulphite of potassium as above. (Trapp, *Ann. Ch. Pharm.* cviii. 386.)

Properties.—Hydride of cumyl is a colourless or slightly yellow liquid, having a strong and persistent odour of cumin, and an acrid burning taste. Boiling point $220^{\circ}C$. (Gerhardt and Cahours); from platinum at 229.4° , or, correcting for the mercurial column in the thermometer, at 236.6° (Kopp). Specific gravity in the liquid state = 0.9727 at $13.4^{\circ}C$. = 0.9832 at 0° (Kopp). Vapour-density = 5.24 (obs.) = 5.13 (calc. 2 vols.). Composition, by analysis (mean), 80.89 per cent. carbon, 8.45 hydrogen, and 10.66 oxygen, the formula requiring 81.08 C, 8.11 H, and 10.81 O. It is isomeric with the essential oils of anise, fennel, star-anise, and tarragon.

Decompositions.—1. Hydride of cumyl may be distilled without alteration in close vessels, but when boiled for some time in contact with the air, it is converted into cuminic acid, together with a resinous substance. The same transformation takes place even at ordinary temperatures, especially in contact with water, or more quickly in contact with a base.—2. By *fuming nitric acid* in the cold, cuminol is converted into cuminic acid; heated with nitric acid, either strong or weak, it yields nitro-cuminic

acid, together with resinous products.—3. By a mixture of *acid chromate of potassium* and *sulphuric acid*, it is converted into cuminic acid (Gerhardt and Cahours); by prolonged action into insolinic acid (Hofmann, Ann. Ch. Pharm. xcvii. 207).—4. With *chlorine* or *bromine* it forms substitution-products in which 1 at. hydrogen is replaced by chlorine or bromine; but with *pentachloride of phosphorus*, it forms the compound $C^{10}H^{12}Cl_2$, derived from hydride of cumyl by the substitution of chlorine for oxygen.—5. Dry *ammonia gas* converts cuminol after some time into a substance resembling hydrobenzamide (Gerhardt and Cahours). Sieveking (Ann. Ch. Pharm. cvi. 357) could not obtain this body.—6. *Sulphide of ammonium* decomposes cuminol, forming thiocuminol, $C^{10}H^{12}S$, in which the oxygen of hydride of cumyl is replaced by sulphur.—7. Heated with *potassium*, it gives off hydrogen and forms cumylide of potassium, $C^{10}H^{11}O.K.$ —8. Cuminol boiled with *aqueous*, or more quickly with *alcoholic potash*, is converted into cuminate of potassium and cymylic alcohol:

—9. Cuminol heated with *solid caustic potash*, yields various products, according to the degree of heat applied and the manner in which the two substances are brought in contact. When the solid potash is covered with cuminol and slightly heated, cumylide of potassium is formed. When cuminol is added by drops to melting potash, the mass first turns red, then quickly white, and forms cuminate of potassium, with elimination of hydrogen:

If, however, the heat applied is comparatively low, cuminic acid and cymene are formed, without evolution of hydrogen:

In this case it may be supposed, that the cuminol is first resolved into cuminic acid and cymylic alcohol, and the latter subsequently into cuminic acid and cymene (Kraut).—10. With chloride of cumyl, cuminol yields hydrochloric acid and cumyl (p. 182).

Combinations.—Hydride of cumyl unites with the acid sulphites of the alkali-metals, forming crystalline compounds. The *ammonium-salt* crystallises in needles; the *potassium-salt* in scales; the *sodium-salt*, $C^{10}H^{12}O.NaHSO_3$, in colourless inodorous needles, which become yellow by keeping.

Derivatives of Hydride of Cumyl.

Cumylide of Potassium, $C^{10}H^{11}O.K.$ —Produced by heating hydride of cumyl with potassium out of contact of air; also by heating solid hydrate of potassium in the midst of hydride of cumyl: in the latter case, water is eliminated and the potash is converted into a gelatinous mass. To obtain pure cumylide of potassium, the product formed by the first process is pressed between filtering paper, and placed in vacuo over sulphuric acid, which absorbs the undecomposed hydride of cumyl.

Cumylide of potassium is an amorphous gelatinous mass, quickly converted into cuminate by contact with the air. Water decomposes it into hydride of cumyl and hydrate of potassium. Heated with chloride of cumyl, it yields chloride of potassium and free cumyl. With chloride of benzoyl, it yields an oil resembling cumyl, probably benzo-cumyl, $C^7H^5O.C^{10}H^{11}O$. (Gerhardt and Chiozza, *loc. cit.*)

Chlorocuminol, $C^{10}H^{11}ClO$.—Produced by passing dry chlorine through dry hydride of cumyl. It is a yellowish oil, heavier than water and having a very powerful odour. By exposure to moist air, it is converted into hydrochloric and cuminic acids:

It is decomposed by dry distillation, yielding hydrochloric acid and a peculiar oil, and leaving a residue of charcoal. Strong sulphuric acid dissolves it, forming a crimson solution and giving off hydrochloric acid. The liquid exposed to moist air, quickly yields crystals of cuminic acid. Chlorocuminol when recently prepared, is scarcely attacked by ammonia, differing in that respect from the isomeric compound, *chloride of cumyl*, which is immediately transformed by ammonia into cuminamide. (Gerhardt and Chiozza, Ann. Ch. Phys. [3] i. 82.)

Bromocuminol, $C^{10}H^{11}BrO$, is a heavy oil resembling chlorocuminol, and obtained by the action of bromine on hydride of cumyl. (Gerhardt and Chiozza.)

CUMYL, CHLORIDE OF, $C^{10}H^{11}O.Cl$.—Obtained by the action of pentachloride of phosphorus on cuminic acid. It is a colourless very mobile liquid, of specific gravity

1.070 at 15° C. Boils between 256° and 258° C. By exposure to moist air, or more rapidly by boiling with caustic potash, it is converted into hydrochloric and cuminic acids. It is strongly heated by contact with strong alcohol, yielding hydrochloric acid and cuminate of ethyl.

With dry ammonia gas, or with carbonate of ammonium, it forms cuminamide; with phenylamine it yields phenylcuminamide or cumanilide. (Cahours, Ann. Ch. Phys. [3] xxiii. 347.)

CUMYLAMIDE. Syn. with CUMINAMIDE (p. 177).

CUMYLENE. $C^{10}H^{12}$.—A hypothetical diatomic radicle, homologous with benzylene (i. 577), of which the following compounds are known.

CHLORIDE OF CUMYLENE, *Chlorocumol*, *Chlorocuminol*, $C^{10}H^{12}Cl^2$. (Cahours, Ann. Ch. Phys. [3] xxiii. 345.—Sieveking, Ann. Ch. Pharm. cvi. 258.—Tütscheff, J. pr. Chem. lxxv. 370.)—Produced by the action of pentachloride of phosphorus on hydride of cumyl:

It is a limpid oily liquid having, a penetrating but not unpleasant odour, heavier than water and insoluble therein; easily soluble in alcohol and ether. Boils between 255° and 260° C. (Cahours); at 255° with slight decomposition. (Tütscheff.)

Decompositions.—1. Heated with alcoholic ammonia in a sealed tube, it forms chloride of ammonium and a thick yellow oil (Sieveking).—2. It does not appear to be decomposed by aqueous potash (Cahours).—3. With sulphhydrate of potassium it yields chloride of potassium, and a viscid product of repulsive odour (Cahours). By prolonged treatment of the alcoholic solution with sulphide of ammonium, it forms a dark-red resin soluble in ether (Sieveking).—4. Freshly precipitated oxide of silver converts it into cuminol (Tütscheff).—5. When 2 at. ethylate of sodium are heated with 1 at. chloride of cumylene, chloride of sodium and a red liquid are obtained. When this product is distilled, first alcohol, and then, between 170° and 238° C., an oil passes over, which behaves with acid sulphites of alkali-metals like cuminol (Sieveking).—6. With acetate of silver, it forms acetate of cumylene (Sieveking), with benzoate of silver, benzoate of cumylene. (Tütscheff.)

ACETATE OF CUMYLENE. *Acetate of Cumoglycol*, *Biacetate of Cumol*. $C^{14}H^{18}O^4 = (C^2H^3O)^2. (C^{10}H^{12})^{''}.O^2$. (Sieveking, *loc. cit.*)—Chloride of cumylene is mixed with excess of acetate of silver, and the reaction, which immediately ensues, is finally aided by a gentle heat. The product is treated with ether; the solution evaporated; and the residue is washed with aqueous carbonate of soda, and crystallised from ether, whereby yellowish crystals, contaminated with an oil, are obtained. When pure it forms colourless crystals, resembling the swallow-tail crystals of gypsum. It melts at a moderate heat, and diffuses a powerful odour of acetic acid and cuminol.

BENZOATE OF CUMYLENE. *Benzoate of Cumoglycol*, *Bibenzoate of Cumol*. $C^{24}H^{22}O^4 = (C^2H^3O)^2. (C^{10}H^{12})^{''}.O^2$. (Tütscheff, *loc. cit.*)—Seven pts. chlorocumol are mixed in a porcelain dish with 16 pts. benzoate of silver; the mass thereby formed is treated with ether, which leaves chloride of silver; and the resulting solution of benzoate of cumoglycol is left to evaporate spontaneously, whereupon a brownish yellow oil, solidifying in crystals in a few days, is deposited. This is pressed between paper, washed with aqueous ammonia, and recrystallised alternately from ether-alcohol and absolute alcohol.

It forms brilliant, colourless needles, melting at 88° C., and solidifying in crystals on cooling; soluble in alcohol, especially in warm strong alcohol, and precipitated by water; soluble in ether, acetone, and chloroform.

It cannot be volatilised without undergoing decomposition. It is dissolved by cold sulphuric acid with dark red colour; the solution blackens by boiling; it is not attacked by boiling nitric acid; it is not affected by ammonia or by concentrated baryta-water; distilled with caustic potash, it yields benzoate of potassium and cuminol.

CUMYLIC ACID. Syn. with CUMINIC ACID.

CUMYL-SALICYLAMIDE.

CUMYL-SULPHOPHENAMIDE.

} See CUMINAMIDE (p. 178).

CUPEL. A shallow cup-shaped vessel made of bone-earth rammed into a mould which gives it its shape. It is used in assaying gold and silver with lead. (See GOLD and SILVER.)

CUPRAMINES, CUPRAMMONIAS, CUPRAMMONIUMS. Bases derived from the types NH^3 and NH^1 by substitution of one or more atoms of copper for an equivalent quantity of hydrogen (p. 79).

CUPREOUS ANGESITE. See LINARITE.

CUPREOUS MANGANESE. A variety of wad or earthy manganese. (See MANGANESE, OXIDES OF, and WAD.)

CUPRIC COMPOUNDS. See COPPER (pp. 41, 55).

CUPRICUM. Cu = 31.6. The radicle of the cupric compounds (p. 41).

CUPRITE. Native cuprous oxide (p. 70).

CUPROPLUMBITE. A sulphide of copper and lead from Chili, occurring in forms of the regular system, with cubic cleavage; also massive, granular. Specific gravity = 6.408 to 6.423. Hardness = 2.5. Lustre metallic. Colour blackish lead-grey. Streak black. Rather sectile and brittle. Fuses readily on charcoal before the blowpipe; yields with soda a cupreous lead-globule; melts and gives off sulphurous anhydride when heated in an open tube.

According to Plattner's analysis (Pogg. Ann. lxi. 672), it contains 64.9 per cent. lead, 19.5 copper, 0.5 silver, and 15.1 sulphur (estimated by loss), whence the formula $2PbS, Cu^2S$, or $\begin{matrix} Pb^4 \\ Cu^2 \end{matrix} \} S^3$.

According to G. Ulrich (Berg. u. hüttenm. Zeitung, xviii. 221), a mineral of the same composition is found in small quantity on the McIvor river in Victoria, Australia. It has the aspect of fine-grained galena. Hardness = 3.0 to 4.0, and apparently rhombohedral cleavage.

CUPROSUM. Ccu = 63.2. — The radicle of the cuprous compounds. (See COPPER, pp. 41, 46.)

CURARA. *Urari*, *Woorara*, *Woorali*, *Wourali*.—A resinous substance used by the Indians of South America for poisoning their arrows, and consisting, according to several authorities, of the aqueous extract of a climbing plant belonging to the genus *Strychnos*. It is a brown-black, shining, brittle, resinous mass, almost wholly soluble in water, either cold or warm; sparingly soluble in absolute, easily in aqueous, alcohol; partially soluble in ether. It has a bitter taste, neutral reaction, and when heated, burns with a yellowish-red flame, giving off vapours which have a disagreeable odour. Its chemical nature is not accurately known. Boussingault and Roulin attribute its poisonous action to the presence of a peculiar alkaloid, curarine (*q. v.*), while others ascribe its effects to the presence of strychnine.

Curara may be introduced with impunity into the alimentary canal, except in very large doses, but if introduced into a puncture in the skin, so that it may mix with the blood, its action is rapidly mortal. Humboldt states that the earth-eating Otomaks on the Orinoco are in the habit of anointing their thumb-nails with it, and that a mere scratch with such a nail is sufficient to produce fatal effects. The Indians use arrows poisoned with curara in the chase, the flesh of animals thus killed being perfectly wholesome. Curara acts chiefly on the motor nerves, the functions of which it completely arrests, while the sensorial nerves retain their activity. Death ensues from paralysis of the nerves of the respiratory organs.

From the researches of Reynoso, it appears that chlorine and bromine decompose curara, and completely neutralise its poisonous action. Iodine also acts as an antidote, though it does not completely decompose the curara. Nitric acid acts but slightly on curara, but may be useful as a caustic in cases of poisoning by that substance.

Curara has been tried, but without success, as an antidote to strychnine. It has also been tried as a remedy in cases of traumatic tetanus, and in one instance with success; in other cases, however, it has been found to produce no effect whatever. (Handw. d. Chem. ii. [3] 271).

CURARINE. (Roulin and Boussingault, Ann. Ch. Phys. [2] xxxix. 24.—A. de Humboldt, *ibid.* xxxix. 30.—Pelletier and Pétröz, *ibid.* xl. 213.—*On the Poisonous Properties of Curarine*; Pelouze and Cl. Bernard, Compt. rend. xxxi. 553.—A. Reynoso, *ibid.* xxxix. 67.—E. Pelikan, *ibid.* xlv. 507.—M. Milleroux, *ibid.* xlvii. 973.)—An alkaloid existing in curara.

To prepare it, Pelletier and Pétröz treat the alcoholic extract of curara with ether, to remove fat and resin; dissolve the residue in water; precipitate the foreign matters with basic acetate of lead, and remove the excess of lead-salt with sulphuretted hydrogen; decolorise the liquid with animal charcoal; evaporate the filtrate and expel the acetic acid by adding sulphuric acid diluted with absolute alcohol; remove the alcohol by evaporation; precipitate the sulphuric acid with hydrate of barium; remove the excess of baryta by means of carbonic acid; and finally evaporate the filtered liquid to dryness.

Curarine thus prepared is a non-crystalline, yellowish, horny mass, translucent in thin fragments. It is deliquescent, and has a bitter taste. When heated, it chars,

emits an odour of burnt horn, and yields a slight sublimate. It dissolves in all proportions in water and alcohol, but is insoluble in ether and in oil of turpentine. It blues litmus paper reddened by acids, and reddens turmeric paper.

It unites with acids, forming bitter salts. The *sulphate*, *hydrochlorate*, and *acetate*, which are the only ones yet known, are uncrystallisable.

According to Pelikan, curarine exhibits with *acid chromate of potassium* and *sulphuric acid*, with *ferrocyanide of potassium* and *sulphuric acid*, and with *peroxide of lead*, the same reactions as strychnine, excepting that with curarine they are more permanent. It likewise exhibits the same deportment as strychnine when subjected to *electrolysis*, a red colour appearing in both cases at the positive pole.

The physiological action of curarine appears to be the same as that of curara. Pelikan found that 0.05 grms. of curarine introduced under the skin of a rabbit killed it in a short time. He is of opinion that there is no antidote to the poisonous action of curara and curarine.

CURCUMA. See TURMERIC.

CURCUMIN. (A. Vogel, Schw. J. xviii. 212. — Pelletier and Vogel, J. Pharm. July 1815, p. 259. — Vogel, Jun., Ann. Ch. Pharm. xlv. 297.)—A yellow resinous substance contained in turmeric root. To extract it, the pulverised root is first boiled with water to remove gummy matters, &c.; the residue then treated with boiling alcohol; the filtered alcoholic solution evaporated; the residue digested with ether; and the ethereal solution evaporated at a gentle heat. The residue consists of curcumin contaminated with a small quantity of essential oil, from which it may be freed by redissolving in alcohol, precipitating with acetate of lead, decomposing the lead-precipitate with sulphuretted hydrogen, and then treating it with boiling ether, which takes up the curcumin.

By evaporating the ethereal solution, the curcumin is obtained in thin resinous plates of the colour of cinnamon, but yellow when reduced to powder. When exposed to sunshine, it gradually loses its colour and becomes yellowish-white. It is heavier than water, and insoluble therein, but dissolves with facility in alcohol, ether, and oils both fixed and volatile. The alcoholic solution is precipitated by gelatin. Curcumin melts at 40° C., and is completely decomposed by distillation.

CUSCONINE. Syn. with ARICINE (i. 357).

CUSPARIN. A non-azotised crystallisable substance, soluble in alcohol, sparingly soluble in water, contained in the bark of the true angustura (*Cusparia febrifuga*) (Saladin, J. Chim. med. 1833, ix. 388). Herzog (Arch. Pharm. [2] xciii. 146) was not able to obtain this substance.

CUTIN. A peculiar modification of cellulose, contained, according to Fremy, in the epidermis of leaves, petals, and fruits, together with ordinary cellulose, albumin, pectous substances, and fat. It is especially distinguished from ordinary cellulose (i. 820) by being insoluble in ammoniacal solution of oxide of copper (*cuprammonia*). To prepare it, the epidermis of leaves, or the leaves themselves, are boiled for half an hour with weak hydrochloric acid and washed with water; the woody fibre is removed from the residue by aqueous cuprammonia; and the undissolved portion is treated successively with water, hydrochloric acid, weak aqueous potash, alcohol, and ether. (Fremy.)

Cutin exhibits under the microscope the aspect of an amorphous perforated film. It is very extensible, contains 73.66 per cent. C, 11.37 H, and 14.97 O, approaching in composition to the fats (Fremy). It decomposes when heated, producing fatty acids. It is not decomposed by cold *nitric acid*, but when boiled with that acid, yields all the products that are formed in like manner from the fats, especially suberic acid. It is not altered by contact with cold *oil of vitriol* or boiling *hydrochloric acid*. It is saponified by boiling concentrated aqueous *potash*, and from the soap thus formed, a liquid fatty acid may be separated, which is soluble in alcohol and ether, but appears to be different from oleic acid. Cutin is not altered by dilute aqueous *alkalis*, by *ammonia*, or by any neutral solvent. (Fremy, Compt. rend. xlviii. 669.)

According to Payen, on the other hand (Compt. rend. xlviii. 893), the epidermis of plants consists of cellulose impregnated with fats, nitrogenous bodies, and inorganic salts; he denies the existence of any peculiar constituent of it not containing nitrogen or cellulose, and regards the cutin of Fremy as a product of the transformation of cellulose by the reagents above mentioned.

CYAMELIDE. Insoluble *Cyanuric acid*, nCNHO. (Liebig, Pogg. Ann. xv. 561; xx, 384). A white crystalline substance polymeric with cyanic acid (perhaps C₂N²H²O²), which is produced, together with liquid cyanic acid, in the dry distillation of cyanuric acid; sometimes forms spontaneously in the aqueous solution of cyanic acid; and is obtained when certain cyanates are treated with concentrated acids; for

example, when cyanate of potassium is triturated with fuming nitric or sulphuric acid, with crystallised oxalic or tartaric acid, or with strong acetic or hydrochloric acid.

Cyamelide is tasteless, inodorous, insoluble in water both hot and cold, also in alcohol, ether, and dilute acids. When heated, it is converted into cyanic acid, which volatilises. Heated with strong sulphuric acid, it decomposes with effervescence, yielding carbonic anhydride and sulphate of ammonium. It is not altered by boiling with hydrochloric or nitric acid. It dissolves easily in potash, and the solution when evaporated yields cyanurate of potassium, a small quantity of ammonia being, however given off, arising from a secondary decomposition. Cyamelide is likewise soluble in ammonia.

CYAMELURIC ACID. $C^6H^3N^7O^3$. An acid discovered in 1850 by Henneberg (Ann. Ch. Pharm. lxxxiii. 236), who assigned to it the formula, $C^6H^1N^7O^3$. Gerhardt (Compt. chim. 1850, 104) regarded it as $C^6H^1N^8O^4$; but Liebig (Ann. Ch. Pharm. xcv. 281) showed that the true formula is $C^6H^3N^7O^3$. The acid is tribasic and may be derived from the type, $NH^4.3HHO$, according to which its rational formula is $(\overset{H^3}{\underset{O^3}{\text{CN}}})^6N$.

Cyameluric acid is formed from mellone by the action of alkalis at the boiling heat, the reaction being represented, according to Liebig, by the equation :

The potassium-salt is prepared by evaporating a mixture of 1 pt. mellonide of potassium, 10 pts. potash-ley of specific gravity 1.2, and 20 pts. water at the boiling heat, the water being renewed as it evaporates, till the concentrated mass is no longer curdy, but exhibits crystals on its surface, and the liquid solidifies on cooling to a magma of needle-shaped crystals. These are washed, first with potash-ley, then with alcohol, and recrystallised from boiling water. On cooling, the cyamelurate of potassium crystallises in colourless prismatic needles having a glassy lustre. Its aqueous solution mixed with hydrochloric acid deposits cyameluric acid as a white powder, and on dissolving this in boiling water containing a few drops of hydrochloric acid, the cyameluric acid crystallises on cooling in white crystalline crusts, containing a few separate crystals in the form of prisms with pyramidal summits.

Crystallised cyameluric acid contains $2\frac{1}{2}$ at. (16.9 per cent.) water of crystallisation its formula being $2C^6H^3N^7O^3 + 5 \text{ aq.}$; the whole of this water is given off at 100°C . The crystals dissolve in about 720 pts. water at 17°C ., more readily in hot water: the solution reddens litmus. The dry acid, exposed to a moderate red heat, turns yellow, gives off vapours of cyanic acid, and yields a white sublimate, probably consisting of cyanuric acid, with a yellow residue of mellone (tricyanuramide).

Cyameluric acid boiled with nitric acid yields a crystalline product, probably cyanuric acid.

CYAMELURATES. Cyameluric acid is tribasic, and forms three classes of salts, viz.; *neutral* or *trimetalllic* = $C^6N^7M^3O^3$; *dimetalllic* = $C^6N^7HM^2O^3$ and *monometalllic* = $C^6N^3H^2MO^3$. It unites directly with bases and decomposes carbonates. Strong acids decompose the cyamelurates, separating cyameluric acid.

Cyamelurate of Ammonium crystallises in needles, which are very soluble in water, and fall to powder when exposed to the air, giving off ammonia and leaving an acid salt.

The *Barium-salt*, $2C^6Ba^3N^7O^3 + \text{aq.}$, obtained by boiling a dilute solution of the potassium-salt with excess of chloride of barium, crystallises in microscopic needles very slightly soluble in water, and giving off the greater part of their crystallisation-water at 100°C .

The *Cupric salt* is bluish white, granulo-crystalline, soluble in ammonia. The *Ferric salt*, precipitated from a perfectly neutral solution of ferric chloride by cyamelurate of potassium, forms a yellow bulky precipitate resembling ferric phosphate. The *Magnesium-salt* is a white crystalline precipitate insoluble in water, soluble in sal-ammoniac.

Cyamelurates of Potassium.—The *tripotassic-salt*, $C^6K^3N^7O^3 + 3 \text{ aq.}$, prepared as above described, forms white shining needles often several inches long, has a strong alkaline reaction, tastes soapy at first, then bitter and irritating. It dissolves in 7.4 pts. water at 18°C ., and in 1 or 2 pts. of boiling water, but is insoluble in alcohol. The solution precipitates the alkalis and alkaline earths. The air-dried salt gives off 3 at.

water when left over oil of vitriol or heated to between 100° and 120° C.; at a low red heat, it melts, giving off first ammoniacal, afterwards acid vapours. The *dipotassic salt*, $\text{C}^6\text{K}^2\text{HN}^3\text{O}^3 + 2 \text{ aq.}$, separates from a moderately strong and slightly warmed solution of the preceding, on addition of acetic acid, in thin laminae, iridescent in sunshine. From a boiling solution, it crystallises by slow cooling in concentric groups of crystalline needles. It is somewhat more soluble in water than cyameluric acid, and has an acid reaction. The crystallisation-water is given off between 120° and 130° C. The salt when heated to redness leaves a yellow-brown fusible residue.

The *Silver-salt*, $\text{C}^6\text{N}^3\text{Ag}^3\text{O}^3 + \text{aq.}$, is obtained by precipitation, as a white curdy substance, forming when dry a white friable mass, sparingly soluble in dilute nitric acid. It retains a small quantity of water at 130° C. When ignited it leaves metallic silver.

The *Sodium-salt*, obtained by decomposing carbonate of sodium with cyameluric acid, crystallises in needles, very soluble in water.

CYAMETHINE. $\text{C}^6\text{H}^3\text{N}^3$. A crystallisable organic base, polymeric with cyanide of methyl ($\text{CN}.\text{CH}^3$), and homologous with cyanethine ($\text{C}^9\text{H}^{13}\text{N}^3$, p. 189), produced, with evolution of carbonic anhydride, by the action of chloride of acetyl on cyanate of potassium:

It has not been analysed, but its composition is inferred from the analogy of the reaction to that of chloride of benzoyl on cyanate of potassium, by which *cyaphenine* (*q. v.*) is produced. (Cloeze, Ann. Ch. Pharm. cxv. 27).

CYANAMIDE. $\text{CN}^2\text{H}^2 = \frac{\text{CN}}{\text{H}^2}\text{N}$. (Bineau, Ann. Ch. Phys. [2] lxxvii. 368; lxx.

251.—Cloeze and Cannizzaro, Ann. Ch. Pharm. lxxviii. 228.—W. Henke, *ibid.* cvi. 286.—Beilstein and Geuther, *ibid.* cviii. 88.—Strecker, Handw. d. Chem. ii. [3] 286.)—Bineau, by mixing dry ammonia-gas with gaseous chloride of cyanogen, obtained a product which he regarded as ammonio-chloride of cyanogen, $\text{CNCl}.\text{2NH}^3$. Cloeze and Cannizzaro (in 1851) showed that this substance was a mixture of sal-ammoniac and cyanamide ($\text{NH}^4\text{Cl} + \text{CN}^2\text{H}^2$), and obtained the amide in the pure state by passing gaseous chloride of cyanogen into a solution of ammonia-gas in anhydrous ether. Sal-ammoniac then separates out, and the ethereal solution, evaporated over the water-bath, yields pure cyanamide. For preparing larger quantities of cyanamide, it is better to pass dry ammonia-gas and chloride of cyanogen simultaneously into anhydrous ether. Liquid chloride of cyanogen, and the bromide and iodide of cyanogen likewise yield, with ammonia-gas, mixtures of ammonium-salt and cyanamide. A compound identical in composition with cyanamide, and exhibiting similar reactions, is obtained by the action of carbonic anhydride on sodamide (Beilstein and Geuther):

Cyanamide is a white crystalline body, which melts at 40° C., often remaining liquid when cooled several degrees lower, and then solidifying suddenly by contact with a solid body. When heated to 150° C., it solidifies, with considerable evolution of heat, and is converted into the polymeric compound melamine, or cyanuramide, $\text{C}^3\text{N}^6\text{H}^6$.

Cyanamide is permanent in dry air and dissolves easily in *water*, but on evaporating the solution, it is converted into an insoluble body, probably melamine. It dissolves easily and without decomposition in *alcohol* and in *anhydrous ether*. *Alkalis* decompose it; with some *acids*, especially with nitric acid, it forms crystalline compounds. On adding a small quantity of nitric acid to its aqueous solution, nitrate of urea is produced:

A solution of cyanamide, mixed with *nitrate of silver* and a small quantity of ammonia, yields a flocculent yellow precipitate (? argento-cyanamide, CN^2Ag^2), soluble in ammonia and in nitric acid. A solution of cyanamide and *acetate of copper* yields, on gradual addition of potash, a brown bulky copper-compound. (Beilstein and Geuther.)

Cyanamide mixed in an aqueous solution with *glycocyl* ($\text{C}^2\text{NH}^3\text{O}^2$), unites with it, forming glycoeyamine, $\text{C}^3\text{N}^3\text{H}^7\text{O}^2$, a base homologous with creatine, which separates after some days in colourless crystalline needles. (Strecker.)

Substitution-derivatives of Cyanamide.—These compounds, derived from cyanamide by the substitution of 1 or 2 at. of an alcohol-radicle for an equivalent quantity of hydrogen, are obtained by the action of chloride of cyanogen on ethylamine, phenylamine, &c. The ethyl and phenyl compounds are the only ones that have been studied. (See CYANETHYLAMIDE and CYANOPHENYLAMIDE.)

Dicyano-diamide, $\text{C}^2\text{N}^4\text{H}^1 = \left\{ \begin{smallmatrix} (\text{CN})^2 \\ \text{H}^1 \end{smallmatrix} \right\} \text{N}^2$. An aqueous solution of cyanamide left to itself for some time, or more quickly if mixed with a small quantity of ammonia, deposits a sparingly soluble substance, crystallising in broad laminae, and apparently consisting of dicyano-diamide, the molecule of which is simply that of cyanamide doubled. It unites with *nitrate of silver*, forming the compound $\text{C}^2\text{N}^4\text{H}^1.\text{AgNO}^3$, which crystallises in very slender needles, very soluble in boiling water, sparingly in cold water and in nitric acid. The solution of this silver-compound mixed with ammonia yields a white insoluble pulverulent precipitate consisting of $\text{C}^2\text{N}^4\text{H}^3\text{Ag}$.

Dicyano-diamide dissolves in *acids*, the solutions yielding by evaporation crystalline salts of the base $\text{C}^2\text{N}^4\text{H}^6\text{O}$. The hydrochlorate, $\text{C}^2\text{N}^4\text{H}^6\text{O}.\text{HCl}$, forms colourless needles, and its concentrated solution yields with *dichloride of platinum*, a crystalline precipitate, $\text{C}^2\text{N}^4\text{H}^6\text{O}.\text{HCl}.\text{PtCl}_2$, which crystallises from hot water in large prisms. The nitrate, $\text{C}^2\text{N}^4\text{H}^6\text{O}.\text{HNO}^3$ (at 120°C .), crystallises in colourless needles grouped in hemispheres. The oxalate $(\text{C}^2\text{N}^4\text{H}^6\text{O})^2.\text{C}^2\text{H}^2\text{O}^4$, is formed on adding a warm concentrated solution of oxalic acid to a solution of dicyano-diamide, and crystallises on evaporating the liquid. Its formation is attended with copious evolution of carbonic oxide and carbonic anhydride, arising from decomposition of part of the oxalic acid added. The sulphate $(\text{C}^2\text{N}^4\text{H}^6\text{O})^2.\text{H}^2\text{SO}^4 + 2 \text{ aq.}$ crystallises in needles which give off their water at 100°C . The base, $\text{C}^2\text{N}^4\text{H}^6\text{O}$, is obtained by heating the solution of the sulphate with carbonate of barium, and evaporating the filtrate, in colourless crystals having an alkaline reaction, easily soluble in water, slightly in alcohol. When boiled with water, it is decomposed, with evolution of ammonia, and formation of a base which appears to belong to the type $\text{NH}^4.\text{H}^2\text{O}$, inasmuch as, when treated with hydrochloric acid, it is converted into a chloride, with elimination of 2 at. water. (H a g, Handwörterbuch, *loc. cit.*)

TRICYANO-TRIAMIDE, $\text{C}^3\text{N}^6\text{H}^6$. See CYANURAMIDE.

CYANDIETHYLAMIDE. See CYANETHYLAMIDE.

CYANETHINE. $\text{C}^9\text{H}^{15}\text{N}^3$. (Frankland and Kolbe, Chem. Soc. Qu. J. i. 69; Ann. Ch. Pharm. lxx. 288).—An organic base, polymeric with cyanide of ethyl ($\text{CN}.\text{C}^2\text{H}^5$), and probably having the constitution of a triamide, $\text{N}^3(\text{C}^2\text{H}^5)^3$ (Hofmann). It is obtained by the action of potassium on that compound. Hydride of ethyl is evolved with brisk effervescence, and a yellow viscid residue is obtained, consisting of cyanide of potassium mixed with a small quantity of cyanethine, from which the cyanide of potassium may be dissolved out by cold water.* It is difficult to account for the evolution of hydride of ethyl in this reaction, unless it be supposed that the potassium used was mixed with hydrate of potassium.

Cyanethine crystallises from boiling water in white nacreous scales. It has no smell, and very little taste, melts at 190°C ., and boils with partial decomposition at 280° . Cold water dissolves it very slightly, boiling water more freely, alcohol in all proportions. The aqueous solution has a faint alkaline reaction. Cyanethine may be boiled and even melted with potash, without alteration.

Cyanethine dissolves easily in all *acids*, forming salts which have a rough and slightly bitter taste, are soluble in water and in alcohol, and often crystallisable. The *acetate* gives off acetic acid when evaporated in *vacuo*, and is converted into an insoluble basic salt. The *hydrochlorate* and the *sulphate* are very soluble in water, and uncrystallisable. The *chloroplatinate*, $\text{C}^9\text{H}^{15}\text{N}^3.\text{HCl}.\text{PtCl}_2$, is obtained by precipitation as a reddish yellow crystalline salt, moderately soluble in alcohol, less in water, and crystallising therefrom by evaporation in large ruby-coloured octahedrons. The alcoholic solution is decomposed by evaporation, yielding chloroplatinate of ammonium. The *nitrate*, $\text{C}^9\text{H}^{15}\text{N}^3.\text{HNO}^3$, crystallises in large colourless prisms, which are perfectly neutral. The *oxalate* forms fine prismatic crystals.

CYANETHOLINE. $\text{C}^9\text{H}^9\text{NO}$. (Cloez, Compt. rend. xlv. 482; Ann. Ch. Pharm. cii. 354).—An organic base isomeric with cyanate of ethyl ($\text{CN}.\text{C}^2\text{H}^5.\text{O}$), produced by the action of gaseous chloride of cyanogen on a solution of ethylate of sodium in absolute alcohol:

On decanting the liquid from the deposit of chloride of sodium, and distilling it in the water-bath, cyanetholine remains as a syrupy liquid of specific gravity 1.127 at 15°C ., which may be freed from chloride of sodium by washing with water. It has a faint odour, like that of sweet oil of wine, and a disagreeable bitter taste. It is insoluble in water, but dissolves in all proportions in alcohol and ether. It is decom-

* The quantity of cyanethine obtained by the process above described is extremely small: it might perhaps be obtained more readily by a process analogous to that by which Cloez has obtained cyaphine (*q. v.*), viz. by the action of chloride of propionyl on cyanate of potassium,

posed by distillation, leaving a carbonaceous residue. By boiling with strong potash-ley it is decomposed, with evolution of ammonia (? ethylamine). When nitric oxide is passed into a solution of the base in nitric acid, nitrogen is evolved, and a crystallisable substance, not yet examined, is deposited.

Cyanetholine dissolves in acids, forming salts which are mostly crystallisable. The *chloroplatinate* is yellow. The *nitrate* forms with nitrate of silver a double salt which separates in large crystals. The *sulphate* crystallises in small prisms when its solution is evaporated over oil of vitriol.

CYANETHYLAMIDE. $\text{C}^3\text{N}^2\text{H}^6 = \left. \begin{matrix} \text{CN} \\ \text{C}^2\text{H}^3 \\ \text{H} \end{matrix} \right\} \text{N}$. (Cloeze and Cannizzaro, Ann.

Ch. Pharm. lxxviii. 288.)—Produced by the action of gaseous chloride of cyanogen on ethylamine:

It is a weak base, uniting with concentrated acids, and forming compounds which are decomposed by water. At 180°C . it is resolved into cyandiethylamide, which distils over at that temperature, and a solid amber-coloured body, which volatilises without decomposition at 300°C . The latter is a feeble base, $\text{C}^4\text{N}^4\text{H}^8$, which forms with hydrochloric acid and dichloride of platinum, a crystalline compound, nearly insoluble in water, but easily soluble in alcohol, especially when heated, and separating in fine yellow scales on cooling.

Cyandiethylamide, $\text{C}^5\text{N}^2\text{H}^{10} = \left(\begin{matrix} \text{CN} \\ \text{C}^2\text{H}^3 \end{matrix} \right)_2 \text{N}$.—Produced as just mentioned, by the decomposition of cyanethylamide:

Also by passing chloride of cyanogen into a solution of diethylamine in anhydrous ether.

It is a colourless liquid which boils at 190°C ., and is decomposed by acids and alkalis into carbonic anhydride, water, and diethylamine:

CYANIC ACID. $\text{CNHO} = \left. \begin{matrix} \text{CN} \\ \text{H} \end{matrix} \right\} \text{O, or } \left(\begin{matrix} \text{CO} \\ \text{H} \end{matrix} \right) \text{N}$. (Wöhler, Gilb. Ann. lxxi. 95; lxxiii. 15.—Pogg. Ann. i. 117; v. 335; Ann. Ch. Pharm. xlv. 351.—Liebig, Kastn. Arch. vi. 145; Schw. J. xlviii. 376; Pogg. Ann. xv. 561, 619.—Liebig and Wöhler, Pogg. Ann. xx. 369.—Baeyer, Ann. Ch. Pharm. cxiv. 156.—Brüning, *ibid.* civ. 198.)—This acid, originally distinguished by the name of *cyanous acid* (cyanuric acid being then regarded as a higher oxide of cyanogen and called *cyanic acid*), was first noticed by Vauquelin in 1818, afterwards obtained in a more definite state and examined by Wöhler in 1822. It is produced: *a*. In the free state: 1. By heating the polymeric compound, cyanuric acid, $\text{C}^3\text{N}^3\text{H}^3\text{O}^3$, which then splits up into 3 atoms of cyanic acid. 2. By heating urea (cyanate of ammonium) with phosphoric anhydride to 40°C ., the mixture then rising spontaneously in temperature to 130° — 140° , and yielding a distillate of cyanic acid mixed with cyamelide (Liebig). 3. By the dry distillation of xanthamide (sulphocarbamate of ethyl), which then splits up into mercaptan (sulphydrate of ethyl) and cyanic acid (Debus):

4. By heating uric acid with peroxide of manganese and sulphuric acid (Döbereiner Gilb. Ann. lxxiv. 121). 5. By heating mercuric urate to redness (Wöhler.)

b. In combination with bases: 1. By passing cyanogen gas into solutions of the alkalis or alkaline earths, or by heating an anhydrous alkaline carbonate to low redness in cyanogen gas, or with an anhydrous metallic cyanide, such as cyanide of mercury:

2. By fusing a cyanide or ferrocyanide of an alkali-metal in contact with the air, or with easily reducible oxides (such as oxide of lead) or with peroxides, or with small quantities of nitrates. 3. By the electrolysis of a solution of cyanide of potassium, the cyanate being then formed at the positive pole (Kolbe). 4. By igniting nitre with excess of finely divided charcoal. 5. By adding melam, ammeline, or ammelide to melting potash-hydrate as long as it dissolves (Liebig). 6. By heating sulphocyanate of ethyl with potash-ley, the products being cyanate of potassium, cyanide of potassium, and disulphide of ethyl (Brüning):

7. A solution of urea mixed with nitrate of silver and evaporated, yields cyanate of silver.

Preparation.—Cyanuric acid, previously dehydrated, is heated in a small retort to commencing redness, and the evolved vapour of cyanic acid is condensed in a receiver surrounded with a freezing mixture (Wöhler). The distillate thus obtained is always more or less clouded by the presence of the insoluble polymeric compound, cyamelide ($C^2N^2H^2O^2$), which likewise sublims in the neck of the retort together with unaltered cyanuric acid. The loss of product thus arising may be diminished, according to Baeyer, by heating the cyanuric acid in a tube bent at right angles, and laid in a combustion-furnace, in such a manner that the heat may reach the bend during the whole of the process, the heating being commenced at the bend and gradually extended backwards. It is best also to pass a stream of carbonic anhydride through the tube during the process.

Cyanic acid cannot be separated from its salts in the ordinary way by the action of aqueous acids, because it then immediately takes up water and splits up into carbonic acid and ammonia. It may, however, be obtained by passing dry hydrochloric acid over dry cyanate of silver and collecting the evolved vapours in a cooled receiver. (Wöhler, Pogg. Ann. v. 386.)

Properties.—Cyanic acid is a thin, colourless liquid, which reddens litmus strongly, and has an extremely pungent odour, like that of glacial acetic acid, and somewhat like that of sulphurous acid. The vapour excites a copious flow of tears, and causes violent smarting in the hands. A drop of the liquid acid instantly produces a white blister, attended with severe pain; indeed, it is almost as dangerous to work with as strong hydrofluoric acid.

Cyanic acid may be regarded either as a hydrate of cyanogen $\begin{smallmatrix} \text{CN} \\ \text{H} \end{smallmatrix} \text{O}$, or as carbimide $\begin{smallmatrix} \text{C} \\ \text{O} \end{smallmatrix} \text{N} \cdot \text{H}$. The first of these formulæ exhibits most clearly the relations of cyanic acid to bases and to other acids; the latter, its decompositions in presence of water, the decompositions of the cyanic ethers by alkalis, &c.

Decompositions.—1. The liquid acid changes spontaneously into cyamelide (insoluble cyanuric acid), a substance which is polymeric with it, the change taking place the more quickly, and with greater rise of temperature, in proportion as the substance is less cooled. At 0°C ., the acid changes in an hour, and without explosion, into dry, hard, snow-white cyamelide; but if it be removed from the frigorific mixture, so that it may assume the ordinary temperature, it soon becomes turbid and milky, begins to boil, thickens to a pasty consistence, and becomes continually hotter, till it explodes; the paste is then scattered about, and changes completely into cyamelide. At ordinary temperatures, the conversion is complete in five minutes; it likewise takes place as quickly under increased external pressure as under the ordinary pressure. Vapour of cyanic acid mixed with an inactive gas appears to remain unchanged for a long time (Liebig and Wöhler). 2. The acid, mixed with water, splits up spontaneously in a short time, at ordinary temperatures, into 1 at. carbonic anhydride and 1 at. ammonia, the acid reaction of the liquid then changing to an alkaline reaction, and a smell of ammonia being produced. (Wöhler.)

Whilst one portion of the cyanic acid is thus converted into acid carbonate of ammonium, another portion takes up the ammonia, driving out the carbonic anhydride with effervescence, and forms cyanate of ammonium, which, on evaporation, is converted into urea; and a third part of the acid is converted into cyamelide, and separates in white flakes. This decomposition is likewise attended with evolution of heat (Liebig and Wöhler). The aqueous acid, when prepared by bringing cyanic acid vapour in contact with ice, in a receiver surrounded with ice, remains nearly unaltered at the temperature of 0° , giving off but a few bubbles of carbonic anhydride (Liebig and Wöhler.) A considerable quantity of water retards the decomposition of the acid into carbonic acid and ammonia; the presence of one of the stronger acids accelerates it, by virtue of the affinity of that acid for the ammonia (Wöhler). 3. The aqueous acid is decomposed by *sulphydric acid* (Liebig). 4. When cyanic acid vapour is passed into *methylic, ethylic, or amyllic alcohol*, the corresponding allophanic ethers (i. 133) are produced: *e.g.*

These ethers were originally mistaken for cyanic and cyanuric ethers (Liebig and

Wöhler). 5. With anhydrous *aldehyde*, cyanic acid forms trigenic acid, with evolution of carbonic anhydride (Liebig and Wöhler.):

Aldehyde. Cyanic acid. Trigenic acid.

6. With *glycol*, *glycerin*, and *eugenic acid*, cyanic acid reacts in the same manner as with alcohol (Baeyer). 7. With *valeraldehyde*, it forms a compound homologous with trigenic acid. 8. When cyanic acid vapour is passed into *triethylphosphine*, no change of composition takes place in either body, but the cyanic acid is polymerised into cyanuric acid, which settles down as a white deposit. (Hofmann, Chem. Soc. Qu. J. xiii. 322.)

Hydrochlorate of Cyanic acid, CNHO.HCl .—When dry hydrochloric acid gas is passed through a long tube containing well-dried cyanate of potassium, great heat is produced, and a colourless liquid distils over. This reaction is always accompanied by the production of cyamelide, which remains behind on dissolving the chloride of calcium in water; and, if the cyanate of potassium be not kept cool, we obtain, instead of the above-mentioned distillate, nothing but a mixture of cyamelide and hydrochloric acid. Cyanate of silver appears to be better adapted for the preparation than the potassium-salt (Wöhler). The compound is a transparent and colourless liquid, which fumes strongly in the air, and smells very strongly of cyanic and hydrochloric acid.

Enclosed in a sealed glass tube, it remains unaltered at 0°C .; but, at ordinary temperatures, it solidifies in a few days into a crystalline mass, consisting of sal-ammoniac and cyamelide, the solidification being accompanied by the evolution of highly compressed carbonic and hydrochloric acid gases (Wöhler). The compound, heated in open vessels, is resolved into cyamelide and hydrochloric acid gas. It dissolves immediately in water, yielding a solution of sal-ammoniac, with great rise of temperature and violent evolution of carbonic anhydride:

Hence it immediately begins to effervesce when exposed to moist air, or when breathed upon, the decomposition going on till nothing remains but a solid mass of sal-ammoniac. When mixed with alcohol, it decomposes immediately, with great evolution of heat, into hydrochloric acid and *allophanic ether*. (Wöhler, Ann. Ch. Pharm. xlv. 357.)

Cyanates. Cyanic acid is monobasic, its salts having the formula CNMO or $\text{CN}\begin{Bmatrix} \text{O} \\ \text{M} \end{Bmatrix}$. They are obtained, sometimes by the methods indicated for the formation of cyanic acid (p. 191); sometimes by bringing the aqueous acid in contact with the base; sometimes by precipitating an aqueous solution of cyanate of potassium or barium with a heavy metallic salt (Wöhler). In the last case, however, according to Haidlen and Fresenius, a carbonate is sometimes thrown down instead of the cyanate, *e.g.* with lead and zinc salts.

Many cyanates, as those of silver and mercury, when heated in the dry state, give off undecomposed cyanic acid, together with carbonic anhydride and nitrogen gases; others, as those of the fixed alkali-metals, remain undecomposed even at a red heat, excepting in presence of moisture, by which the salt is decomposed, at a moderate heat, into carbonate of ammonium, fixed alkaline carbonate, and a substance resembling paracyanogen; the same decomposition is produced even by repeated solution in water and evaporation:

Cyanates are decomposed by the stronger *acids*, the cyanic acid being wholly or partly decomposed by the water present, into carbonic anhydride and ammonia, so that the reaction is attended with effervescence, and the liquid, if subsequently heated with excess of potash, gives off ammonia. The pungent odour of cyanic acid is always more or less perceptible. Cyanates detonate when heated with chlorate of potassium (Wöhler). Strong sulphuric acid, dilute hydrochloric acid, and aqueous oxalic acid eliminate from cyanates scarcely any but carbonic acid, retaining the ammonia; crystallised oxalic acid, or concentrated hydrochloric acid, expels cyanic acid, which is then converted into cyamelide. Dilute sulphuric acid eliminates, together with the carbonic acid, a quantity of undecomposed cyanic acid vapour, which may be recognised by its intensely pungent odour. Some acids, as acetic acid (and likewise mineral acids, *e.g.* hydrochloric acid, according to Campbell), if added to the concentrated solution of the potassium-salt, likewise throw down crystals of acid cyanurate of potassium (Wöhler). The odour of cyanic acid is slowly, and therefore most perceptibly, evolved on dissolving cyanate of potassium in water containing cream of tartar. (Hünefeld, Schw. J. lx. 477.)

The cyanates of the alkali-metals, alkaline earth-metals, and a few others, are soluble in water. The solutions form white precipitates with nitrate of lead or silver, or with mercurous nitrate, greenish-brown with nitrate of copper, and brownish-yellow with chloride of gold (Wöhler). They do not form any precipitate with stannous or stannic chloride, ferrous or ferric chloride, or with mercuric chloride. Neither do they form prussian blue with iron-salts, on addition of sulphydric acid or sulphate of ammonium.

Cyanates of Ammonium.—The neutral salt $\text{CN.NH}^4\text{O}$, which is isomeric with carbamide(urea), $\left. \begin{smallmatrix} \text{CO} \\ \text{H} \end{smallmatrix} \right\} \text{N}^2$, has not been prepared in the solid state, but may be obtained in solution by decomposing cyanate of silver with aqueous sal-ammoniac. The filtered liquid exhibits the reactions of a cyanate, but when heated or left to evaporate spontaneously, it is converted into urea.

Basic salt.—When vapour of cyanic acid is mixed with dry ammonia-gas, the two condense, with great evolution of heat, to a snow-white powder, very soluble in water. The solution, when evaporated, gives off ammonia, and deposits urea. The dry salt undergoes the same transformation, gradually on exposure to the air, immediately when heated; in an atmosphere of ammonia it may be preserved unaltered. (Wöhler.)

Cyanate of Amyl.—See CYANIC ETHERS.

Cyanate of Barium, CNBaO , may be obtained by passing cyanogen-gas into baryta-water, whereby cyanate and cyanide of barium are produced, decomposing the cyanide with carbonic acid, and removing the carbonate of barium by filtration (Wöhler); by mixing concentrated aqueous solutions of cyanate of potassium and acetate of barium, and adding alcohol, which throws down a precipitate of cyanate of barium (Berzelius); or most easily by heating cyanurate of barium in a retort till it melts (Berzelius). The salt crystallises in small prisms. Its aqueous solution is decomposed by boiling, into ammonia and carbonate of barium.

Cyanate of Calcium.—Obtained by passing cyanic acid vapour into milk of lime. It does not crystallise.

Cyanate of Copper.—Greenish-brown precipitate, obtained by mixing the solutions of cyanate of barium and acetate of copper.

Cyanate of Ethyl.—See CYANIC ETHERS.

Cyanate of Lead, CNPbO , is obtained by mixing the solutions of acetate of lead and cyanate of potassium, as a white precipitate composed of fine needles, and soluble in boiling water. When heated in an open vessel, it takes fire, burns with sparkling, and leaves metallic lead.

Cyanate of Methyl.—See CYANIC ETHERS.

Cyanate, Mercurous.—White precipitate, obtained by adding a solution of the barium-salt to mercurous nitrate.

Cyanate of Naphthyl. } —See CYANIC ETHERS.

Cyanate of Phenyl. }

Cyanate of Potassium, CNKO .—For the various modes of formation of this salt, see page 190. It is prepared by oxidising the cyanide with metallic oxides: 1. Crude cyanide of potassium, prepared by fusing the ferrocyanide with carbonate of potassium, and containing 5 at. cyanide of potassium to 1 at. cyanate, is heated to the melting point in an earthen or iron crucible; somewhat more than three times the quantity of pulverised and gently ignited litharge is then introduced, the fused mass being stirred at the same time; the mixture is heated till the metallic lead has collected at the bottom, then poured out; and the solidified saline mass is pulverised and boiled with alcohol as long as the resulting solution continues to yield cyanate of potassium on cooling (Liebig):

According to Clemm (Ann. Ch. Pharm. lxvi. 382), the best mode of preparing cyanate of potassium is to add 15 parts of minium, by small portions at a time, to the fused and somewhat cooled, but still fluid mass of 8 pts. ferrocyanide and 3 pts. carbonate of potassium, taking care that the temperature does not rise too high. The crucible is then to be returned to the fire, and the contents stirred, poured out, and left to cool.—2. A finely-pulverised mixture of ferrocyanide of potassium and peroxide of manganese is raised to a very low red heat (if the heat be stronger, the cyanic acid is decomposed, with formation of carbonic anhydride and protoxide of manganese) (Wöhler). Or an intimate mixture of 1 pt. crystallised ferrocyanide of potassium and from $1\frac{1}{2}$ to 2 pts. manganese, is formed into a cone, the point of which is set on fire by a red-hot coal, whereupon a slow combustion extends throughout the

mass (Liebig). Or better: a very finely-pulverised and intimate mixture of 2 pts. dehydrated ferrocyanide of potassium and 1 pt. manganese is heated to low redness on an iron plate, with constant stirring, the mass gradually burning with a glimmering light. The oxygen of the manganese is far from sufficient for the formation of the cyanate of potassium, but the air likewise takes part in the action; if more manganese be used, a considerable quantity of carbonate of potassium is produced (Liebig).—3. An intimate mixture of 3 pts. dehydrated ferrocyanide of potassium, 1 pt. dry carbonate of potassium, and 4 pts. very finely pounded manganese, is gently ignited in a crucible till a sample dissolved in water after cooling no longer forms Prussian blue with ferric salts. The mass, when cold, is finely pounded and boiled with 80 per cent. of alcohol (Berzelius, *Lehrbuch*).—4. A mixture of 4 pts. ferrocyanide of potassium and 3 pts. nitre, is thrown by small portions into a red-hot crucible. Strong detonation then takes place, and there remains a black mixture of undecomposed ferrocyanide, charcoal, ferric oxide, and carbonate and cyanate of potassium, the quantity of the latter amounting to 1 part. (Wöhler.)

To obtain the cyanate of potassium in a purer state from the residues of these processes, they must be boiled with alcohol of the strength of 86 per cent. as long as the resulting liquid continues to yield cyanate of potassium on cooling. The alcoholic mother-liquid serves to repeat the exhaustion of the residue. The crystals must be several times washed with absolute alcohol, pressed, rapidly dried at $100^{\circ}\text{C}.$, or in vacuo over oil of vitriol, and preserved in a well-closed bottle, because the salt is very easily resolved by the action of moisture into carbonate of ammonium and acid carbonate of potassium. (Berzelius.)

Cyanate of potassium crystallises in small colourless laminæ and needles, similar to those of chlorate of potassium. It fuses at a temperature much below redness to a transparent and colourless liquid. It is inodorous, and tastes like nitre. (Wöhler.) It dissolves readily in water, sparingly in cold hydrated alcohol, more easily in boiling hydrated alcohol; in absolute alcohol it is insoluble. (Wöhler.)

The dry salt is not decomposed by ignition; but if water be dropped upon it at that temperature, it is rapidly resolved into carbonate of potassium and carbonate of ammonium. The same change takes place when an aqueous solution of the salt is evaporated in the air, either at the ordinary or at a higher temperature (Wöhler):

Hydrogen gas passed over the red-hot salt, abstracts all the oxygen and reduces it to cyanide of potassium; but the water thereby produced decomposes another portion of the cyanate of potassium into carbonate of potassium and carbonate of ammonium (Wöhler). *Charcoal* at a red heat likewise converts cyanate of potassium into cyanide (Gmelin). *Potassium* dissolves quite quietly in melting cyanate of potassium, forming a mixture of potash and cyanide of potassium:

Red-hot *iron-flings* form, with the salt, a mixture of cyanide of potassium, ferrocyanide of potassium, and protoxide of iron (Wöhler). *Sulphur* fuses with the salt, forming a mixture of sulphocyanate, sulphide, and sulphate of potassium (Wöhler). In this case, other decomposition-products are probably formed at the same time.—*Sulphuric acid* converts the melted salt into a yellow mixture of sulphide and sulphocyanate of potassium, a small quantity of sulphhydrate of ammonium being sublimed at the same time (Wöhler.) Dry *hydrochloric acid gas*, passed over the heated salt, produces sal-ammoniac and chloride of potassium (Wöhler); probably also phosphene is formed at the same time:

When cyanate of potassium is heated with *chloride of benzoyl*, carbonic anhydride is evolved, and chloride of potassium is formed, together with cyaphenine, a crystalline base polymeric with cyanide of phenyl (benzonitrile), and a small quantity of an oil boiling at $190^{\circ}\text{C}.$, which appears to be cyanide of phenyl:

A similar reaction takes place with *chloride of acetyl*, carbonic anhydride being evolved and a crystalline base produced, probably cyamethine, $\text{C}^6\text{H}^9\text{N}^3$ (p. 290). (Cloeze Ann. Ch. Pharm. cxv. 27.)

Cyanate of Silver, CNAgO , is obtained by decomposing cyanate of potassium with nitrate of silver, as a white precipitate, of specific gravity 4.004, and somewhat soluble in boiling water. Dilute nitric acid dissolves and immediately decomposes it. When heated, it melts, burns with incandescence, and leaves charcoal and metallic

silver containing nitrogen. It dissolves in ammonia, the solution yielding by evaporation, large semitransparent crystalline laminae, consisting of ammonio-cyanate of silver, or cyanate of argentammonium. When exposed to the air or immersed in water, they give up their ammonia and become opaque. (Wöhler.)

Cyanate of Sodium is crystallisable.

Cyanate of Yttrium.—Anhydrous salt, insoluble in water and in alcohol; separates after a while from a mixture of the alcoholic solutions of cyanate of potassium and an yttrium-salt. (Berlin.)

CYANIC ETHERS. These compounds, the cyanates of the alcohol-radicles, are obtained by distilling cyanate of potassium with ethyl-sulphate of potassium, or by the action of the iodides of the alcohol-radicles on cyanate of silver. They are volatile liquids which give, with potash and with ammonia, reactions analogous to those of cyanic acid (cyanate of hydrogen), yielding, in the first case, carbonate of potassium, and an ammonia in which 1 at. hydrogen is replaced by an alcohol-radicle, and in the second, a carbamide, or urea, in which 1 at. hydrogen is similarly replaced.

Cyanate of Allyl, $C^3H^5NO = CN.C^3H^5.O$, or $N.\overset{O}{C}.C^3H^5$. (Cahours and Hofmann, Phil. Trans. 1857, 555.)—Produced by the action of iodide of allyl on cyanate of silver. The heat produced by the reaction is sufficient to distil over nearly the whole of the volatile product. It is a transparent colourless liquid, having a pungent and intensely tear-exciting odour. It boils at $82^\circ C$. Vapour-density = 3.045 (exp.) = 2.88 (calc. 2 vols.) It dissolves easily, with rise of temperature, in ammonia,

and the solution when evaporated yields crystals of allyl-urea, $H^3(C^3H^5)\left\{ \overset{O}{C} \right\} N^2$. With ethylamine, in like manner, it yields ethyl-allyl-urea. Distilled with potash it yields allylamine, $N.H^2.C^3H^5$.

Cyanate of Amyl, $C^6H^{11}NO = CN(C^5H^{11})O$, or $N.\overset{O}{C}.C^5H^{11}$. (A. Wurtz, Ann. Ch. Phys. [3] xlii. 43.)—Prepared by heating 2 pts. of amylsulphate with 1 pt. cyanate of potassium:

If a small quantity of mercury be added to the mixture, it may be distilled rapidly over the open fire. The distillate, if rich in cyanate of amyl, is tolerably mobile. When purified by rectification from a small quantity of a less volatile compound, it boils at about $100^\circ C$. With ammonia it yields amyl-urea, $N^2.(CO).C^5H^{11}.H^3$, and when heated with potash it yields amylamine, $N.H^2.C^5H^{11}$.

Cyanate of Ethyl. *Cyanic ether*. $C^2H^5NO = CN.C^2H^5.O$, or $N.\overset{O}{C}.C^2H^5$. (Wurtz, loc. cit.)—Obtained, together with cyanuric ether, by distilling cyanate of potassium with the ethylsulphate. The cyanic ether is easily separated by rectification, being very volatile, whereas the cyanuric ether, which has a triple atomic weight, does not boil till raised to a very high temperature. It may be purified by several rectifications over chloride of calcium.

Cyanate of ethyl is a transparent, colourless, very mobile liquid, of specific gravity 0.8989, and having a very high refracting power. Boils at $60^\circ C$. Vapour-density = 2.475 (exp.) = 2.460 (calc. 2 vols.) The vapour is very irritating, and excites a copious flow of tears.

Decompositions.—1. Cyanate of ethyl is decomposed by water into carbonic anhydride and diethyl-carbamide:

2. It dissolves in aqueous ammonia, the solution yielding by evaporation beautiful prisms of ethyl-carbamide:

With ethylamine, phenylamine, conine, &c., it yields, in like manner, carbamides in which 2 at. hydrogen are replaced by alcohol-radicles, e.g.

3. Boiled with potash in a sealed tube, it yields carbonate of potassium and ethylamine:

4. Heated in like manner with anhydrous *ethylate of sodium* (or *potassium*) it yields *triethylamine*:

Sometimes, however, a different reaction takes place, yielding *carbtriethyltriamine* and other products (Hofmann, pp. 554, 560).—5. Cyanate of ethyl mixed with *glacial acetic acid*, yields carbonic anhydride and *ethylacetamide*:

6. Heated to 180° C. in a sealed tube with *acetic anhydride*, it yields *ethyldiacetamide*:

7. When cyanic ether is mixed with concentrated *formic acid*, violent evolution of carbonic anhydride takes place, and if the tube be then sealed and heated to 100° C., *ethyl-formamide*, $\text{C}^3\text{H}^7\text{NO} = \text{N.CHO.C}^2\text{H}^5.\text{H}$, is produced.—8. With *alcohol*, cyanate of ethyl forms *ethylcarbamate of ethyl* (*ethyl-urethane*):

It does not act upon *ether*, even when strongly heated with it in sealed tubes for several days.—9. Cyanate of ethyl dissolves *urea* (carbamide) at a moderate heat, and the solution, heated to 100° C. for about a quarter of an hour, and then left to cool, solidifies to a crystalline mass, chiefly consisting of the compound $\text{C}^2\text{H}^{14}\text{N}^4\text{O}^3$, formed by the union of 1 at. carbamide ($\text{CH}^4\text{N}^2\text{O}$) and 2 at. cyanic ether ($\text{C}^3\text{H}^5\text{NO}$). This compound, which crystallises from hot water in white silky needles, and dissolves readily in alcohol,

ether, and dilute acids, is diethyl-tricarbo-tetramide, $\left(\begin{smallmatrix} (\text{C}\ddot{\text{O}})^3 \\ \text{H}^4 \end{smallmatrix}\right) \text{N}^4$; it contains

also the elements of diethyl-cyanurate of ammonium, $\left(\begin{smallmatrix} (\text{CN})^3 \\ \text{C}^2\text{H}^5^2.\text{NH}^4 \end{smallmatrix}\right) \text{O}^3$; but it does not exhibit the characters of an ammonium-salt, not yielding diethylcyanuric acid when treated with mineral acids, or being precipitated by dichloride of platinum, or giving off ammonia when treated with cold potash, in which indeed it dissolves without decomposition; it is only when boiled with potash that it suffers decomposition, being then resolved into 2 at. ammonia, 3 at. ethylamine, and 3 at. carbonic anhydride (Hofmann, Proc. Roy. Soc. xi. 274).—10. Cyanate of ethyl, mixed with *triethylphosphine*, is gradually converted into cyanurate of ethyl; the odour of the cyanate soon disappears, and if the liquid be then treated with dilute hydrochloric acid to remove the phosphorus-base, the oil which floats on the surface quickly solidifies to a crystalline mass of cyanuric ether. (Hofmann, Chem. Soc. Qu. J. xiii. 322.)

Hydrochlorate of Cyanic Ether, $\text{C}^3\text{H}^5\text{NO.HCl}$.—Obtained by passing dry hydrochloric acid gas into cyanic ether, or by the action of that gas on diethyl-carbamide:

It is likewise the chief product of the action of chlorine on ethyl-carbamide. It is a liquid which has a pungent tear-exciting odour, boils at 95° C., and is immediately decomposed by water, yielding carbonic anhydride and hydrochlorate of ethylamine. (Habich and Limpricht, Ann. Ch. Pharm. cv. 395.)

Cyanate of Methyl, $\text{C}^2\text{H}^3\text{NO} = \text{CN.CH}^3.\text{O}$, or $\text{N.C}\ddot{\text{O}}.\text{CH}^3$. (Wurtz, loc. cit.)—Obtained by heating 2 pts. of crystallised and well dried methyl-sulphate of potassium with 1 pt. of cyanate of potassium, collecting the distillate in a well cooled receiver, and rectifying to separate the cyanate of methyl from the much less volatile cyanurate formed at the same time. It is a very volatile liquid, boiling at 90° C., and emitting highly pungent choking vapours. When sealed up in a tube, it changes in a few weeks, and often indeed in a few hours, into crystallised cyanurate of methyl. Its reactions with potash, ammonia, water, &c., are analogous to those of cyanate of ethyl.

Cyanate of Naphthyl, $\text{C}^{11}\text{H}^7\text{NO} = \text{CN.C}^{10}\text{H}^7.\text{O}$, is obtained, together with other products, by the action of phosphoric anhydride on dinaphthyl-carbamide. (V. Hall, Proc. Roy. Soc. ix. 366.)

Cyanate of Phenyl, Anilocyanic Acid, Carbanil, Anilcarbamide, Phenyl-carbamide, $\text{C}^7\text{H}^5\text{NO} = \text{CN.C}^6\text{H}^5.\text{O} = \text{N.C}\ddot{\text{O}}.\text{C}^6\text{H}^5$.—This compound, discovered by Hof-

mann in 1850 (Ann. Ch. Pharm. lxxiv. 9), was originally obtained by the dry distillation of melanoximide ($\text{C}^{15}\text{H}^{11}\text{N}^3\text{O}^2$). This substance, when heated, suffers a very complicated decomposition, giving off large quantities of carbonic oxide and a small quantity of carbonic anhydride, and yielding a distillate of cyanate of phenyl mixed with diphenyl-carbamide (see MELANOXIMIDE). The latter crystallises out as the distillate cools, and on filtering the liquid and rectifying in a perfectly dry apparatus, the cyanate of phenyl is obtained pure. Cyanate of phenyl is also produced in small quantity by the dry distillation of melaniline (Hofmann, *loc. cit.*) More recently Hofmann has found that it may be obtained by the action of phosphoric anhydride, chloride of zinc, or strong hydrochloric acid, on diphenyl-carbamide, the substance then splitting up into phenylamine and cyanate of phenyl:

the decomposition being precisely analogous to that of carbamide (urea) into ammonia and cyanic acid. As diphenyl-carbamide is difficult to prepare, it may be replaced for

this purpose by diphenyl-oxamide, $\text{N}.\text{C}^2\text{O}^2.(\text{C}^6\text{H}^5)^2.\text{H}^2$, which, under the influence of phosphoric anhydride, splits up into carbonic oxide and diphenyl-carbamide. (Hofmann, Proc. Roy. Soc. ix. 274.)

Cyanate of phenyl is a thin, transparent, colourless, strongly refracting liquid, heavier than water, and boiling between 178° and 180° C. Its vapour has an extremely powerful odour of cyanogen, hydrocyanic acid, and phenylamine together, exciting a copious flow of tears, and producing a feeling of suffocation when inhaled.

In contact with *acids* or *alkalis*, cyanate of phenyl takes up 1 at. water, and is resolved into phenylamine and carbonic anhydride:

With *strong sulphuric acid*, the products are carbonic anhydride and phenyl-sulphamic acid:

With *water*, cyanate of phenyl yields carbonic anhydride and diphenyl-carbamide:

With *ammonia*, it evolves great heat, and immediately solidifies in the form of phenyl-carbamide:

With *phenylamine*, it also becomes heated, and yields a solid mass of diphenyl-carbamide:

Other organic bases, such as *benzylamine*, *chinoline*, *cumenylamine*, &c., likewise form with cyanate of phenyl, solid products which appear to be analogous to diphenyl-carbamide. In contact with *triethylphosphine*, it is converted into solid cyanurate of phenyl. (Hofmann, Chem. Soc. Qu. J. xiii. 322.)

Cyanate of phenyl dissolves in *methylic*, *ethylic*, *amyllic*, and *phenylic alcohols*, the liquid becoming hot, and depositing, after a while, splendid crystals, which melt at the heat of boiling water, are insoluble in water, but dissolve in all proportions in alcohol and ether. The bodies thus obtained have not been analysed, but they appear to be the phenyl-carbamates of methyl, ethyl, &c. (Hofmann.)

CYANIDES. Compounds of cyanogen (CN, or Cy), formed on the hydrogen-type HH, or more generally $n\text{HH}$. The following are examples:

Cyanide of Hydrogen (Hydrocyanic acid)	H.Cy
Cyanide of Potassium.	KCy
Cyanide of Ethyl	$\text{C}^2\text{H}^5.\text{Cy}$
Cyanide of Mercury*	$\text{Hg}'''\text{Cy}^2$
Cyanide of Zinc and Potassium	$\left. \begin{matrix} \text{K} \\ \text{Zn} \end{matrix} \right\} \text{Cy}^2$
Cyanide of Ferricum (Ferric cyanide)	$(\text{Fe}^2)'''\text{Cy}^3$
Cyanide of Potassium and Ferrosium (Ferrocyanide of Potassium)	$\left. \begin{matrix} \text{K}^4 \\ \text{Fe}^2 \end{matrix} \right\} \text{Cy}^6$
Cyanide of Potassium and Ferricum (Ferricyanide of Potassium)	$\left. \begin{matrix} \text{K}^3 \\ (\text{Fe}^2)''' \end{matrix} \right\} \text{Cy}^6$
Cyanide of Potassium and Cobalticum (Cobalticyanide of Potassium)	$\left. \begin{matrix} \text{K}^3 \\ (\text{Co}^2)''' \end{matrix} \right\} \text{Cy}^6$

* Hg. = 200.

Cyanides, Metallic. These compounds are not found in nature ready formed, but are produced in numerous processes :

1. A few metals, potassium among the number, are converted into cyanides when heated in cyanogen gas or vapour of hydrocyanic acid, in the latter case with separation of hydrogen.—2. Cyanogen gas, passed over the heated hydrates or carbonates of the alkali-metals, forms a mixture of cyanide and cyanate of the metal; it acts in the same manner on solutions of the fixed alkalis, excepting that a brown substance like paracyanogen is also formed.—3. When nitrogen gas is passed over a mixture of charcoal and hydrate or carbonate of potassium at a bright red heat, cyanide of potassium is formed (Fownes, *J. pr. Chem.* xxvi. 412; Wöhler, *Jahresber. d. Chem.* 1850, p. 550; Rieckhen, *Ann. Ch. Pharm.* lxxix. 77; Delbruck, *ibid.* lxiv. 296.—Bunsen, *Reports of the British Association*, 1845, p. 185). Cyanide of potassium also exudes from blast-furnaces in which iron-ores are smelted with charcoal.—4. Cyanides are formed abundantly when nitrogenous organic compounds, or the nitrogenous charcoal obtained from them, are ignited with fixed alkalis. This is the principal method by which cyanides are prepared on the large scale, *e.g.* ferrocyanide of potassium, by fusing carbonate of potassium with iron filings and waste animal matter. The same reaction is used for the detection of nitrogen in organic compounds (*i.* 225). 5. Cyanides are also formed by igniting nitrates or nitrites with organic substances, either nitrogenous or non-nitrogenous: thus, nitre, fused with excess of tartrate or acetate of potassium, yields a considerable quantity of cyanide.—6. Cyanide of ammonium is formed when a mixture of ammonia-gas and carbonic oxide is passed through a red-hot tube:

also when ammonia-gas is passed over organic bodies, charcoal, or even graphite, at a red heat, the reaction being attended with elimination of hydrogen :

or sometimes according to Kuhlmann, of marsh-gas :

7. Cyanides are formed one from the other by double decomposition. Hydrocyanic acid converts metallic oxides into cyanides, sometimes anhydrous, as in the case of silver, but more generally hydrated. To convert an aqueous alkali (which should be free from carbonic acid) completely into cyanide, hydrocyanic acid must be added to it till it no longer precipitates sulphate of magnesium. Soluble cyanides treated with nitrate of silver yield a precipitate of cyanide of silver, and the precipitate, digested with the aqueous solution of an alkaline protosulphide, yields sulphide of silver and cyanide of the alkali-metal.

Properties and Reactions.—The cyanides of the alkali-metals are easily soluble in water, but most cyanides of the heavy metals are insoluble; cyanide of mercury, however, is soluble. The cyanides of the alkali-metals, cyanide of mercury, and many double cyanides containing it, are soluble in alcohol. None of the metallic cyanides are soluble in ether.

Some cyanides are crystallisable. Some are colourless, others exhibit various colours. The cyanides of the alkali-metals in the state of aqueous solution, exhibit a strong alkaline reaction, and have a bitter and alkaline taste; the solution remains alkaline, even when mixed with a very large excess of hydrocyanic acid.

Cyanide of ammonium, or hydrocyanate of ammonia, volatilises undecomposed when heated. The compounds of cyanogen with the alkali-metals sustain a red heat without decomposition, provided air and moisture be excluded. The cyanides of many of the heavy metals, *e. g.* lead, iron, cobalt, nickel, copper, &c., under these circumstances, give off all their nitrogen in the form of gas, and are converted into a compound or mixture of 1 at. metal and 1 at. carbon: $\text{CNM} = \text{CM} + \text{N}$.—Cyanide of mercury is resolved into metallic mercury and cyanogen gas; and cyanide of silver gives off half its cyanogen in the gaseous form, the other half, perhaps converted into paracyanogen, remaining combined with the silver.

All cyanides, when heated in the presence of *water*, are destroyed, those of the heavy metals generally giving off carbonic oxide, carbonic anhydride, and ammonia, and leaving the metal, together with a small quantity of charcoal. The cyanides of the alkali-metals are converted by continued boiling with water into ammoniacal gas and alkaline formates, *e. g.* :

The cyanides of some of the alkali-metals, *e. g.* cyanide of potassium, when heated in contact with the *air*, first take up 1 at. oxygen, and are converted into cyanates (CNKO), and these, when further heated, give off nitrogen and half the carbonic anhydride formed, and are converted into alkaline carbonates. The cyanides of the

heavy metals take fire readily when heated, yielding nitrogen, carbonic acid, and metal or oxide. Cyanides detonate by percussion with chlorate of potassium. (Johnston, Schw. J. lvii. 379.)

Chlorine gas decomposes many cyanides, converting them into chlorides, and liberating cyanogen, chloride of cyanogen, either fixed or volatile, and a yellow oil, the products varying according to the presence or absence of light and water, the nature of the cyanide, and the proportion of chlorine present: *e. g.*

Chlorine, gradually introduced, converts cyanide of lead or cyanide of silver into metallic chloride and free cyanogen, which does not take up any chlorine till all cyanide is decomposed (Liebig, Pogg. Ann. xv. 571). Aqueous *chloride of lime* acts upon cyanide of silver with violent effervescence, evolving carbonic acid and nitrogen, together with a small quantity of cyanogen; but no cyanic acid is formed (Liebig). *Iodine* forms metallic iodide and cyanogen, or iodide of cyanogen. It decomposes the cyanides of the alkali-metals in the state of aqueous solution, also cyanide of silver or cyanide of copper dissolved in aqueous cyanide of potassium, forming a metallic iodide and liberating cyanogen (Gerdy, Compt. rend. xvi. 25; also J. pr. Chem. xxix. 181). With boiling aqueous cyanide of potassium, it forms iodide of potassium and iodide of cyanogen (Liebig, Ann. Ch. Pharm. l. 335). It decomposes dry cyanide of mercury, forming iodide of mercury and iodide of cyanogen.

Strong *nitric acid* decomposes all metallic cyanides, with evolution of carbonic acid, nitrogen, &c. Excess of strong *sulphuric acid* decomposes metallic cyanides at high temperatures, forming a sulphate of the metal, acid sulphate of ammonium, and carbonic oxide (Fownes):

Most cyanides, when treated with *dilute acids*, give off their cyanogen in the form of hydrocyanic acid: *e. g.*

The cyanides of the alkali-metals, which, in the state of aqueous solution, may also be regarded as hydrocyanates, are decomposed by the weakest acids, even by carbonic acid; hence their solution, if it does not contain excess of alkali, gives off hydrocyanic acid on exposure to the air, that acid being gradually expelled by the carbonic acid of the air. On the other hand, it is only the alkaline sulphhydrates and soap-solutions that are decomposed by hydrocyanic acid. (Scheele.)

The compounds of cyanogen with the heavy metals are of a more intimate nature. Some, as the cyanides of zinc and lead, give off hydrocyanic acid when treated with dilute solutions of the stronger mineral acids, such as sulphuric acid; others, as the cyanides of mercury and silver, are not decomposed, even by the strongest oxygen-acids, in the state of aqueous solution; but hydrogen-acids, such as hydrochloric and sulphydric acid, decompose them; others again, as protocyanide of gold and protocyanide of iron, withstand the action of dilute sulphuric, hydrochloric, or nitric acid, even at a boiling heat.

From the solutions of the alkaline cyanides, many heavy metallic oxides separate part of the alkali-metal, in the form of oxide, which remains dissolved, forming at the same time a heavy metallic cyanide, or a compound of that cyanide with the cyanide of the alkali-metal:

The cyanides of some metals form crystallisable compounds with the oxides of the same metal; with various metallic iodides, bromides, and chlorides; also with nitrates and chromates.

Double Cyanides.—Cyanides have a strong tendency to unite with one another, and form definite compounds, called *Cyanogen-salts*, or *Double Cyanides* (analogous to the iodides, bromides, and chlorides), *e. g.* cyanide of nickel and potassium, $\text{KCy.NiCy} = \text{KNiCy}^2$; ferrocyanide of potassium, $2\text{KCy.FeCy} = \text{K}^2\text{FeCy}^3$. (See Table p. 197.)

The most numerous of these double salts are the compounds of the alkaline cyanides (including cyanide of ammonium, NH^4Cy), with the cyanides of the heavy metals; they are formed and prepared as follows:

1. By saturating the aqueous solution of the cyanide of an alkali-metal with a heavy metallic cyanide, or, if the latter be soluble in water, adding it to the alkaline cyanide in the proportion determined by calculation.—2. By saturating the aqueous solution of the alkaline cyanide with a heavy metallic oxide or hydrate. In this case, part of the alkali-metal is separated in the form of hydrate, which remains mixed with the solution, and the heavy metal passes over to the cyanogen-compound:

3. By digesting a heavy metallic cyanide with an aqueous alkali. In this case, on the contrary, part of the heavy metal is separated in the form of hydrate:

4. By adding aqueous hydrocyanic acid to a mixture, in equivalent proportions, of a heavy metallic oxide or its carbonate, and a caustic or carbonated alkali, till the acid retains its odour even after long agitation at a gentle heat. In this case, the hydrocyanic acid drives out all the carbonic acid that may be present, and the heavy metallic oxide is dissolved.—5. By saturating with caustic potash or carbonate of potassium, the acid compound which hydrocyanic acid forms with certain heavy metallic cyanides.—6. Platinocyanides may be formed by fusing platinum with cyanide of potassium. In this case, part of the cyanide of potassium is decomposed, yielding cyanide of platinum and free potassium (which oxidises to potash), while the undecomposed portion of the cyanide of potassium unites with the cyanide of platinum formed.

The proportions in which the heavy metallic cyanides may thus be made to unite with the cyanide of an alkali-metal, *e.g.* with cyanide of potassium, are the following:

- a. 3 at. Cyanide of potassium to 1 at. Hemicyanide of a heavy metal, $3\text{KCy}.\text{Cu}^2\text{Cy} = \text{K}^3\text{Cu}^2\text{Cy}^4$.
- b. 1 at. Cyanide of potassium to 1 at. Hemicyanide of a heavy metal, $\text{KCy}.\text{Cu}^2\text{Cy}$.
- c. 2 at. Cyanide of potassium to 1 at. Protocyanide of a heavy metal, $2\text{KCy}.\text{FeCy}$.
- d. 1 at. Cyanide of potassium to 1 at. Protocyanide of a heavy metal, $\text{KCy}.\text{ZnCy}$; $\text{KCy}.\text{CdCy}$; $\text{KCy}.\text{NiCy}$; $\text{KCy}.\text{AgCy}$; $\text{KCy}.\text{AuCy}$; $\text{KCy}.\text{PtCy}$; $\text{KCy}.\text{PdCy}$.
- h. 1 at. Cyanide of potassium to 2 at. Protocyanide of a heavy metal, $\text{KCy}.\text{2FeCy}$.
- f. 2 at. Cyanide of potassium to 1 at. Sesquicyanide of a heavy metal, $2\text{KCy}.\text{Pt}^2\text{Cy}^3$.
- g. 3 at. Cyanide of potassium to 1 at. Sesquicyanide of a heavy metal, $3\text{KCy}.\text{Cr}^2\text{Cy}^3$; $3\text{KCy}.\text{Mn}^2\text{Cy}^3$; $3\text{KCy}.\text{Fe}^2\text{Cy}^3$; $3\text{KCy}.\text{Co}^2\text{Cy}^3$; $3\text{KCy}.\text{Ir}^2\text{Cy}^3$.
- k. 1 at. Cyanide of potassium to 1 at. Tricyanide of a heavy metal, $\text{KCy}.\text{AuCy}^3$.

Almost all these double cyanides are crystallisable and soluble in *water*. Towards vegetable colours they are neutral or slightly alkaline, whereas the pure cyanides of the alkali-metals have a strong alkaline reaction; the double cyanides likewise emit little or no odour of hydrocyanic acid. They are also much less easily decomposable than the pure cyanides of the alkali-metals.

Both the metallic cyanides contained in these compounds behave, when ignited in a close vessel, just in the same manner as when they are ignited separately. Thus, in ferrocyanide of potassium, $2\text{KCy}.\text{FeCy}$, the cyanide of potassium remains undecomposed, while the cyanide of iron is resolved into nitrogen and carbide of iron.

By *acids* the double cyanides are decomposed with various degrees of facility. The alkali-metal is always easily withdrawn, and its place supplied by the hydrogen of the acid. With many double cyanides, however, this change takes place without any alteration of structure in the molecule, thus:

In other cases, only the alkaline cyanide is decomposed, with evolution of hydrocyanic acid, while the heavy metallic cyanide separates out; *e.g.*

If the separated cyanide is likewise decomposable by the acid used, an excess of the acid actually produces this decomposition, eliminating the whole of the cyanogen as hydrocyanic acid:

In other cases, the excess of the acid produces no further decomposition, as when cyanide of silver and potassium is acted upon by nitric acid:

Sulphydric acid precipitates the heavy metal, in the form of sulphide, from the dissolved compounds of the alkaline with the heavy cyanides, sometimes easily, as with cadmium, mercury, and silver; sometimes not at all, or but slowly and partially, as with zinc, iron, cobalt, nickel, and copper.

When the solution of such a compound of a cyanide of an alkali-metal with the cyanide of a heavy metal, is mixed with the salts of other heavy metals, precipitates are formed, exhibiting strong and varied colours, and generally consisting of compounds of the heavy cyanide already present, with another heavy cyanide formed by double decomposition between the cyanide of the alkali-metal and the salt of the heavy metal which has been added. Thus, ferrocyanide of potassium forms with sulphate of copper a red precipitate of ferrocyanide of copper:

But these precipitates often retain part of the original cyanogen-salt in a state of intimate combination, so that in many cases it cannot be completely extracted even by boiling water.

On account of the different behaviour of the several double cyanides with acids, it is usual to divide them into two classes. 1. The *easily decomposable double cyanides*, which give off hydrocyanic acid when treated with a stronger acid, even in the cold. These are regarded as true double salts, that is to say, as compounds formed by the addition of two simple cyanides, *e. g.* cyanide of nickel and potassium, $KCy.NiCy$.—2. The *less easily decomposable double cyanides*, which, when treated with acids, do not evolve hydrocyanic acid, but merely exchange their alkali-metal with the hydrogen of the acid, as is the case with the double cyanides of iron, chromium, cobalt, and manganese. In these compounds, the cyanogen is usually supposed to be more intimately combined with the heavy metal, forming a compound radicle, which, like chlorine or cyanogen itself, can unite with metals, forming salts which are decomposed by acids, and yield the hydrogen-salt of the same compound radicle. Thus, the yellow cyanide of iron (ferrosium) and potassium, K^2FeCy^3 , is regarded as the potassium-salt of the radicle *ferrocyanogen*, $FeCy^3 = C^3N^3Fe$, usually denoted by Cfy ; hence it is called *ferrocyanide of potassium*. In like manner, the red cyanide of iron (ferricum) and potassium, $C^6N^6Fe^2K^3 = K^3Fe^2Cy^6$, may be regarded as *ferri-* or *ferrid-cyanide of potassium*, $K^3Fe^2Cy^6$, or $K^3.Cfdy$, a compound of potassium with *ferri-* or *ferrid-cyanogen*, Fe^2Cy^6 . Similar compound radicles are supposed to exist in the double cyanides of chromium, cobalt, and manganese.

This view of the composition of the second class of double cyanides is convenient, when a particular class of reactions is under consideration, *viz.* the interchange of the alkali-metal of the double cyanide for hydrogen, or for a heavy metal; but it is by no means necessary to regard them in this way; in fact, the behaviour of a double cyanide with acids appears to depend rather upon the peculiar nature of the heavy metal contained in it than on any particular molecular arrangement. The first stage of the decomposition is the same in all cases, the alkali-metal being replaced by hydrogen; but the hydrocyanic acid thus formed remains, in some cases, combined with the heavy metallic cyanide, while in others it separates:

If now we turn our attention to the reactions which take place when these double cyanides are decomposed by *metallic salts*, instead of by the corresponding acids (hydrogen-salts), *e. g.*

we find that the combination or separation of the resulting cyanides is not determined by the constitution of the original double cyanide, since the components of the same double cyanide (cyanide of nickel and potassium for example), may separate when the alkali-metal is replaced by hydrogen, whereas, when it is replaced by a metal, the resulting cyanides remain united.

Neither can any difference of constitution in the two classes of double cyanides be inferred from the fact that some of these compounds, containing two heavy metals, the cyanide of nickel and copper, for example, are decomposed by acids, whereas others, as the cyanide of iron and copper, are not, this difference being due rather to the different nature of the metals present. Prussian blue, which is a ferrocyanide of iron, Fe^2Cy^3 , or $(Ffe)^2Fe^3Cy^3$,* produced by the action of ferrocyanide of potassium on sesquichloride of iron, is not at all attacked by dilute acids, whereas, if one portion of the iron existed within the radicle and the rest without, the latter portion might be expected to dissolve in acids while the former remained. So likewise with the different

* $Ffe = Fe^2$.

behaviour of double cyanides with sulphydric acid; it is the nature of the heavy metal that determines whether decomposition shall take place or not, rather than any peculiarity of molecular constitution; thus, cadmium, mercury, and silver are easily precipitated by sulphydric acid from solutions of their double cyanides; nickel, copper, zinc, and manganese slowly and very imperfectly; iron and cobalt not at all.

With *alkalis*, the various double cyanides exhibit, for the most part, similar reactions. Those which contain alkali-metals are not decomposed at all by alkalis, even at the boiling heat. Those which contain only heavy metals, ferrocyanide of copper and the prussian blues for example, are decomposed in such a manner that part of the heavy metal is replaced by an alkali, so that a soluble double cyanide is formed, and a metallic oxide separated; but these decompositions often take place in such a manner as to show that no particular part of the metal is more intimately combined with the cyanogen than the rest; thus ferricyanide of iron (Turnbull's blue), Fe^3Cy^6 , or $\text{Fe}^3\text{Fe}''\text{Cy}^6$, yields with potash, not ferricyanide of potassium and ferrous oxide, but ferrocyanide of potassium and ferroso-ferric oxide.

Mercuric oxide and *mercuric sulphate* decompose all double cyanides, except the platinocyanides; thus, ferrocyanide of potassium and prussian blue are completely converted by them into cyanide of mercury, with formation of oxides or sulphates of iron.

All cyanides which give off prussic acid when treated with dilute acids, such as cyanide of potassium, cyanide of nickel and potassium, &c., are poisonous, like prussic acid itself, whereas the more stable cyanides, like ferrocyanide of potassium, are not at all poisonous.

Cyanides of Alcohol-radicles. *Cyanhydric or Hydrocyanic Ethers.* These compounds may be regarded either as analogous in composition to the metallic cyanides (*i.e.* as hydrocyanic acid having its hydrogen replaced by an alcohol-radicle), or as the *nitriles* of acid radicles containing 1 at. carbon more than the alcohol-radicle in combination with the cyanogen: thus,

Cyanides containing the Alcohol-radicles, $\text{C}^n\text{H}^{2n+1}$.

Cyanide of Methyl, or Acetonitrile	$\text{C}^2\text{H}^3\text{N} = \text{CH}^3.\text{Cy}.$
Cyanide of Trichloromethyl, or Chloracetone	$\text{C}^2\text{Cl}^3\text{N} = \text{CCl}^3.\text{Cy}.$
Cyanide of Ethyl, or Propionitrile	$\text{C}^3\text{H}^5\text{N} = \text{C}^2\text{H}^5.\text{Cy}.$
Cyanide of Tetryl, or Valeronitrile	$\text{C}^5\text{H}^9\text{N} = \text{C}^4\text{H}^9.\text{Cy}.$
Cyanide of Amyl, or Capronitrile	$\text{C}^6\text{H}^{11}\text{N} = \text{C}^5\text{H}^{11}.\text{Cy}.$
&c. &c.	

Cyanides containing the Alcohol-radicles, $\text{C}^n\text{H}^{2n-7}$.

Cyanide of Phenyl, or Benzonitrile	$\text{C}^7\text{H}^5\text{N} = \text{C}^6\text{H}^5.\text{Cy}.$
Cyanide of Nitrophenyl, or Nitro-benzonitrile	$\text{C}^7\text{H}^4\text{N}^2\text{O}^2 = \text{C}^6\text{H}^4(\text{NO}^2).\text{Cy}.$
Cyanide of Benzyl	$\text{C}^8\text{H}^7\text{N} = \text{C}^7\text{H}^7.\text{Cy}.$
Cyanide of Cumenyl, or Cumonitrile	$\text{C}^{10}\text{H}^{11}\text{N} = \text{C}^9\text{H}^{11}.\text{Cy}.$

The cyanides of the alcohol-radicles are obtained: 1. By distilling a mixture of cyanide of potassium with an ethyl-sulphate (or homologous salt), *e.g.*

2. By the action of heat or of phosphoric anhydride on the ammonium-salts of the corresponding acids containing the radicles $\text{C}^n\text{H}^{2n-1}\text{O}$, or $\text{C}^n\text{H}^{2n-9}\text{O}$; thus,

This last reaction gives the means of obtaining cyanides corresponding to alcohols which have not yet been formed.

The alcoholic cyanides are for the most part volatile liquids, having an odour somewhat like that of prussic acid. When treated with strong acids or alkalis, they take up water, and reproduce the ammonia-salts from which they may be formed. This action is analogous to that of cyanide of hydrogen (prussic acid), which, under the influence of acids or alkalis, yields ammonia and formic acid ($\text{CHN} + 2\text{H}^2\text{O} = \text{NH}^3 + \text{CH}^2\text{O}^2$). In fact, cyanide of hydrogen (or formonitrile, CH.N) may be regarded as the lowest term of the series of homologous alcoholic cyanides $\text{C}^n\text{H}^{2n-1}\text{N}$.

Cyanides of Acid Organic Radicles. Two only of these compounds are known, viz. the cyanides of benzoyl, C^7H^5O , and cinnamyl, C^9H^7O . They are obtained by distilling the chlorides of the corresponding acid radicles with metallic cyanides. Their reactions are analogous to those of the corresponding chlorides.

CYANIDE OF ALLYL. $C^3H^3N = C^3H^3Cy$. (Lieke, Ann. Ch. Pharm. cxii. 316.)—Obtained by heating equivalent quantities of cyanide of silver and iodide of allyl, and warming the resulting viscid oil with alcohol or ether, or distilling it with water. The product is a limpid mobile liquid, having a disagreeable pungent odour. Specific gravity = 0.794 at $17^\circ C$. Boils between 96° and $106^\circ C$. Somewhat soluble in water, miscible in all proportions with alcohol and ether.

CYANIDE OF ALUMINIUM does not appear to exist in the separate state. Hydrate of alumina does not dissolve in prussic acid, and when cyanide of potassium is added to an aluminium-salt, hydrate of alumina is precipitated free from prussic acid. A ferrocyanide of aluminium has, however, been obtained. (See CYANIDES OF IRON.)

CYANIDE OF AMMONIUM. *Hydrocyanate of ammonia.* $CN^2H^4 = NH^4Cy = NH^3.HCy$.—Ammonia-gas and vapour of hydrocyanic acid unite in equal volumes, without condensation, and produce this salt. It is likewise formed, as already observed (p. 198), when ammonia-gas is passed through a red-hot tube together with carbonic oxide, or over ignited carbonaceous matter; also when charcoal in excess is ignited in a retort with sal-ammoniac and lime, or litharge. Lastly, it is sometimes formed by the action of nitric acid, nitrous acid, or nitric oxide, on organic bodies.

The dry salt may be prepared by heating in the water-bath 3 pts. ferrocyanide of potassium with 2 pts. sal-ammoniac, the materials being perfectly dry, and condensing the product in a receiver surrounded with ice and salt. Cyanide of mercury or cyanide of potassium may also be used instead of the ferrocyanide. Langlois prepares the salt by passing dry ammonia-gas over dry charcoal heated to redness in a porcelain tube.

Cyanide of ammonium crystallises in colourless cubes, often grouped like fern-leaves, very soluble in water and alcohol. It has a strong pungent odour of ammonia and prussic acid together. It boils at $36^\circ C$. The vapour is very inflammable and burns with a bluish flame, depositing carbonate of ammonia. The density of the vapour is anomalous, the molecule $NH^3.HCy$ occupying four volumes instead of two. But as hydrocyanic acid unites directly with ammonia, we may suppose that the vapour of cyanide of ammonium is a mixture of these two bodies (the molecule of each occupying two volumes), and that the salt exists only in the solid form, being decomposed at its boiling point.

Cyanide of ammonium is very instable, and gradually changes into a brown substance, *azulmic acid* (i. 480). Chlorine and bromine decompose it, forming chloride or bromide of cyanogen.

Cyanide of ammonium is highly poisonous, and yet ammonia is generally said to act as an antidote to prussic acid; according to Langlois, the beneficial action is due to the stimulating properties of the ammonia.

CYANIDE OF AMYL. *Capronitrile.* $C^6H^{11}N = C^6H^{11}Cy$. (Balard, Ann. Ch. Phys. [3] xii. 294.—Frankland and Kolbe, Ann. Ch. Pharm. lxxv. 288.—Brazier and Gossleth, *ibid.* lxxv. 251.—Medlock, *ibid.* lxxv. 229.)—This compound is obtained by distilling equivalent quantities of amylsulphate and cyanide of potassium; also by the action of cyanide of potassium on chloride or oxalate of amyl. It is a very mobile oil, of specific gravity 0.8061 at $20^\circ C$, and vapour-density 3.335 (2 vol.). Boils at $146^\circ C$; is less soluble in water than cyanide of ethyl, and dissolves in alcohol in all proportions. Boiling potash converts it into ammonia and caproate of potassium:

Potassium decomposes it, with evolution of gas, and formation of an alkaloid resembling cyanethine.

CYANIDE OF BARIUM, $BaCy$, may be obtained in the dry state by igniting ferrocyanide of barium (Berzelius), or ferrocyanide of barium and potassium (Schulz), in a close vessel,—and in solution, by adding prussic acid to baryta-water till it no longer precipitates chloride of magnesium (Ittner). Margueritte and De Sourdeval (Compt. rend. l. 1100) prepare it on the large scale by passing air over an ignited mixture of carbonate of barium and finely divided carbon: the formation of the cyanide is said to take place with great facility. It is very soluble in water (F. and E. Rodgers), sparingly (Schulz, J. pr. Chem. lxxviii. 257), moderately soluble in alcohol, easily decomposed by carbonic acid. Heated to $300^\circ C$ in a stream of aqueous vapour, it gives off the whole of its nitrogen in the form of ammonia. (Margueritte and De Sourdeval).

CYANIDE OF BENZOYL. $C^8H^5O = C^7H^5O.CN$. Already described (i. 568).

204 CYANIDE OF BENZYL—CYANIDES OF CHROMIUM.

CYANIDE OF BENZYL. *Cyanide of TolyI or Toluenyl.* $C^6H^7N = C^7H^7.CN$. (See i. 573.)

CYANIDE OF BISMUTH has not been obtained. Alkaline cyanides added to bismuth-salts throw down only oxide of bismuth. (Haidlen and Fresenius.)

CYANIDE OF BUTYL. See CYANIDE OF TETRYL.

CYANIDE OF CACODYL. (i. 406.)

CYANIDE OF CADMIUM. $CdCy$. Obtained in white anhydrous crystals by dissolving recently precipitated hydrate of cadmium, at a gentle heat, in hydrocyanic acid. It is permanent in the air. According to Rammelsberg, cadmium-salts are not precipitated by alkaline cyanides. According to L. Gmelin, on the contrary (Handb. vii. 426), sulphate of cadmium forms with cyanide of potassium a white precipitate, soluble in excess of the cyanide,—a result confirmed by the observations of Wittstein, of Haidlen and Fresenius, and of Schöler. (Ann. Ch. Pharm. lxxxvii. 34.)

Cyanides of Copper and Cadmium.—a. $2CdCy.Cu^2Cy = Cd^2CuCy^3$.—Recently precipitated cadmic hydrate dissolves very slowly in excess of hydrocyanic acid, but quickly, and with evolution of carbonic acid and cyanogen, on the addition of recently precipitated cupric carbonate. If the addition of the latter substance be discontinued before the oxide of cadmium is completely dissolved, there remains a lavender-blue residue, which dissolves partially in boiling water (leaving pure oxide of cadmium) and forms a liquid, which soon becomes turbid and deposits a viscid milky substance, becoming crystalline as it cools, and apparently consisting of a mixture of two different salts. But if the addition of carbonate of copper be continued till the cadmic oxide is completely dissolved, a liquid is obtained which is colourless at first, but afterwards assumes a purple-red colour, gradually in the cold, more quickly at 20° to 25° C., and after being concentrated at 100° , soon deposits crystals of a dingy brown-red colour. The latter compound is sparingly soluble in cold water. From the solution in a small quantity of boiling water, it separates in the form of a red tenacious mass, which gradually solidifies to a net-work of crystals; but when recrystallised from a large quantity of boiling water, it forms shining, rose-coloured, oblique rhombic prisms, which are permanent in the air, and are not decomposed at 150° , but at higher temperatures become opaque, fuse, and quickly decompose. (Schöler, Ann. Ch. Pharm. lxxxvii. 48.)

b. $2CdCy.CuCy = Cd^2CuCy^3$.—When cadmic hydrate and cupric hydrate are dissolved together in hydrocyanic acid, and the colourless solution left to evaporate in the air, colourless, shining, oblique, rhombic prisms are obtained, which at 100° C. give off 18.4 per cent. of their weight, and crumble to a fine mealy powder. The salt is readily decomposed by acids. Both this and the preceding have a decided alkaline reaction and a peculiar metallic taste, leaving an irritating sensation in the throat. (Schöler).

Cyanide of cadmium forms several other double salts:

The *ferrous salt* is a yellow precipitate, obtained by mixing ferrous sulphate with cyanide of cadmium and potassium. It turns green when exposed to the air. The *lead-salt*, $CdPb^2Cy^3 = CdCy.2PbCy$, is a white precipitate, obtained in like manner with acetate of lead and the potassium-salt. It is decomposed by washing. The *mercury-salt*, $2CdCy.3Hg^2Cy^2$, obtained by dissolving cadmic hydrate and mercuric oxide in hydrocyanic acid, forms white, opaque, rectangular prisms, easily soluble in water and permanent in the air (Schöler). The *nickel-salt* is a white precipitate, soluble in excess of cyanide of cadmium and potassium, insoluble in acids. The *potassium-salt*, $CdKCy^2$, is obtained in shining regular octahedrons, anhydrous and permanent in the air, by evaporating a mixture of acetate of cadmium and cyanide of potassium. Weak acids separate prussic acid from it. Sulphydic acid precipitates all the cadmium. The *silver-salt* is a white precipitate, likewise soluble in excess of cyanide of cadmium and potassium.

CYANIDE OF CALCIUM. Obtained in aqueous solution by saturating aqueous prussic acid with slaked lime, filtering, and adding more prussic acid to the filtrate till it no longer precipitates magnesium-salts. It is decomposed by boiling, also by carbonic acid. C. Schulz prepares it in the same manner as the barium-salt, and finds that it crystallises in cubes.

CYANIDE OF CERIUM. Cyanide of potassium forms with cerous salts, a white gummy precipitate, which, however, quickly gives off hydrocyanic acid, and is converted into cerous hydrate. (Berenger, Ann. Ch. Pharm. xlii. 139.)

CYANIDE OF CETYL. $C^{16}H^{33}Cy$. (See i. 840.)

CYANIDES OF CHROMIUM. *Chromous Cyanide*, $CrCy$, is obtained on mixing a solution of chromous chloride in boiled water with a solution of cyanide of

potassium, as a white precipitate, soluble in excess of the alkaline cyanide; but it oxidises very quickly during washing, and is converted into a mixture of chromic cyanide and chromic oxide.

Chromic Cyanide, Cr^2Cy^3 , is precipitated on mixing a chromic salt with cyanide of potassium. If an aqueous solution of chromic chloride be added to a solution of cyanide of potassium, a light bluish grey precipitate is formed, insoluble in excess of the alkaline cyanide; but when the latter is added, drop by drop, to a solution of chromic chloride, the first portions of the precipitate redissolve in excess of the chromic salt; an excess of cyanide of potassium renders the precipitate persistent in the cold, but soluble on heating; and to render the precipitate quite permanent, a still larger quantity of cyanide of potassium must be added.

When a mixture of chromic hydrate, potash, and hydrocyanic acid is exposed to the air, it turns brown and yields crystals of a double cyanide of chromium and potassium, analogous in composition to ferricyanide of potassium, and capable of forming by double decomposition salts of corresponding constitution, called *chromicyanides*.

Chromicyanide of Cobalt is a blue precipitate.

Chromicyanide of Hydrogen, or *Hydrochromicyanic acid*, $3\text{HCy}.\text{Cr}^2\text{Cy}^3$, is obtained in crystals by decomposing the silver-salt suspended in water with sulphydric acid, and evaporating the filtrate in vacuo.

Chromicyanide of Lead is a white precipitate while moist, greyish when dry.

Chromicyanide of Potassium, $3\text{KCy}.\text{Cr}^2\text{Cy}^3$, forms crystals isomorphous with the ferricyanide, and exhibiting the faces $\infty\text{P} . + \text{P} . - \text{P} . [\text{P}\infty]$. The solution gives a white precipitate with *zinc-salts*, brick-red with *ferrous salts*, white with nitrate of silver; it does not precipitate nitrate of lead or ferric salts.

CYANIDE OF CINNAMYL. $\text{C}^{10}\text{H}^7\text{NO} = \text{C}^9\text{H}^7\text{O}.\text{Cy}$ (i. 990).

CYANIDES OF COBALT. *Protocyanide of Cobalt*, or *Cobaltous Cyanide*, is obtained by adding cyanide of potassium to a cobaltous salt, as a flesh-coloured or light cinnamon-coloured precipitate. It dissolves in excess of the alkaline cyanide; and the solution exposed to the air is converted into a double cyanide of cobalt and potassium, analogous in composition to the ferricyanides, and yielding by double decomposition a series of salts called *Cobalticyanides*, whose composition

is expressed by the general formula $3\text{MCy}.\text{Co}^2\text{Cy}^3 = \frac{\text{M}^3}{(\text{Co}^2)^3} \text{Cy}^6$; if we suppose these salts to contain *cobalticum*, $\text{co} = \frac{2}{3} \text{Co}$, the formula may be reduced to $\text{MCy}.\text{coCy} = \frac{\text{M}}{\text{co}} \text{Cy}^2$.

The *Sesquicyanide of Cobalt*, supposed to exist in these salts, is not known in the separate state.

Cobalticyanide of Ammonium, $(\text{NH}^1)^3\text{Co}^2\text{Cy}^6 + \frac{1}{2} \text{aq.} = 3\text{NH}^1\text{Cy}.\text{Co}^2\text{Cy}^3 + \frac{1}{2} \text{aq.}$, obtained by neutralising hydrocobalticyanic acid with ammonia, crystallises in rhombic tablets, very soluble in water, sparingly soluble in alcohol, and decomposing at 230°C .

Cobalticyanide of Barium, $\text{Ba}^2\text{Co}^2\text{Cy}^6 + 12 \text{aq.}$, obtained by dissolving carbonate of barium in hydrocobalticyanic acid, crystallises in colourless prisms, very soluble in water, insoluble in alcohol, efflorescing in warm air, and more quickly at 100°C .

Cobalticyanide of Cadmium is obtained as a brown precipitate, which afterwards turns white. It is soluble in acids and in excess of cobalticyanide of potassium.

Cobalticyanide of Cobalt, $\text{Co}^3\text{Cy}^6 = 3\text{CoCy}.\text{Co}^2\text{Cy}^3$, or $\frac{\text{Co}}{\text{co}} \text{Cy}^2$, analogous in composition to *Turnbull's blue* (see CYANIDES OF IRON), is prepared as follows:

1. Cobalticyanide of potassium forms with sulphate of cobalt, a light red precipitate, which may be completely freed from the potassium-salt by washing. The same precipitate is formed by adding hydrocobalticyanic acid to cobalt-salts.—2. When hydrocobalticyanic acid in the dry state is heated with strong sulphuric acid, and water added before the decomposition is complete (*vid. inf.*), cobalticyanide of cobalt is precipitated in the form of a pale red amorphous body. The product obtained by (1) contains 7 at. water, part of which it loses at 100°C , turning blue at the same time, and the rest at a higher temperature. The product obtained by (2) contains only 6 at. water; when heated it gives off water, and turns blue. Cobalticyanide of cobalt is perfectly insoluble in water. Caustic potash decomposes it, separating hydrated protoxide of cobalt. Ammonia dissolves it partially, forming a reddish solution, and separating a green powder. Mercuric oxide has no action upon it. The product (2) resists the action even of strong nitric and hydrochloric acids; from (1), however, strong acids extract water and turn it blue. The anhydrous compound has a deep blue colour; in contact with moist air, it rapidly absorbs water and turns red; when water is poured upon it, combination takes place, attended with great evolution of heat. (Zwenger, Ann. Ch. Pharm. lxii. 172.)

Cobaltcyanide of Copper, $3\text{CuCy}.\text{Co}^2\text{Cy}^6$.—The dense sky-blue precipitate which cobaltcyanide of potassium forms with cupric salts (Gmelin). It is also formed by precipitating cupric salts with hydrocobaltcyanic acid. It is insoluble in water and in acids; warm potash-ley separates cupric oxide from it; ammonia dissolves it completely, forming a blue solution. (Zwenger, Ann. Ch. Pharm. lxii. 170.)

Ammonio-cobaltcyanide of Copper, $2\text{NH}^3.\text{Cu}^3\text{Co}^2\text{Cy}^6$.—Crystallises by slow evaporation from the ammoniacal solution of cobaltcyanide of copper, in small, shining, azure-coloured, four-sided prisms, with octagonal summits; alcohol added to the ammoniacal solution throws down the compound as a blue, slightly crystalline powder of much lighter colour. The crystals are insoluble in water; when exposed to the air or heated to 100°C . they give off ammonia, become opaque, and assume a lighter colour. Acids withdraw the ammonia completely, leaving cobaltcyanide of copper in the form of a light blue powder. When the compound is heated with potash, ammonia is given off, cupric oxide separated, and cobaltcyanide of potassium left in solution. (Zwenger, loc. cit.)

Cobaltcyanide of Hydrogen, or *Hydrocobaltcyanic acid*, $\text{H}^3\text{Co}^2\text{Cy}^6 = 3\text{HCy}.\text{Co}^2\text{Cy}^3$.—Obtained (1.) by passing sulphuretted hydrogen through water in which cobaltcyanide of lead [or of copper] is diffused, then filtering and evaporating to the crystalline point.—2. By decomposing the concentrated aqueous solution of cobaltcyanide of potassium with a slight excess of sulphuric or nitric acid, adding absolute alcohol, and recrystallising the mass which remains after evaporation. Crystallises in deliquescent, colourless, transparent needles, having a strongly acid taste. When heated above 100°C . it first gives off water, then hydrocyanic acid, hydrocyanate of ammonia, and carbonate of ammonia, and at 250°C . leaves a blue powder, which at a higher temperature is converted into black carbide of cobalt. The aqueous solution suffers scarcely any decomposition by boiling. This acid decomposes carbonates and dissolves iron and zinc, with evolution of hydrogen. It dissolves in alcohol, but is insoluble in anhydrous ether; it is not decomposed by hydrochloric acid, fuming nitric acid, or aqua-regia. When heated with oil of vitriol, it is resolved into carbonic oxide, carbonic anhydride, sulphurous anhydride, sulphate of ammonium, and sulphate of cobalt; the addition of water before complete decomposition, gives rise to the separation of red cobaltcyanide of cobalt, which, when heated, gives off water and turns blue. (Zwenger, Ann. Ch. Pharm. lxii. 147.)

Cobaltcyanide of Iron (ferrosus) is a white precipitate obtained with ferrous sulphate and cobaltcyanide of potassium. Ferric salts give no precipitate with the latter. (Zwenger.)

Cobaltcyanide of Lead, $\text{Pb}^3\text{Co}^2\text{Cy}^6 + 2\text{aq.}$, obtained by decomposing carbonate of lead with hydrocobaltcyanic acid, crystallises in nacreous scales, very soluble in water, insoluble in alcohol. Ammonia added to the aqueous solution throws down a basic salt, $2\text{Pb}^3\text{Co}^2\text{Cy}^6.\text{PbHO}.3\text{Pb}^2\text{O}$. (Zwenger.)

Cobaltcyanide of Manganese is a white precipitate.

Cobaltcyanide of Mercurous is a white precipitate. *Mercuric salts* are not precipitated by cobaltcyanide of potassium.

Cobaltcyanide of Nickel, $\text{Ni}^3\text{Co}^2\text{Cy}^6$.—Cobaltcyanide of potassium forms with sulphate of nickel, a flaky precipitate of a light sky-blue colour (Gmelin), light-green (F. and E. Rodgers). The precipitate is not attacked by boiling hydrochloric acid (Liebig).—According to Zwenger, the precipitate obtained by adding cobaltcyanide of potassium to nickel-salts always contains cobaltcyanide of potassium, which cannot be removed by washing. To obtain cobaltcyanide of nickel in a state of purity, it is necessary to precipitate a nickel-salt with excess of hydrocobaltcyanic acid. The precipitate thus obtained is gelatinous, of a light blue colour, and when exposed to the air, dries up to a transparent, greenish-blue, vitreous mass, exhibiting a conchoidal fracture. It is perfectly insoluble in water and in acids. Potash-ley decomposes it, separating hydrated oxide of nickel, but ammonia dissolves it completely. Dried at 100°C ., it contains 6 at. water. At a higher temperature, it gives off its water and turns grey; but the anhydrous compound, when exposed to the air, quickly absorbs a quantity of water equal to that which it has lost, and resumes its original colour. (Zwenger, Ann. Ch. Pharm. lxii. 173.)

Ammonio-cobaltcyanide of Nickel, $2\text{NH}^3.\text{Ni}^3\text{Co}^2\text{Cy}^6 + \frac{7}{2}\text{aq.}$.—Recently precipitated cobaltcyanide of nickel dissolves readily in ammonia, forming a bluish solution, which, when slowly evaporated, deposits the ammonia-compound in bluish crystalline scales. The compound may also be precipitated from the ammoniacal solution by alcohol; the precipitate is white at first, but when allowed to settle down quietly, it assumes a bluish colour. The precipitate is amorphous, and insoluble in water. Acids withdraw the ammonia, and leave cobaltcyanide of nickel in the form of a light blue powder. This compound undergoes no alteration when heated in the air to 100°C .; at a higher temperature it takes fire, and burns away with strong intumescence. (Zwenger, loc. cit.)

Cobalticyanide of Potassium, $K^3Co^2Cy^6 = 3KCy.Co^2Cy^3$.—Obtained: 1. By treating protoeyanide of cobalt with aqueous cyanide of potassium, or by gently heating carbonate of cobalt with potash and hydrocyanic acid. If the action takes place in a close vessel, it is attended with evolution of hydrogen (Gmelin):

in contact with the air, however, no evolution of hydrogen takes place, but oxygen is absorbed. The product is purified by recrystallisation. If the crystals are contaminated with cyanide or carbonate of potassium, these salts must be decomposed with acetic acid, and the solution precipitated by alcohol.

Cobalticyanide of potassium forms anhydrous flattened prisms, transparent, slightly yellow, and isomorphous with ferrocyanide of potassium. Ordinary combination $+P. -P. \infty P\infty. [\infty P\infty]$, the face $-P$ sometimes predominating over $+P$. Twin crystals likewise occur. The salt is very soluble in water, insoluble in alcohol. When heated it melts to a dark olive-green mass, and if not in contact with the air, gives off nitrogen and cyanogen, ultimately leaving cyanide of potassium and carbide of cobalt. Sulphuric or nitric acid, added in excess to a strong solution of the salt, throws down cobalticyanide of hydrogen. The dry salt heated with strong sulphuric acid, is completely decomposed, giving off a mixture of carbonic oxide and carbonic anhydride, and leaving sulphate of cobalt mixed with sulphate of ammonium.

Cobalticyanide of Silver, $Ag^3Co^2Cy^6 = 3AgCy.Co^2Cy^3$, obtained by precipitating nitrate of silver with cobalticyanide of potassium, is a white curdy mass, anhydrous, insoluble in water and in acids, not altered by light.

It dissolves in ammonia, and the solution yields by evaporation colourless prisms of *ammonio-cobalticyanide of silver*, $NH^3.Ag^3Co^2Cy^6 + \frac{1}{2} aq.$, or *cobalticyanide of silver and argentammonium*, $Co^2Cy^3 \left\{ \begin{array}{l} (NH^3Ag)Cy \\ 2Ag\ Cy \end{array} \right\} + \frac{1}{2} aq.$

Cobalticyanide of Sodium, $Na^3Co^2Cy^6 + 2 aq.$, prepared by saturating hydro-cobalticyanic acid with carbonate of sodium, forms colourless transparent needles, very soluble in boiling water.

Cobalticyanide of Tin (stannous), is a white precipitate.

Cobalticyanide of Zinc is a white precipitate.

CYANIDES OF COPPER. Cyanogen unites with copper in three different proportions, forming the cupric, cuprous, and cuproso-cupric cyanides, the last of which may be regarded as a compound of the other two.

PROTOCYANIDE OF COPPER or **CUPRIC CYANIDE**, $CuCy$, is known only in the hydrated state, and is obtained as a brown-yellow precipitate by adding cyanide of potassium, not in excess, to cold solutions of cupric salts (Scheele), or hydrocyanic acid to solution of cupric acetate (Pagenstecher). It is very unstable, decomposing spontaneously, even at ordinary temperatures, into cyanogen and hydrated cuproso-cupric cyanide; hence its properties are but little known.

According to Buignet (J. Pharm. [3] xxxv. 168), cupric cyanide is produced only when cupric sulphate is added to excess of cyanide of potassium, as a yellow-green precipitate which subsequently redissolves; if, on the contrary, the cyanide of potassium is added to excess of the cupric salt, cyanogen is evolved and cuprous cyanide is formed.

Cuprico-cyanide of Potassium, $KCy.CuCy$, separates on evaporation from the above-mentioned solution of cupric cyanide in cyanide of potassium, in rhombohedral crystals. It dissolves in $\frac{3}{4}$ of its weight of water at $15^\circ C.$, and in $\frac{1}{2}$ pt. at the boiling heat. The saturated solution boils at about 120° . The solution, which is colourless, is precipitated by fixed alkalis and coloured by ammonia (Baignet).

HEMICYANIDE OF COPPER, or **CUPROUS CYANIDE**, Cu^2Cy , or $CuCy$. *Dicyanide of Copper*.—This compound is obtained in the form of a white hydrated powder by adding cyanide of potassium or hydrocyanic acid to a solution of hemichloride of copper in hydrochloric acid, or to a solution of cupric sulphate mixed with sulphurous acid. The precipitate is soluble in aqueous ammonia, dilute acids, and alkaline cyanides. It melts when heated, giving off water, and leaving a light brown-red tumefied mass.

Cuprous cyanide may be obtained in anhydrous crystals, possessing considerable lustre, by suspending in water the compound of cuprous cyanide and cyanide of lead, and passing sulphydric acid gas into the liquid, taking care to avoid an excess. *Hydrocuprocyanic acid* (cyanide of cuprosium and hydrogen) appears then to be formed, and if the filtered liquid be left to evaporate spontaneously, it gives off hydrocyanic acid and deposits cuprous cyanide (Wöhler, Ann. Ch. Pharm. lxxviii. 370).—According to Dauber (*ibid.* lxxiv. 216), the crystals belong to the monoclinic system, the

dominant faces being ∞P , $\infty P\infty$, $\circ P$. Inclination of ∞P : ∞P in the plane of the clinodiagonal and principal axis = $68^\circ 32'$; $\circ P$: $\infty P = 70^\circ 16'$; $\circ P$: $\infty P\infty = 53^\circ 10'$. Ratio of orthodiagonal to clinodiagonal = $0.5453 : 1$. Cleavage perfect, parallel to $\circ P$.

Cuprous cyanide unites with the cyanides of the alkali-metals, forming colourless salts, which may be called cuproso-cyanides, from which acids, added to their solutions, precipitate cuprous cyanide in thick white flakes with evolution of hydrocyanic acid.

Cuprosocyanide of Ammonium, $NH^4Cu^2Cy^2$, or $NH^4Cy.CuCy$.—If in the preparation of diammoniacal cuproso-cupric cyanide (p. 209), the passage of the gas be continued after the needles of the green cyanide have formed, these crystals first redissolve, after which the liquid gradually loses its colour. When concentrated and left to cool slowly, it deposits beautiful, colourless, prismatic needles of cuprosocyanide of ammonium. This salt is but sparingly soluble in water, and decomposes when continuously boiled therein. At $100^\circ C$, it gives off cyanide of ammonium, and at a temperature a little above, is rapidly converted into cuprous cyanide. (Dufau, Compt. rend. xxxvi. 1099.)

Cuprosocyanide of Barium.—When aqueous hydrocyanic acid is poured upon a mixture of carbonate of copper and hydrate of barium, the whole dissolves with brisk effervescence, forming a crimson solution, which leaves a colourless residue when evaporated. Water poured upon the residue dissolves out the colourless double cyanide, leaving a residue of carbonate of barium. (Meillet.)

Cuprosocyanide of Bismuth.—Cuprosocyanide of potassium *a* (p. 210) forms, with bismuth-salts, a yellowish-white precipitate, which dissolves in acids with evolution of hydrocyanic acid. (Ittner.)

Cuprosocyanide of Cadmium.—Cyanide of cadmium and potassium, added to solution of sulphate of copper, throws down a brownish-white precipitate, with evolution of cyanogen gas. (Rammelsberg.)

Cuprosocyanide of Copper, or *Cuproso-cupric Cyanide*, $Cu^3Cy^2 = CuCy.Cu^2Cy$
 $= \begin{matrix} Cu \\ Cu \end{matrix} \} Cy^2$ —The brownish-yellow hydrated cupric cyanide precipitated by cyanide of potassium from cold solutions of cupric salts (p. 207) gradually gives off cyanogen, and is converted into cuproso-cupric cyanide (Wöhler, Gmelin). The same compound is obtained by precipitating a cupric salt with cuprosocyanide of potassium (Rammelsberg). When washed and dried at ordinary temperatures, it forms siskin-green crystalline granules, or transparent prisms, having a strong lustre.

According to Dufau (Compt. rend. xxxvi. 1099), cuprous and cupric cyanide form two compounds, one having the composition just given, the other containing 2 at. cuprous to 1 at. cupric cyanide.

a. Dufau prepares the preceding compound by passing into a tolerably dilute solution of a cupric salt, a solution equally dilute of cyanide of potassium or hydrocyanic acid, in such proportion as to leave a considerable quantity of the copper-salt undecomposed;—or by passing a stream of hydrocyanic acid vapour into water in which cupric oxide is suspended. The precipitate formed is yellow at first, but rapidly becomes green, and gives off a considerable quantity of cyanogen. The green precipitate, which has a crystalline aspect, contains $\frac{1}{2}$ at. water, so that its formula is $Cu^3Cy^2 + \frac{1}{2} aq$. At $100^\circ C$, it gives off water without decomposing, but at higher temperatures it gives off cyanogen, and is converted into cuprous cyanide. Acids separate white cuprous cyanide from it, producing at the same time a cupric salt, and eliminating hydrocyanic acid. Caustic potash transforms it into cuprocyanide of potassium and cupric oxide. Ammonia dissolves it very easily, forming a blue liquid, which, by spontaneous evaporation deposits beautiful green needles of diammoniacal cuproso-cupric cyanide (p. 209).—It dissolves very readily in aqueous cyanide of potassium, forming a colourless or slightly bluish liquid, which soon changes to a crystalline mass, having a nacreous aspect, and consisting of cuprosocyanide of potassium; its formation is attended with evolution of cyanogen.

b. $2Cu^2Cy.CuCy + \frac{1}{2} aq. = \begin{matrix} Cu \\ Cu \end{matrix} \} Cy^3 + \frac{1}{2} aq$.—When a cupric salt is precipitated by a moderately concentrated solution of cyanide of potassium added in sufficient quantity to throw down nearly all the copper, an amorphous powder is obtained of an olive-yellow colour, and a large quantity of cyanogen is given off: the precipitate has the composition above stated.—Both this compound and the preceding (*a*) are very instable, sometimes decomposing spontaneously, sometimes on the slightest rise of temperature, and, especially in presence of a large excess of hydrocyanic acid, giving off cyanogen, and leaving cuprous cyanide. (Dufau.)

Ammoniacal Cuproso-cupric Cyanide, $NH^3.Cu^2Cy.CuCy. + \frac{1}{2} aq. = \begin{matrix} NH^3Cu \\ Cu \end{matrix} \} Cy^2 + \frac{1}{2} aq$

—When a solution of cyanide of ammonium is mixed with a cupric salt, a considerable quantity of cyanogen is disengaged, and a bluish-green precipitate is formed containing ammonia, and having the composition just stated. — Bluish green amorphous powder, slightly soluble in cold water, to which it imparts a faint blue colour; when boiled in water, it gives off ammonia and is resolved into cuprocyanide of ammonium, which remains in solution, and cuprous cyanide, which is precipitated. — The cuprous cyanide obtained in this and in certain similar reactions has more or less of a brown colour, but is identical in composition with the white cyanide. The compound is permanent in the air at ordinary temperatures, but gives off water and ammonia at 100°C.; a heat somewhat greater converts it rapidly into cuprous cyanide. (Dufau.)

Diammoniacal Cuproso-cupric Cyanide, $2\text{NH}^3.\text{Cu}^2\text{Cy}.\text{CuCy} = \frac{\text{NH}^3\text{Cu}}{\text{NH}^3\text{Ceu}} \left\{ \text{Cy}^2 \right\} \cdot 1$. The preceding compound dissolves readily in ammonia, forming a sky-blue liquid, which by spontaneous evaporation deposits beautiful green needles, having the composition just stated. — 2. A more convenient method of obtaining this compound is to pass a stream of hydrocyanic acid vapour into ammonia containing cupric oxide in suspension. The oxide of copper dissolves at first under the influence of the hydrocyanic acid; but, after a while, small brilliant green needles appear in the liquid, and increase rapidly in quantity; the operation is then to be stopped, and the liquid left to cool, whereupon it deposits another crop of the green needles. — 3. This salt is also formed by dissolving cuprous cyanide in ammonia. The solution remains colourless if protected from the air, but, if oxygen has access to it, in ever so small a quantity, it rapidly turns blue, and when evaporated, deposits the green needles of the diammoniacal salt. — Diammoniacal cuprosocupric cyanide forms beautiful green prismatic needles, having a metallic lustre; it is unalterable in the air, insoluble in water, and exhibits with various reagents the same actions as cuprosocupric cyanide and the monammoniacal compound. (Dufau.)

Triammoniacal Cuproso-cupric Cyanide, $3\text{NH}^3.\text{Cu}^2\text{Cy}.\text{CuCy} = \frac{\text{NH}^3\text{AmCu}}{\text{NH}^3\text{Ceu}} \left\{ \text{Cy}^2 \right\}$. — The diammoniacal compound dissolves readily in warm aqueous ammonia; and if the ammonia be constantly kept in excess by passing a stream of ammoniacal gas into the liquid, the solution, when afterwards left to cool, deposits, either prismatic needles or crystalline plates of a fine blue colour. — This salt, when exposed to the air, gives off ammonia and turns green. It may also be prepared from cuprosocupric cyanide, or the monammoniacal compound. (Dufau.)

Diammoniacal Dicroso-cupric Cyanide, $2\text{NH}^3.\text{CuCy}.2\text{Cu}^2\text{Cy} = \frac{\text{NH}^3\text{Cu}}{\text{Ceu}} \left\{ \text{Cy}^2 \right\}$. —

When an ammoniacal solution of cupric oxide is poured into aqueous hydrocyanic acid, till the odour of ammonia decidedly predominates, the slightly yellow liquid then heated to the boiling point, the heat kept up, and the gradual addition of the ammoniacal copper-solution continued till its dark blue colour no longer disappears, micaceous crystalline laminae make their appearance after a while. If the liquid be then filtered, it yields, on cooling, green rectangular laminae of remarkable lustre. They have a composition denoted by the preceding formula together with 1 at. water. On heating them with equal volumes of solution of caustic ammonia and carbonate of ammonium not too dilute, a blue solution is obtained, which, after boiling for an hour, deposits shining blue laminae of the anhydrous compound. The green laminae also turn blue when treated with the fixed alkalis or their carbonates, even in the cold.

The compound is quite insoluble in cold water, and is decomposed by boiling water, with formation of a brown substance. Dilute acids separate from it white cuprous cyanide, which dissolves on boiling, with evolution of hydrocyanic acid. (Hilkenkamp, Ann. Ch. Pharm. xeviii. 218.)

Monthiers (J. Pharm. [3] xi. 257), by precipitating cupric sulphate with cyanide of cuprosum and ammonium, obtained a yellow precipitate, to which he assigned the formula $\text{NH}^3.\text{CuCy}.2\text{Cu}^2\text{Cy}.\text{HO}$.

Cuprosocyanide of Iron. — *a*. Cuprosocyanide of potassium, *a*, forms, with ferric salts, a greenish yellow precipitate, from which acids dissolve out cuprous cyanide, leaving a residue of protocyanide of iron (Ittner). The precipitate is white, but turns yellow when exposed to the air, the surface becoming yellowish green (Rammelsberg). — *b*. Cuprosocyanide of potassium *c* forms a yellow precipitate, which turns greenish on exposure to the air (Rammelsberg); according to F. & E. Rodgers, the precipitate is white. With ferrous sulphate free from ferric oxide, no precipitate is formed (Gmelin). For the other double cyanides of copper and iron, see CYANIDES OF IRON.

Cuprosocyanide of Lead.—*a.* The potassium-salt forms, with lead-salts, a whitish green precipitate (white, according to Rammelsberg), which dissolves in acids with evolution of hydrocyanic acid (Ittner).—*b.* The copper-salt *b* precipitates lead-salts in fine, white, curdy flakes. (Gmelin.)

Cuprosocyanide of Manganese.—*a.* Cuprosocyanide of potassium *a* forms with manganous salts a yellowish white precipitate, which dissolves in acids with evolution of hydrocyanic acid (Ittner).—*b.* The potassium-salt *c* forms a white precipitate with manganous salts. (Gmelin.)

Cuprosocyanide of Potassium.—Cuprous cyanide forms three compounds with cyanide of potassium.

a. $\text{KCy.Cu}^2\text{Cy} = \frac{\text{K}}{\text{Cu}} \left\{ \text{Cy}^2 \right\}$.—This salt was discovered by Ittner, and further investigated by Leopold Gmelin and Rammelsberg.

Preparation.—1. Cupric hydrate or cuproso-cupric cyanide, is dissolved in aqueous cyanide of potassium, and the filtrate evaporated to the crystallising point (Ittner). Monthiers pours excess of potash on hydrated cupric oxide, and adds hydrocyanic acid till the hydrate is dissolved, and the liquid becomes quite colourless. To obtain a perfectly white salt, he avoids the application of heat.—2. Cuprous cyanide is precipitated by cyanide of potassium from the solution of cuprous chloride in hydrochloric acid, and potash added to the liquid till it reddens turmeric, then hydrocyanic acid till its odour becomes permanent, then potash again, and so on alternately; the residual white powder is then dissolved by adding a large quantity of water and boiling, and the liquid is evaporated and cooled. The salt *a* crystallises out first, afterwards the more soluble salt *b* (Gmelin).—3. This compound may also be obtained by adding cyanide of potassium to the aqueous solution of acetate of copper till the precipitate which forms at first is redissolved. The solution, which is formed with evolution of cyanogen, assumes at first a purple-red colour, but afterwards on further addition of cyanide of potassium and heating, turns yellow (Rammelsberg).—The solution, whether prepared according to 1, 2, or 3, yields on evaporation or cooling, first, a comparatively small quantity of the crystallised salt *a*, and then, by further evaporation and cooling, a larger quantity of the crystals *c*. (Rammelsberg.)

The salt forms transparent monoclinic crystals, exhibiting the faces $\text{oP} + 2\text{P}\infty - 2\text{P}\infty - \infty\text{P} - \text{P} [\text{P}\infty]$. The crystals are often much elongated in the direction of the orthodiagonal. Inclination of $\infty\text{P} : \infty\text{P}$ in the clinodiagonal section = $94^\circ 30'$; $\text{oP} : -\text{P} = 131^\circ 54'$; $\text{oP} : -2\text{P}\infty = 126^\circ 13'$; $\text{oP} : [\text{P}\infty] = 136^\circ 46'$. Inclination of clinodiagonal to principal axis = $77^\circ 8'$ (Rammelsberg, Pogg. Ann. cvi. 491). The crystals are pale yellow according to Ittner and Gmelin, but colourless according to Rammelsberg, who regards the colouring as incidental; also according to Meillet (J. Pharm. [3] iii. 443) and Monthiers (*ibid.* xi. 255). Taste bitter and metallic.

The crystals, when heated, give off a small quantity of water [probably only hygroscopic], become white and opaque, and afterwards fuse to a transparent liquid, pale blue by transmitted light, but having fine brown-red particles floating in it, which impart a brown-red colour to it by reflected light; no further decomposition ensues at a moderate red heat (Gmelin). These brown-red particles, which separate from the originally colourless liquid, consist of very finely divided copper, whence also proceeds the blue colour which the liquid afterwards exhibits by transmitted light (Rammelsberg). Sulphuretted hydrogen passed through the aqueous solution, throws down but a small quantity of copper, even after a long time (Ittner, Rammelsberg). The stronger acids added in small quantity throw down white cuprous cyanide and eliminate hydrocyanic acid (Gmelin). The same effect is produced by the salts of ferric and stannic oxide, excepting that the hydrates of these oxides are at the same time precipitated (Ittner). Mercuric salts throw down cupric [? cuprous] cyanide, with formation of cyanide of mercury and a potassium-salt. Alkalis have no action on this compound (Ittner.) The crystals dissolve sparingly in water, with partial separation of cuprous cyanide, whereby they become opaque, and afterwards crumble to a white powder. The solution when evaporated first yields crystals of the salt *a*, then of *c*; the former is therefore rendered soluble in water only through the medium of the latter. (Rammelsberg.)

b. $2\text{KCy}.3\text{Cu}^2\text{Cy} = \frac{\text{K}^2}{\text{Cu}^3} \left\{ \text{Cy}^5 \right\}$.—Formed by the action of potash on cuprous cyanide. (Rammelsberg, Pogg. Ann. lxiv. 65.)

c. $3\text{KCy.Cu}^2\text{Cy} = \frac{\text{K}^3}{\text{Cu}} \left\{ \text{Cy}^4 \right\}$.—Discovered by Gmelin, more minutely examined by Rammelsberg. Prepared in the same manner as the salt *a*. In some cases, the salt *a* crystallises first from the liquid, and afterwards the salt *b*; or, if the quantity of cyanide of potassium present be considerable, the salt *b* crystallises out alone. According to Prince Bagration (J. pr. Chem. xxx. 367), copper dissolves in aqueous

cyanide or ferrocyanide of potassium, and in this reaction the same salt is produced together with free potash.

This salt forms colourless, transparent, rhombic prisms, truncated on the lateral edges, and having 6-sided summits (Gmelin). Permanent in the air (Rammelsberg); acquires a bluish white tint after long keeping (Gmelin). The crystals decrepitate when heated, and at a temperature much below redness they fuse without loss of water, and form a liquid which is likewise blue by transmitted, and brown-red by reflected light, and does not undergo any further decomposition at a moderate red heat; on cooling, it solidifies into a mass coloured reddish white by admixed particles of copper. Small quantities of the stronger acids precipitate cuprous cyanide from the solution, and liberate hydrocyanic acid (Gmelin). A similar effect is produced by ferric salts, a precipitate of hydrated ferric oxide being, however, formed at the same time (Rammelsberg). Mercurous nitrate forms a green precipitate (Gmelin). The salt dissolves readily in water, and its warm concentrated solution takes up a considerable quantity of the salt *a*, so that, as it cools, crystals of *a* separate out (Rammelsberg). The solution of the salt *c* forms a pale yellow precipitate with cupric salts (Gmelin, F. & E. Rodgers). This precipitate should be $\text{Cu}^{\text{c}}\text{Cy}^{\text{d}}$ or $\text{Cu}^{\text{c}}\text{CuCy}^{\text{d}}$.

This salt forms colourless, transparent, monoclinic prisms, exhibiting the faces $\infty\text{P} \cdot \text{oP} \cdot -\text{P} \cdot [2\text{P}\infty]$, with the inclinations $\infty\text{P} : \infty\text{P}$ in the clinodiagonal principal section = $102^\circ 32'$; $\text{oP} : \infty\text{P} = 102^\circ 10'$; $\text{oP} : -\text{P} = 142^\circ 59'$; $\text{oP} : [2\text{P}\infty] = 130^\circ 57'$.

Cuproso-cyanide of Sodium.—Formed by precipitating the solution of the corresponding barium-salt with an equivalent quantity of sulphate of sodium. On evaporating the filtrate, it remains in the form of small needles permanent in the air. (Meillet, J. Pharm. [3] iii. 413.)

Cuproso-cyanide of Uranyl.—The potassium-salt *c* added to uranic chloride throws down a pale yellow powder. (Gmelin.)

Cuproso-cyanide of Zinc.—The potassium-salt *a* forms with zinc-salts a white precipitate, which dissolves in acids with separation of prussic acid (Ittner). The potassium-salt *c* forms curdy white flakes. (Gmelin.)

CYANIDE OF CUMENYL. See CUMONITRILE (p. 283).

CYANIDE OF ETHYL. *Propionitrile, Metacetonitrile, Hydrocyanic ether*, $\text{C}^3\text{H}^5\text{N} = \text{C}^3\text{H}^5\text{Cy}$.—This compound was discovered by Pelouze in 1834 (Ann. Ch. Pharm. x. 249), further examined by Frankland and Kolbe (*ibid.* lxx. 269, 288; Chem. Soc. Mem. iii. 386; Chem. Soc. Qu. J. i. 60), and by Dumas, Malaguti and Leblanc, Ann. Ch. Pharm. lxxiv. 329). It is obtained; 1. By distilling cyanide of potassium with ethylsulphate of potassium or barium, the distillate being purified by washing with water, drying over chloride of calcium, and rectification; but the preparation by this method is attended with the evolution of an intolerable odour, arising from a small quantity of a cyanogen-compound not yet examined, and the purification is very difficult.—2. By distilling pulverised cyanide of potassium with oxalate of ethyl (Löwig).—3. By distilling cyanide of potassium with iodide of ethyl mixed with four times its volume of alcohol, the condensing apparatus being so arranged that the distilled liquid may continually run back again, till, on being tested, it shows no trace of iodine; the contents of the retort are then distilled to dryness (Williamson, Phil. Mag. [4] vi. 205). According to Buckton and Hofmann (Chem. Soc. Qu. J. ix. 250), the cyanide of ethyl thus obtained contains a considerable quantity of alcohol, from which it cannot be freed by fractional distillation; and to obtain it pure it must first be converted into propionate of potassium by the action of caustic potash (*vid. inf.*), this salt freed from alcohol by distillation, then converted into propionic ether (by heating it with alcohol and sulphuric acid),—the ether converted into propionamide ($\text{N.H}^2.\text{C}^3\text{H}^5\text{O} = \text{C}^3\text{H}^5\text{NO}$) by the action of ammonia under pressure,—and the propionamide into propionitrile (cyanide of ethyl) by the action of phosphoric anhydride. Buckton and Hofmann, however, regarded this as the best method of obtaining pure cyanide of ethyl.

Cyanide of ethyl is a colourless liquid, of specific gravity 0.78 (Pelouze), 0.7889 at 12.6°C . (Frankland and Kolbe). It boils at 82°C . (Pelouze), at 88° (Frankland and Kolbe). It has a strong alliaceous odour, and is very poisonous (Pelouze). It is very soluble in water (Pelouze), moderately soluble, but separates on the addition of common salt (Frankland and Kolbe). It mixes in all proportions with alcohol and ether.

Cyanide of ethyl cohobated with *aqueous potash* is converted into propionate of potassium, with evolution of ammonia:

212 CYANIDE OF ETHYLENE—CYANIDES OF GOLD.

A similar decomposition is produced by *dilute sulphuric acid* (1 pt. strong acid to 2 pts. water), the products being propionic acid and sulphate of ammonium :

According to E. Meyer (J. pr. Chem. lxxvii. 147), sulphate of ethylamine is likewise formed. Heated with *fuming sulphuric acid*, it yields disulphetholic acid, $\text{C}^2\text{H}^4\text{S}^2\text{O}^6$, together with acid sulphate of ammonium and carbonic anhydride (Buckton and Hofmann (Chem. Soc. Qu. J. ix. 250) :

Cyanide of ethyl, treated with potassium at ordinary temperatures, is partly decomposed, yielding cyanide of potassium and hydride of ethyl, and partly polymerised into cyanethine, $\text{C}^9\text{H}^{15}\text{N}^3$ (Frankland and Kolbe). The formation of hydride of ethyl in this reaction must be due, either to the presence of water or alcohol in the cyanide of ethyl, or to the resolution of the liberated ethyl into hydride of ethyl and ethylene.

Cyanide of Ethyl and Silver.—When iodide of ethyl and cyanide of silver in equivalent quantities are heated together to 100°C . in a sealed glass tube, this compound is obtained as a viscid oil, which solidifies in the crystalline state on cooling. It is also obtained in fine shining crystals on heating to 100°C . a mixture of iodide of ethyl, cyanide of silver, and water. It does not yield pure cyanide of ethyl by dry distillation, but when distilled with water, or with potash, it yields a distillate which smells of cyanide of ethyl, and when treated with an acid, loses its odour and is converted into a salt of ethylamine. (E. Meyer, *loc. cit.*)

Cyanide of ethyl forms solid compounds with certain *metallic chlorides*, viz. $\text{C}^3\text{H}^5\text{N}.\text{SbCl}^3$, $\text{C}^3\text{H}^5\text{N}.\text{AuCl}^3$, $\text{C}^3\text{H}^5\text{N}.\text{PtCl}^2$, $2\text{C}^3\text{H}^5\text{N}.\text{SnCl}^4$, $2\text{C}^3\text{H}^5\text{N}.\text{TiCl}^4$; and liquid compounds with *chloride of carbonyl*, $\text{C}^3\text{H}^5\text{N}.\text{COCl}^2$, and *chloride of cyanogen*, $\text{C}^3\text{H}^5\text{N}.\text{CyCl}$. (Henke, Ann. Ch. Pharm. cvi. 280.)

CYANIDE OF ETHYLENE. $\text{C}^4\text{H}^4\text{N}^2 = (\text{C}^2\text{H}^2)^2.\text{Cy}^2$. (Maxwell Simpson, Proc. Roy. Soc. x. 574. Geuther, Ann. Ch. Pharm. cxx. 268.)—Produced by the action of cyanide of potassium on bromide or chloride of ethylene :

A mixture of 1 at. bromide of ethylene and 2 at. cyanide of potassium, with a considerable quantity of alcohol of specific gravity 0.840, is cohobated in the water-bath till the reaction is complete; the alcoholic liquid is then decanted and freed from alcohol by distillation; the semi-fluid residue is filtered at 100°C .; the filtrate is treated with a saturated solution of chloride of calcium; and the cyanide of ethylene, which rises to the surface in the form of a reddish oil, is washed with ether, and heated for some time to 140°C . to free it from admixed bromide of ethylene: this treatment does not, however, render it quite pure (Simpson). Geuther prepared the compound from chloride of ethylene, but the preparation is more difficult than with the bromide.

Cyanide of ethylene is, at ordinary temperatures, a brownish, semi-solid, crystalline mass, melting at 50°C . It dissolves readily in water and alcohol, less in ether. It cannot be distilled, but bears a tolerably high temperature without much decomposition. With nitric acid it forms a body which crystallises from alcohol in long needles. Heated with alcoholic potash, it acts similarly to cyanide of ethyl, giving off ammonia, and yielding succinate of potassium :

CYANIDES OF GOLD. Gold unites with cyanogen in two proportions, forming the aurous and auric cyanides; the latter, however, is known only in combination.

PROTOCYANIDE OF GOLD OR AUROUS CYANIDE, AuCy , is obtained by heating aurocyanide of potassium with nitric or hydrochloric acid. It is a lemon-yellow, crystalline powder, which, when examined by the microscope, appears to consist of hexagonal plates. It is insoluble in water, alcohol, and ether, has neither taste nor smell, and is not altered by exposure to the air. When heated, it gives off cyanogen and leaves metallic gold. It is not decomposed by nitric, hydrochloric, or sulphuric acid, even at the boiling heat; nitro-hydrochloric acid decomposes it slowly. Sulphydric acid has no action upon it; sulphhydrate of ammonium dissolves it to a colourless liquid, from which acids throw down sulphide of gold. It is soluble in ammonia. Potash decomposes it at the boiling heat, throwing down metallic gold. It is likewise soluble in hyposulphite of sodium.

Protocyanide of gold dissolves in the alkaline cyanides, forming double salts called aurocyanides, which precipitate the salts of other metals.

Aurocyanide of Ammonium, NH^4AuCy^2 , or $\text{NH}^4\text{Cy}.\text{AuCy}$, is obtained by mixing the saturated solutions of sulphate of ammonium and aurocyanide of potassium, pre-

precipitating the sulphate of potassium and the excess of sulphate of ammonium with absolute alcohol, and leaving the filtrate to crystallise by evaporation. It forms colourless anhydrous crystals having a strong metallic taste.

The solution of protocyanide of gold in boiling aqueous ammonia yields, on cooling, grey, shining scales, which give up their ammonia when heated, or on addition of hydrochloric acid.

Aurocyanide of Potassium, KAuCy_2 , may be obtained by dissolving aurous cyanide, auric oxide, or fulminating gold, in cyanide of potassium, the solution being attended with evolution of cyanogen in the second case, and of ammonia in the third. A convenient method of preparation is to dissolve 7 pts. of gold in nitro-muriatic acid, precipitate by excess of ammonia, and introduce the precipitate, after thorough washing, into a boiling solution of 6 parts of cyanide of potassium. The colourless solution, if not too dilute, deposits the aurocyanide in crystals on cooling. The mother-liquor yields by evaporation a fresh quantity of the salt, but very impure; it is evaporated with excess of hydrocyanic acid, and the residual aurous cyanide is washed with water and dissolved in cyanide of potassium (77 pts. cyanide of gold to 23 pts. of cyanide of potassium). The crystals are purified by recrystallisation from boiling water.

According to Prince Bagration (*J. pr. Chem.* xxxi. 367), metallic gold precipitated by ferrous sulphate dissolves in aqueous cyanide of potassium, slowly also in ferrocyanide of potassium, forming aurocyanide of potassium. The action requires, however, access of air, as shown by Elsner (*ibid.* xxxvii. 333), and is attended with formation of caustic potash:

Aurocyanide of potassium forms colourless elongated rhomboidal octahedrons or nacreous scales. It is permanent in the air, moderately soluble in water, sparingly in alcohol, insoluble in ether. Heated in a close vessel, it gives off cyanogen gas and leaves a mixture of gold and cyanide of potassium. Aqueous acids slowly decompose the solution, eliminating hydrocyanic acid, and precipitating aurous cyanide. Boiled with hydrochloric acid, it yields about 88 per cent. cyanide of potassium, together with chloride. A similar decomposition is produced by sulphuric, nitric, oxalic, and tartaric acids. Alkaline sulphhydrates do not decompose it. The aqueous solution mixed with mercuric chloride, yields, without evolution of hydrocyanic acid, a yellow precipitate, which increases on boiling, and assumes the deep yellow colour of aurous cyanide: the liquid contains cyanide of mercury and chloride of potassium, but no gold.

Aurocyanide of potassium is extensively used in electro-gilding. Its aqueous solution, especially when hot, gilds copper and silver, even without the aid of a voltaic battery, its place in the solution being supplied by an equivalent quantity of the other metal.

To obtain the gold which remains in the solution after it has been used for gilding, it should be evaporated to dryness, the residue finely pulverised and intimately mixed with an equal weight of litharge, then melted at a strong red heat, and the lead extracted from the button of lead and gold by warm nitric acid; the gold then remains in the form of a loose, yellowish-brown, spongy mass. (Böttger, *J. pr. Chem.* xxxvi. 169.)

The solution of aurocyanide of potassium forms a white precipitate with zinc-salts; yellowish-white with tin-salts; white with lead-salts; white with ferrous salts, changing to blue on addition of nitric acid; white with nitrate of silver; with chloride of manganese it forms small crystals.

TRICYANIDE OF GOLD, OR AURIC CYANIDE. AuCy_3 .—This compound is obtained, in the free state, according to Himly, by decomposing auricyanide of potassium with any of the stronger acids. It is more probable, however, as pointed out by L. Gmelin (*Handbook*, viii. 37), that the substance thus separated is auricyanide of hydrogen, HCy.AuCy_3 :

Moreover, as observed by Himly himself, the compound, when heated, gives off at first, not cyanogen, but hydrocyanic acid.

To prepare *auricyanide of hydrogen*, or *auriprussic acid*, an aqueous solution of auricyanide of potassium is mixed with excess of nitrate of silver; the liquid, containing the excess of the silver-salt, together with nitrate of potassium, is filtered; the precipitate, consisting of AgCy.AuCy_3 , is thoroughly washed with water, then diffused in water, and decomposed with frequent agitation, and at the ordinary, or at a very slightly elevated temperature (at higher temperatures a yellow colouring will appear, and protocyanide of gold will be formed), by a quantity of hydrochloric acid, not sufficient to decompose the whole; and the filtrate is evaporated to dryness in

vacuo over oil of vitriol and lime.—Or, auricyanide of potassium is mixed with hydrofluosilicic acid and evaporated to dryness; the residue exhausted with absolute alcohol; and the solution filtered from the silico-fluoride of potassium, and left to evaporate (Himly). The product thus obtained generally has a yellowish colour, arising from the admixture of a small quantity of protocyanide; it must therefore be dissolved in the smallest possible quantity of water or alcohol, and the filtrate left to evaporate in the air or in vacuo; for the application of heat would reproduce protocyanide of gold. (Himly.)

Auricyanide of hydrogen forms large colourless laminæ and tables, containing 3 at. water of crystallisation = $2\text{Au}^{\text{III}}\text{HCy}^4 + 3\text{H}^2\text{O}$ (Himly). They fuse at 50°C ., first giving off hydrocyanic acid, then cyanogen gas, and leave carbide of gold, which burns readily in the air, and is converted into pure gold. The aqueous solution, when evaporated over the water-bath, deposits part of the gold in the form of protocyanide. A boiling aqueous solution of *oxalic acid* exerts no reducing action. *Mercurous* or *mercuric nitrate*, heated with the solution, throws down protocyanide of gold, while cyanide of mercury remains in solution. *Mercuric chloride* forms no precipitate, even when the solution is heated. Auricyanide of hydrogen does not become moist when exposed to the air, but dissolves in water in every proportion, and almost as easily in alcohol and ether. (Himly.)

Auricyanide of Ammonium, $(\text{NH}^4)\text{Au}^{\text{III}}\text{Cy}^4$.—Hydrated auric oxide is added to hydrocyanate of ammonia, obtained by distilling ferrocyanide of potassium with sal-ammoniac and water, as long as it continues to dissolve; the colourless filtrate is heated, which causes a large quantity of ammonia to escape; the filtrate evaporated over the water-bath, during which process it becomes covered with a rusty yellow film; the dry residue exhausted with water; and the filtrate left to evaporate till it crystallises. The salt forms large, colourless, four and six-sided tables, which give off 5.06 per cent. of water at 100°C ., and turn reddish-white, yellow at a higher temperature, and give off hydrocyanate of ammonia, and when ignited in the air leave 58.7 per cent. of pure gold. They dissolve readily in water and alcohol, but are nearly insoluble in ether. (Himly, Ann. Ch. Pharm. xlii. 343.)

Auricyanide of Potassium, $\text{KAu}^{\text{III}}\text{Cy}^4$.—Formed by converting 7 pts. of gold into a solution of the chloride as neutral as possible, and gradually adding this liquid to a hot concentrated aqueous solution of 8 pts. cyanide of potassium. The colourless mixture, as it cools, deposits crystals, which may be purified by recrystallisation:

(Himly, Ann. Ch. Pharm. xlii. 340.) A similar process is adopted by Rammelsberg (Pogg, Ann. xlii. 133). According to Glassford and Napier, on the other hand, this mode of preparation yields, not auricyanide, but aurocyanide of potassium.

The salt forms large, colourless tables, which, when exposed to the air, effloresce quickly and turn milk-white; in vacuo (Himly) or at 100°C . (Rammelsberg), they give off all their water of crystallisation. The residue then melts to a brown liquid, from which part of the gold separates out, an evolution of cyanogen taking place at the same time (Rammelsberg). The salt, when heated, gives off 2 at. cyanogen, and is converted into aurocyanide of potassium, $\text{KC}y.\text{AuCy}$ (Himly).—Chlorine exerts a decomposing action only when aided by heat, chloride of cyanogen being then formed (Rammelsberg). Acids added to the solution of the salt produce no precipitate, but colour it yellow and eliminate hydrocyanic acid (Rammelsberg). *Mercurous nitrate*, boiled with the solution, forms a yellowish precipitate (Himly). The salt does not dissolve in absolute alcohol (Himly). Its aqueous solution is the best of all materials for galvanic gilding. (Meillet.)

Auricyanide of Silver is a curdy precipitate, formed by mixing the potassium-salt with nitrate of silver. It is soluble in ammonia, insoluble in nitric acid.

CYANIDE OF HYDROGEN. *Hydrocyanic* or *Cyanhydric acid*, CNH or $(\text{C}^2\text{NH})=\text{HCy}$. *Prussic acid*, *Acidum borussicum*, *Blausäure*, *Berlinerblausäure*.—This acid was discovered by Scheele in 1782 (*Opuscula*, ii. 148), further examined by Berthollet (*Mém. de l'Acad. d. Sc. de Paris*, 1787, p. 148), Proust (Ann. Chim. ix. 185, 225) and Ittner (*Beiträge zur Geschichte der Blausäure*, 1809), and first obtained in the pure and liquid state by Gay-Lussac in 1811 (Ann. Chim. lxxvii. 128; xcv. 136). It appears, however, to have been known to the Egyptian priests, who used it for poisoning the initiated who had been guilty of divulging the sacred mysteries. (Hoefer, *Histoire de Chimie*, i. 226.)

Occurrence.—The kernels of bitter almonds, peaches, apricots, plums, cherries, and quinces,—the blossoms of the peach, sloe, and mountain-ash,—the leaves of the peach, cherry-laurel, and Portugal laurel,—the young branches of the peach,—the stem-bark of the Portugal laurel and mountain-ash, and the roots of the last-named tree, when

soaked in water and distilled after a while, yield hydrocyanic acid, together with bitter almond oil. The juice of the root of *Jatropha Manihot* also yields hydrocyanic acid when distilled. But it is only in the moister parts of these substances that the acid exists ready formed; the greater part is produced during immersion in water, the amygdalin contained in the plants being then resolved, by the fermentative action of the emulsin, also present, into glucose, bitter almond oil, and hydrocyanic acid (i. 202), the last two substances passing over in the distillation.

Formation.—1. From metallic cyanides, by the action of sulphydric, sulphuric or hydrochloric acid.—2. In the dry distillation of azotised bodies, and by the action of nitric acid on certain organic substances,—in the preparation of nitrous ether for example. It is also found among the products obtained by distilling albumin, fibrin, casein, or gelatin with sulphuric acid and chromate of potassium, or sulphuric acid and peroxide of manganese.—3. By the action of heat on formate of ammonium: $\text{CH}(\text{NH}')\text{O}^2 = \text{CNH} + 2\text{H}^2\text{O}$ (Döbereiner, Buchner's Report. xv. 425).—4. By the decomposition of amygdalin (i. 222).—5. By the decomposition of various cyanogen compounds and of fulminates.

Preparation.—I. *Of the aqueous acid.*—a. *From hydrated Ferrocyanide of potassium.*—This salt, which consists of $\text{K}^4\text{Fe}^2\text{Cy}^6 \cdot 3\text{H}^2\text{O}$, is decomposed when heated above 100°C . with sulphuric acid and water, in such a manner that half the cyanogen passes over in the form of hydrocyanic acid, whilst a yellowish-white powder, $\text{K}^2\text{Fe}^4\text{Cy}^6$, is precipitated, and the residual liquid contains acid sulphate of potassium. The best proportion is 2 at. ferrocyanide of potassium to 6 at. sulphuric acid; therefore 2 . 211.4 pts. (=422.8 pts.) ferrocyanide of potassium, to 6 . 49 (=294 pts.) oil of vitriol (diluted with any convenient quantity of water),—therefore nearly 10 pts. of the ferrocyanide to 7 pts. oil of vitriol (Everitt, Phil. Mag. [3] vi. 97):

According to this calculation, 422.4 pts. ferrocyanide of potassium yield 3 . 27 (=81) pts. hydrocyanic acid (in the anhydrous state), or 100 pts. ferrocyanide yield 19.16 pts. of the acid. Geiger obtained by experiment 17.07, and Wackenroder 17.26.—A larger quantity of sulphuric acid does not act further on the precipitated KFe^2Cy^3 , and cannot therefore lead to a more abundant evolution of hydrocyanic acid; on the contrary, as it can no longer be taken up by the potash, it decomposes part of the liberated hydrocyanic acid into ammonia and formic acid, and consequently the hydrocyanic acid which distils over is smaller in quantity and contaminated with formic acid. It is better indeed to reduce the quantity of sulphuric acid to one-half (3.5 pts. oil of vitriol to 10 pts. ferrocyanide of potassium), so that neutral sulphate of potassium may be formed instead of acid sulphate; as, however, the neutral sulphate is but sparingly soluble, and is therefore deposited in the crystalline form during the distillation, it increases the percussive ebullition caused by the white crystalline powder, so that drops of the mixture are often thrown up, and mix with the distillate. Hence it is good to throw a few clippings of platinum-foil into the mixture.

The greater part of the hydrocyanic acid goes over in the beginning of the distillation at a temperature somewhat above 100°C .; and when the residual liquid attains a higher temperature, the water follows, containing but little hydrocyanic acid. A good condensing apparatus is therefore necessary; otherwise the hydrocyanic acid, which passes over at first,—since its boiling point is not above 27°C .,—will for the most part escape in vapour together with the air of the apparatus. Water in the receiver likewise tends to prevent this loss. It is not necessary to boil the residue down to dryness; it is sufficient indeed to distil off from $\frac{2}{3}$ to $\frac{3}{4}$ of the liquid, according to the quantity of water present.

It is unnecessary to dissolve the ferrocyanide in water before adding the sulphuric acid, as it readily dissolves in the water as the distillation goes on.

The distillatory apparatus must be so arranged as to prevent any portion of the mixture from spiriting over—to contain but little air, inasmuch as the air in escaping always carries hydrocyanic acid vapour with it—and to present the greatest possible amount of cooling surface.

If the distillate should become contaminated with sulphate of potassium and prussian blue by spiriting, it must be carefully rectified over a small quantity of magnesia, chalk, or carbonate of barium, in an apparatus affording ready means of condensation. This, however, occasions loss of prussic acid, and the rectified acid is much more prone to spontaneous decomposition.

b. *From Cyanide of Potassium.*—This salt is sometimes used for the preparation of hydrocyanic acid, because it is easily decomposed by dilute acids, even at ordinary temperatures. There is, however, greater difficulty in obtaining it in a pure and definite state, and, consequently of determining the exact amount of prussic acid that it will yield, a point of great importance in the preparation of the medicinal acid. Ordinary cyanide

of potassium, prepared by Liebig's process (see CYANIDE OF POTASSIUM), is not well adapted for the purpose, because it contains a considerable quantity of cyanate and carbonate of potassium, and the carbonic acid evolved by the decomposition of these salts prevents, to a considerable extent, the condensation of the hydrocyanic acid; moreover, the cyanic acid which also passes over is soon resolved into carbonic acid and ammonia, and the latter induces spontaneous decomposition of the hydrocyanic acid. It is necessary, therefore, to use cyanide of potassium free from cyanate, which, according to Wöhler, may be prepared by fusing in a covered crucible a mixture of dehydrated ferrocyanide of potassium, burnt tartar, and charcoal powder (p. 217). The cooled mass is then lixiviated with cold water, and the filtered solution of cyanide of potassium is distilled with sulphuric acid.

By the following method an acid of nearly definite strength may be obtained without distillation.

To a solution of 9 pts. tartaric acid in 60 pts. water, contained in a well-stoppered bottle nearly filled with it, 4 pts. of pure cyanide of potassium are added; the vessel is shaken, frequently dipped into cold water, and then left in the cold for twelve hours; and the aqueous hydrocyanic acid, which contains but a very small quantity of tartrate of potassium, is poured off from the crystallised tartrate (Th. Clarke, Lond. Med. Surg. J. vi. 524; also J. Chim. méd. vii. 544). According to calculation, this acid contains 3.6 per cent. of anhydrous prussic acid.

c. From Cyanide of Mercury.—1. Cyanide of mercury is agitated with iron filings, sulphuric acid, and water in a well-stoppered bottle, till the liquid no longer tastes of mercury—or better, till a portion of it taken out is no longer blackened by sulphuretted hydrogen—the solution then decanted from the iron and mercury into a retort, and distilled (Scheele):

According to this equation, 126 pts. cyanide of mercury require 49 pts., or rather more, of oil of vitriol, together with a considerable quantity of water, and at least 28 pts. of iron filings; an excess of iron, however, accelerates the decomposition. If the cyanide of mercury be carefully weighed, this method is very well adapted to produce an acid of definite strength. The acid distils over at a gentle heat. (Gmelin.)

2. Sulphydic acid gas is passed through an aqueous solution of cyanide of mercury as long as it is absorbed, and the solution separated by filtration from the sulphide of mercury (Proust, Vauquelin):

Vauquelin, who employs a solution of 1 pt. cyanide of mercury in 8 pts. water, frees the solution from excess of sulphuretted hydrogen by agitation with carbonate of lead, till fresh portions of that salt are no longer browned by it, and filters the liquid again. But even if these filtrations be performed in a well-covered filter, a considerable quantity of prussic acid is lost by evaporation, so that this process never yields an acid of definite strength; moreover, the acid thus prepared is apt to be somewhat contaminated with sulphocyanic acid and oxide of lead.

d. From Cyanide of Silver.—200 pts. of pure cyanide of silver are shaken up with 240 pts. hydrochloric acid of specific gravity 1.129, and, when the decomposition is complete, the hydrocyanic acid is separated from the chloride of silver by decantation (Everitt, Phil. Mag. [3] vi. 100).—This hydrocyanic acid may contain a small quantity of hydrochloric acid, but has the advantage of definite strength.

e. From Cyanide of Lead.—Pure cyanide of lead is decomposed by an equivalent quantity of dilute sulphuric acid (Thomson). As, however, the cyanide of lead is difficult to dry, the quantity of sulphuric acid required cannot be exactly determined; if too little be used, lead remains in solution. (Souberain, N. J. Pharm. i. 121.)

f. Hydrocyanic acid of perfectly definite strength can only be obtained by mixing weighed quantities of the anhydrous acid and water. Acid of the so-called Scheele's strength contains 5 per cent. of the anhydrous acid.

II. *Preparation of Anhydrous Hydrocyanic Acid.*—The great volatility and highly poisonous character of hydrocyanic acid renders this process very dangerous; it should therefore only be performed in winter, and with the aid of a freezing mixture.

It may be prepared directly by slowly passing dry sulphydic acid gas through a tube filled with dry cyanide of mercury—except at the further end, where there is placed a small quantity of carbonate of lead—and connected with a U-tube surrounded with ice and salt. The anhydrous acid then passes over and collects in the receiver in the liquid form. The passage of the gas must be stopped as soon as the carbonate of lead begins to blacken. (Vauquelin.)

A better mode of preparation, however, is to dehydrate the strong aqueous acid, obtained by either of the preceding processes, with fused and pulverised chloride of

calcium. Trautwein (Repert. xi. 13) distils 15 pts. of ferrocyanide of potassium with 9 pts. oil of vitriol and 9 pts. water, till 4 or 5 pts. of strong acid have passed over into the receiver, which must be surrounded with ice, or with a mixture of ice and salt; pours the acid into a strong bottle provided with a good stopper and kept cold by a freezing mixture; and adds pulverised chloride of calcium in small successive portions, and with frequent agitation, so that no great development of heat may take place. The mixture, after being left at rest for a while, separates into two layers, the lower one consisting of aqueous chloride of calcium, and the upper of hydrocyanic acid freed from part of the water. The acid is then poured into another bottle, and again treated with chloride of calcium; and this treatment is continued till fresh quantities of chloride of calcium added to the acid no longer become pasty and cake together, but remain pulverulent. By this treatment, Trautwein obtains from 2 to $2\frac{1}{2}$ pts. of anhydrous acid. Since a considerable quantity of acid is lost at each decantation, and moreover the vapour which escapes may exert a poisonous action, it is better to leave the acid in the first bottle and draw off the solution of chloride of calcium by a siphon. This siphon is filled with a saturated solution of chloride of calcium, closed with the finger at the end of the longer arm, and not opened till the shorter arm is depressed to the lowest part of the bottle held in a somewhat inclined position. As soon as the chloride of calcium solution has completely run out, the siphon is again closed with the finger and taken out. More chloride of calcium is then introduced, &c. As soon as a fresh portion of that substance no longer becomes pasty, the acid may be decanted into a well-cooled bottle containing pulverised chloride of calcium, and finally into a clean bottle (Gmelin). Or the acid, after being left for some time in contact with chloride of calcium, may be distilled off at the heat of the water-bath, the bottle being connected by a bent tube with a U-tube immersed in ice and salt.

Another method is to pass the vapour of the aqueous acid directly over chloride of calcium, which abstracts the water. A mixture of 8 pts. ferrocyanide of potassium, 3 pts. burnt tartar, and 1 pt. charcoal is fused in a covered crucible; the fused mass digested with six times its weight of water in a vessel which can be closed; and the clear solution decanted from the sediment of iron and charcoal into a tubulated retort, which is connected with a glass tube horizontal in the nearer part, bent downwards at a certain distance from the retort, and passing into a U-tube. This U-tube is placed within a cylinder containing cold water, and is filled with chloride of calcium, excepting at the end where the vapours enter, and at this end are placed small pieces of the fused mixture above mentioned. The other end of the U-tube is connected by a bent tube with the glass which serves as a receiver, and is surrounded with ice, or better, with a freezing mixture. A cooled mixture of 1 pt. oil of vitriol (the fused mixture whose solution is contained in the retort being supposed = 2) and 1 pt. water, is then poured into the retort by small portions at a time through a funnel-tube adapted to the tubulus. The mixture starts spontaneously into strong ebullition, so that the sulphuric acid must be added slowly; and the greater part of the hydrocyanic acid distils over without the application of heat. Finally, when all the sulphuric acid has been added, and the boiling has ceased, the retort is heated till the contents begin to boil gently; and the cylinder in which the chloride of calcium tube is immersed is emptied of cold water, and filled with water at 30° — 35° , to volatilise the prussic acid there condensed, and cause it to pass over into the receiver (Wöhler, *Berzelius Lehrb.* i. 816). As the U-tube sometimes becomes stopped up, Wöhler further recommends that the neck of the retort be inclined upwards at an angle of about 45° , and an intermediate vessel, containing a small quantity of chloride of calcium or cyanide of potassium, placed between the retort and the U-tube. The chloride of calcium tube and the intervening vessel are immersed, from the beginning of the operation, in water at 30° C., and the prussic acid vapour is condensed in a tall narrow vessel, surrounded with a mixture of ice and salt; the acid is then obtained in the form of a crystalline mass.

Properties.—Anhydrous hydrocyanic acid is, at common temperatures, a colourless liquid, of sp. gr. 0.7058 at 7° C., and 0.6969 at 18° C. (Gay-Lussac); it solidifies at 15° C., in feathery crystals. It boils at 26.5° C. Vapour-density, 0.947 by experiment (Gay-Lussac), by calculation, $\frac{26 + 1}{2} = 13.5$, referred to hydrogen as unity, $= 13.5 \times 0.0693 = 0.9405$ referred to air. It dissolves in water in all proportions, forming a solution which is lighter than water, and reddens litmus slightly; it is also miscible with alcohol.

The anhydrous acid or the strong aqueous solution burns with a faint violet flame. It has a peculiar odour like that of bitter almonds. It is excessively poisonous; a drop of the anhydrous acid producing instant death when swallowed. The vapour of the anhydrous or of the highly concentrated aqueous acid, is likewise instantly fatal when inhaled; the vapour diluted with air produces, when inhaled in small quantity, a peculiar irritation in the throat; in larger quantity, giddiness and head-ache. The

dilute aqueous acid has a cooling taste, with pungent bitter aftertaste; it is much used in medicine to allay irritation.

Decompositions.—1. The anhydrous acid quickly undergoes spontaneous decomposition, giving off ammonia and leaving a brown substance. The aqueous acid undergoes the same decomposition, part of it being, however, converted into formate of ammonium: $\text{CNH} + 2\text{H}^2\text{O} = \text{CH}(\text{NH}^4)\text{O}^2$. The decomposition takes place more quickly as the acid is stronger; the addition of a small quantity of another acid renders it more permanent; alkalis, on the other hand, accelerate the decomposition. Exposure to light also causes the change to take place more quickly; hence the acid should always be kept in the dark, or in bottles covered with black paper.—2. The vapour of hydrocyanic acid passed through a *red-hot tube*, is partly resolved into cyanogen and hydrogen gases; at the same time, however, a small quantity of nitrogen is set free and charcoal separated.—3. By *electricity*. The vapour of hydrocyanic acid is but slowly decomposed by the electric spark, with separation of a small quantity of carbon. The aqueous acid is decomposed by the voltaic current, hydrogen being evolved at the negative pole, while the cyanogen set free at the positive pole either remains dissolved or unites with the metal which forms the pole.—4. By *oxidation*. The anhydrous acid and its vapour, when set on fire, burn in contact with air or oxygen gas, producing carbonic anhydride, nitrogen, and water. The vapour mixed with oxygen explodes with great violence on the passage of an electric spark. For complete combustion, 2 volumes of the vapour require $2\frac{1}{2}$ vols. oxygen, and after the explosion, there remain 3 vols. of gas consisting of 2 vols. carbonic anhydride and 1 vol. nitrogen. Hence the composition of the vapour is determined: for the 2 vols. carbonic anhydride contain 2 vols. oxygen; consequently, the remaining $\frac{1}{2}$ vol. oxygen has been consumed in combining with the hydrogen (1 vol.) to form water. Hence the 2 vols. hydrocyanic vapour contain 1 at. carbon, 1 at. nitrogen, and 1 at. hydrogen. Many *metallic oxides* decompose hydrocyanic acid even at common temperatures; peroxide of lead forms with it, according to Liebig, cyanide of lead, water, and cyanogen.—The vapour of the acid mixed with hydrogen gas is completely absorbed by peroxide of manganese, without separation of cyanogen (Gay-Lussac). Basic metallic oxides generally convert the acid into water and a metallic cyanide.—5. By *chlorine*. The anhydrous acid poured into a bottle filled with dry chlorine, and exposed to sunshine, forms hydrochloric acid and solid chloride of cyanogen.

In presence of aqueous vapour, but little chloride of cyanogen is formed, the chief products of the reaction being sal-ammoniac, carbonic oxide, and carbonic anhydride:

Chlorine gas passed into dilute hydrocyanic acid forms hydrocyanate of chloride of cyanogen, $\text{C}^2\text{N}^2\text{Cl}^2.\text{CNH}$ (Wurtz, Ann. Ch. Pharm. lxxix. 280). When chlorine gas is passed into a mixture of strong aqueous hydrocyanic acid and alcohol, till carbonic acid begins to escape, a crystalline compound, $\text{C}^4\text{H}^2\text{NClO}^2$, is formed, sparingly soluble in cold water and in ammonia, somewhat more in boiling water, easily in alcohol and in ether. The same compound is formed on passing chlorine into an alcoholic solution of cyanide of mercury (*q. v.*) (Stenhouse.)

6. Bromine decomposes the aqueous acid, forming bromide of cyanogen. 7. *Iodine* does not decompose the vapour of hydrocyanic acid (Gay-Lussac). With the aqueous acid it forms hydriodic acid and liberates cyanogen. (Porrett.)

8. By *acids*. Strong hydrochloric or moderately dilute sulphuric acid decomposes hydrocyanic acid in a few minutes, even in the cold, and more quickly with aid of heat, into formic acid and ammonia, $\text{CNH} + 2\text{H}^2\text{O} = \text{CH}^2\text{O}^2 + \text{NH}^3$. Hydrochloric acid acts more quickly than sulphuric acid; the latter, if too strongly heated, further resolves the formic acid into water and carbonic oxide (Pelouze, Ann. Ch. Pharm. ii. 84). Small quantities of either of these acids, however, retard the spontaneous decomposition of prussic acid. (Gm. vii. 403.)

9. The *fixed alkalis*, at high temperatures, likewise resolve hydrocyanic acid into ammonia and formic acid.

10. *Potassium* burns when heated in the vapour of hydrocyanic acid, with formation of cyanide of potassium and evolution of hydrogen.

Detection and Estimation of Hydrocyanic acid.—1. Free hydrocyanic acid, if not too dilute or mixed with other odoriferous substances, may be recognised by its characteristic odour (*p. 217*).—2. On making the solution alkaline with *potash*, adding a solution of *ferrous sulphate* oxidised by exposure to the air, and then sufficient hydrochloric acid to dissolve the precipitated ferrous-ferrie oxide, prussian blue remains undissolved if hydrocyanic acid was present; otherwise a clear yellow-green solution is formed. If the quantity of hydrocyanic acid present is very small, the liquid appears clear at first, but after standing for some time, deposits dark blue flocks.—3. The liquid to

be tested is mixed with a few drops of *yellow sulphide (persulphide) of ammonium* and evaporated to dryness over the water-bath, to convert the hydrocyanic acid into sulphocyanate of ammonium. On dissolving the residue in water and testing with sesquichloride of iron, the liquid assumes the deep blood-red colour of ferric sulphocyanate. This test, according to Taylor (*Ann. Ch. Pharm.* lxx. 263), is capable of distinctly showing the presence of $\frac{1}{3930}$ of a grain of anhydrous prussic acid in a very

dilute liquid, whereas the prussian blue test will not detect less than $\frac{1}{780}$ of a grain.

—4. Hydrocyanic acid gives, with *nitrate of silver*, a white precipitate of cyanide of silver, which dissolves in ammonia as easily as the chloride, but is distinguished therefrom by not blackening when exposed to light, and by dissolving in strong nitric acid at the boiling heat with evolution of carbonic acid. The precipitated cyanide shaken up with dilute hydrochloric acid, emits the characteristic odour of prussic acid.

—5. On rendering the liquid alkaline with potash, then adding *sulphate of copper*, and just sufficient hydrochloric acid to dissolve the blue precipitate of cupric hydrate, white cuprous cyanide remains undissolved if the liquid contained prussic acid (*Lassaigne*). This reaction is, however, less characteristic than those before mentioned, inasmuch as a similar effect is produced by hydriodic acid.

When liquids containing blood, articles of food, or parts of the animal body, are to be examined for prussic acid, as in cases of poisoning, advantage is taken of the extreme volatility of the acid, to separate it from the substances which might disguise its reactions. A good method of testing is to place a portion of the suspected matter on a watch-glass, cover it with another watch-glass, on the concave surface of which is placed a drop of yellow sulphide of ammonium, leave it for ten minutes, then evaporate the sulphide of ammonium to dryness at a gentle heat, and moisten the residue with a drop of solution of ferric chloride, which, if prussic acid was present, will produce the blood-red colour above mentioned. If larger quantities of material have to be operated on, it is best to distil off the acid at the heat of the water-bath, acidulating with tartaric acid if the original liquid is alkaline. The distillate may then be tested by any of the methods above given.

Quantitative Estimation.—The strength of aqueous prussic acid cannot be determined by its specific gravity, the variation from 1.6 to 16 per cent. being only from 0.9979 to 0.9570. The percentage of real acid is therefore determined by one of the following methods:

1. By *Mercuric oxide*. To a weighed quantity of the aqueous acid, a weighed quantity of finely pulverised red oxide of mercury is added, by small portions and with agitation, till the last portions added remain undissolved, and the odour of hydrocyanic acid is no longer perceptible. The weight of the remaining quantity of mercuric oxide deducted from the original weight, gives the weight of the quantity dissolved; and since 108 pts. of mercuric oxide require for solution 27 pts. of anhydrous prussic acid, it follows that 4 pts. of mercuric oxide dissolved indicate the presence of 1 pt. of anhydrous acid in the liquid under examination (*Ure, Quart. J. of Sc.* xiii. 321; also *Schw. J.* xxxvi. 282). As the cyanide of mercury thus formed is capable of taking up more of the mercuric oxide, even at ordinary temperatures, forming indeed, the compound $\text{Hg}^{\circ}\text{O.Hg}^{\circ}\text{Cy}^2$, this method is apt to give too great an amount of hydrocyanic acid, especially if the liquid be not kept cool, and the addition of mercuric oxide stopped as soon as the odour of hydrocyanic acid has disappeared. Moreover, it must first be ascertained that the prussic acid to be examined is free from hydrochloric acid, which would likewise dissolve mercuric oxide. In this case, Geoghegan saturates the hydrochloric acid with carbonate of calcium before adding the mercuric oxide.—This method is not applicable to cherry-laurel water, bitter almond water, &c., because these waters contain a vegetable acid, probably benzoic acid, which likewise dissolves mercuric oxide. (*Duflos, Kastn. Arch.* xiv. 88.)

2. *Nitrate of silver*, mixed with a small quantity of ammonia, such that the liquid after precipitation may be rather acid than alkaline, is dropped into the hydrocyanic acid, as long as any precipitate of cyanide of silver is produced; the precipitate is collected on a small filter, previously dried at 100° C. and weighed; and the precipitate and filter are washed and dried together at 100° and weighed. 134 pts. of cyanide of silver indicate 27 pts. of anhydrous prussic acid. The acid may also be precipitated by a mixture of nitrate of silver and ammonia, and nitric acid then cautiously added to the liquid till a slight acid reaction is produced (*Duflos*). This method is the most accurate of all.

If the liquid contains metallic chlorides, it is acidulated and treated with excess of nitrate of silver; and the mixed precipitate of cyanide and chloride of silver is dried and weighed as above, then treated with dilute hydrochloric acid, which converts it wholly

into chloride of silver, and weighed again. By the conversion of the cyanide of silver into chloride, the weight increases by 9.5 pts. [$35.5 (\text{Cl.}) - 26 (\text{Cy.})$], so that every 9.5 pts. increase in the weight corresponds to 27 pts. anhydrous prussic acid.

The same method is applicable to the determination of hydrocyanic acid in presence of hydrobromic or hydriodic acid. From acids not precipitated by nitrate of silver from acid solutions, such as sulphuric and phosphoric acid, hydrocyanic acid is easily separated by this reagent.

3. *Volumetric method.*—1 at. cyanide of potassium forms with 1 at. cyanide of silver a soluble double cyanide, which is not decomposed by excess of alkali. If, then, a liquid containing hydrocyanic acid be mixed with solution of caustic potash till a strong alkaline reaction is produced, and then with a standard solution of nitrate of silver till the liquid begins to show turbidity, 1 at. of silver used will correspond exactly to 2 at. hydrocyanic present in the liquid. If the silver-solution be prepared by dissolving 3.160 grm. fused nitrate of silver in water, and diluting the solution to 1000 cub. cent., each cub. cent. of it used will correspond to 1 milligramme of anhydrous prussic acid. The presence of formic or hydrochloric acid has no influence on the result. This method is quite as accurate as the last, and is applicable to bitter almond water and laurel water, as well as to medicinal prussic acid. Bitter almond water, which is turbid from the presence of oily drops, must first be mixed with three or four times its bulk of water, to render it clear; otherwise the limit of the reaction will not be seen. (Liebig, *Ann. Ch. Pharm.* lxxvii. 102; *Chem. Soc. Qu. J.* iv. 219.)

Compounds of Hydrocyanic acid with Metallic Chlorides.

Hydrocyanate of Antimonic Chloride, $\text{SbCl}_5 \cdot 3\text{HCy.}$ —When the vapour of anhydrous prussic acid is brought in contact with pentachloride of antimony heated to 30°C. , this compound is produced in the form of clear definite prisms, which volatilise between 70° and 100°C. , but at the same time undergo partial decomposition, even in an atmosphere of carbonic acid. The compound is deliquescent; does not fume in the air; is decomposed by water, with separation of antimonious acid; and unites with ammonia, forming a brown-red pulverulent mass. (Klein, *Ann. Ch. Pharm.* lxxiv. 86.)

Hydrocyanate of Ferric Chloride, $\text{Fe}^3\text{Cl}_3 \cdot 2\text{HCy.}$ —Sublimed ferric chloride and anhydrous prussic acid unite, with a hissing noise, and form a brown-red liquid, which soon solidifies in the crystalline state. The compound deliquesces in the air, giving off hydrocyanic acid; melts at 100°C. ; and unites with ammonia, forming a greenish black powder, which dissolves in water, with separation of prussian blue and therefore contains protochloride of iron. The compound, when heated, yields ferruginous sal-ammoniac, hydrocyanic acid, and protochloride of iron. (Klein, *loc. cit.*)

Hydrocyanate of Stannic Chloride, $\text{SnCl}_4 \cdot 2\text{HCy.}$ —Tetrachloride of tin unites with anhydrous prussic acid, without sensible rise of temperature, forming a solid crystalline body; if the acid in the gaseous state be passed through a tube in which the stannic chloride is placed, so as to expose a large surface, the compound will be obtained in fine crystals. The crystals are colourless, refract light strongly, and appear to be isomorphous with the corresponding titanium-compound. In a stream of dry air they volatilise as quickly as anhydrous prussic acid, becoming at the same time white and opaque. They are decomposed by water and by damp air. They unite with ammoniacal gas, forming a white substance which may be sublimed. No analysis was made of this compound, on account of its great volatility; but it appears to be analogous to the titanium-compound. (Klein, *loc. cit.*)

Hydrocyanate of Titanic Chloride, $\text{TiCl}_4 \cdot \text{HCy.}$ —When anhydrous prussic acid is poured into tetrachloride of titanium, combination takes place, attended with rise of temperature and ebullition (on which account the substances must be cooled to 0°C. before mixing, or the hydrocyanic acid must be passed in the form of gas into the titanite chloride), and formation of a yellow pulverulent mass; the excess of prussic acid is then distilled off, and the compound sublimed by careful heating. It is very volatile, subliming below 100°C. , in the form of clear, shining, lemon-yellow crystals (rhombic pyramids and combinations thereof), which, if rapidly sublimed, unite into a coherent mass. It fumes slightly in the air; smells strongly of hydrocyanic acid; quickly turns white, and deliquesces to a clear viscid solution. Water dissolves it, with rise of temperature, and forms a clear solution; if the quantity of water be small, gaseous hydrocyanic acid is given off as the substance dissolves. It is not altered by sublimation in chlorine gas. When its vapour is passed through a red-hot glass tube, it covers the tube with copper-coloured nitride of titanium mixed with charcoal. (Wohler, *Ann. Ch. Pharm.* lxxiii. 226.)

CYANIDES OF IRIDIUM. The only known compound of iridium and cyanogen is the sesquicyanide, which forms with basic cyanides a group of salts, the

iridiocyanides, $3\text{MCy}.\text{Ir}^3\text{Cy}^3 = \text{M}^3\text{Ir}^3\text{Cy}^6$, analogous to the ferricyanides. They have been chiefly studied by C. A. Martius. (Ann. Ch. Pharm. cxvii. 357.)

Iridiocyanide of Barium, $\text{Ba}^2\text{Ir}^3\text{Cy}^6 + 9\text{aq.}$ —To prepare this salt, platinumiferous iridiocyanide of copper, obtained in the treatment of platinum-residues by Martius' method*, is digested with baryta-water, the excess of baryta removed by carbonic acid, and the filtrate left to crystallise: it then first deposits crystals of platinocyanide, and afterwards of iridiocyanide of barium. The latter forms hard transparent crystals belonging to the trimetric system, and efflorescing in the air to a white powder still retaining 3 at. water. The salt dissolves easily in water, is insoluble in alcohol, and scarcely decomposable by acids. The aqueous solution forms with cupric salts a light blue precipitate, with mercurous, ferrous, lead, and zinc salts, white, and with ferric salts a yellow precipitate.

Iridiocyanide of Hydrogen, $\text{H}^3\text{Ir}^3\text{Cy}^6$.—Obtained by decomposing the barium salt with sulphuric acid, exhausting with ether, and evaporating. It forms small white crystalline crusts, has a strong acid reaction, decomposes carbonates, dissolves easily in water and in alcohol, with difficulty in ether, and has a nauseous metallic taste. Above 300°C. it assumes a colour varying from yellow to dark green, and gives off prussic acid. The aqueous solution mixed with hydrochloric acid deposits after a while, green sesquicyanide of iridium. (Martius.)

Iridiocyanide of Potassium, $\text{K}^3\text{Ir}^3\text{Cy}^6$.—Prepared: 1. By gently igniting a mixture of ferrocyanide of potassium and metallic iridium in a glass flask, exhausting the mass with hot water; filtering and evaporating, the liquid then depositing, first, crystals of ferrocyanide of potassium, and afterwards of the iridiocyanide (Wöhler and Booth, Pogg. Ann. xxxi. 167).—2. By melting chloriridiate of ammonium with $1\frac{1}{2}$ pts. pulverised cyanide of potassium in a porcelain crucible for 10 or 15 minutes, dissolving the mass in boiling water, and leaving the liquid to crystallise by cooling (Claus, Jahresber. d. Chem. 1855, p. 445).—3. By decomposing the copper-salt with potash-ley, or the barium-salt with sulphate of potassium (Martius). The salt is anhydrous, insoluble in alcohol, easily soluble in water, and separates from the aqueous solution in large, transparent, colourless, prismatic twin-crystals belonging to the trimetric system. It is not decomposed, even by ignition in a current of chlorine or hydrochloric acid. (Martius.)

Rammelsberg's analysis of this salt agrees best with the formula $\text{K}^3\text{Ir}^3\text{Cy}^3$, or $2\text{KCy}.\text{Ir}^3\text{Cy}^3$; but those of Claus and of Martius lead to the formula $\text{K}^3\text{Ir}^3\text{Cy}^6$, corresponding with those of the other iridiocyanides.

CYANIDES OF IRON. (Scheele, *Opuscula*, ii. 148.—Ittner, *Beiträge zur Geschichte der Blausäure*, Freib. Const. 1809.—Proust, Ann. Chim. lx. 185 and 225.—Vauquelin, *ibid.* v. 113.—Berzelius, Ann. Ch. Phys. [2] xv. 144 and 225; Pogg. Ann. xv. 385.—Porrett, Phil. Trans. 1814, p. 527; Ann. Phil. xii. 214; xiv. 295.—Robiquet, Ann. Ch. Phys. [2] xii. 275; xvii. 196; xlv. 279.—Thomson, Ann. Phil. xii. 202; xv. 392; xvi. 217.—Gay-Lussac, *ibid.* xvi. 73.—L. Gmelin, Schw. J. xxxiv. 325.—Pelouze, Ann. Ch. Phys. [2] lxix. 40.—Rammelsberg, Pogg. Ann. xxxviii. 364; xlii. 3.—Bunsen, *ibid.* xxxiv. 131; xxxvi. 464.—Williamson, Ann. Ch. Pharm. lviii. 225.—Gm. vii. 429.—Gerh. i. 320.)

The protocyanide and sesquicyanide of iron have not been obtained in very definite form. On adding cyanide of potassium to a ferrous salt, a yellowish-red flocculent precipitate is formed, consisting essentially of ferrous cyanide, FeCy , but always containing a certain quantity of cyanide of potassium, smaller, however, the more the iron-salt is in excess. This precipitate dissolves in excess of cyanide of potassium, and is converted into ferrocyanide of potassium; dilute potash-ley also converts it into ferrocyanide, with separation of ferrous hydrate:

When exposed to the air, it takes up oxygen and turns blue. (Fresenius, Ann. Ch. Pharm. cvi. 210.)

Sesquicyanide of Iron, or Ferric Cyanide, Fe^2Cy^3 , is not known in the solid form. Ferricyanide of potassium forms with sesquichloride of iron a dark brown liquid, which may be regarded as a mixture of chloride of potassium and sesquicyanide of iron:

* Chloriridiate of ammonium (containing platinum and ruthenium) is fused with $1\frac{1}{2}$ pt. cyanide of potassium, the cooled mass dissolved in a very small quantity of water, and the yellow filtrate (after all the free cyanide of potassium has been decomposed by dilute hydrochloric acid), is precipitated by sulphate of copper, whereby a precipitate is formed consisting mainly of platinocyanide and iridiocyanide of copper. (See IRIDIUM and PLATINUM-METALS.)

but this solution decomposes on evaporation, becoming covered with a film of prussian blue, and giving off cyanogen or chlorine gas, according as the cyanide or the chloride is in excess. Neither is ferric cyanide obtained by adding cyanide of potassium to ferric chloride, the products formed being chloride of potassium, free hydrocyanic acid, and a precipitate of ferric hydrate.

Some of the compounds called prussian blues have the composition of cyanides of iron, intermediate between the proto- and sesquicyanide; but, from their mode of formation, they appear rather to be double cyanides.

The protoeyanide and sesquicyanide of iron unite with other metallic cyanides, forming two very important groups of compounds, viz.:

It will be seen from these formulæ that the ferro- and ferri-cyanides differ from one another only by one atom of metal; and, accordingly, it is found that the former are easily converted into the latter by the action of oxidising (metal-abstracting) agents, and the latter into the former, by the action of reducing (metal-adding) agents. Thus ferrocyanide of potassium, $\text{K}^4\text{Fe}^2\text{Cy}^6$, is easily converted into the ferrieyanide, $\text{K}^3\text{Fe}^3\text{Cy}^6$, by the action of chlorine, and many double ferrocyanides may be formed from ferrieyanides by the action of alkalis in presence of a reducing agent, *e.g.* $\left. \begin{smallmatrix} \text{NH}^4 \\ \text{K} \end{smallmatrix} \right\} \text{Fe}^2\text{Cy}^6$, from $\text{K}^3\text{Fe}^3\text{Cy}^6$, by the action of ammonia in presence of grape-sugar. For the several views entertained respecting the composition of these double cyanides, see page 201.

Ferrocyanides, $\text{M}^4\text{Fe}^2\text{Cy}^6$.

Ferroproussiates, Hydroferrocyanates.—The general formulæ of these compounds might evidently be halved, and, in fact, it is often more convenient to represent them by the simpler formula, M^2FeCy^3 ; but the tetrabasic formula is justified by the existence of double ferrocyanides containing three atoms of one metal and one of another, such as $(\text{NH}^4)\text{K}^3\text{Fe}^2\text{Cy}^6$; and, as already observed, it has the advantage of showing clearly the relation between the ferro- and ferrieyanides.

The ferrocyanides of the alkali-metals are obtained by neutralising ferroproussic acid with caustic alkalis or alkaline carbonates; by dissolving protoeyanide of iron in aqueous solutions of alkaline cyanides, or in a mixture of alkaline carbonate and hydrocyanic acid; by treating protoeyanide of iron, or a mixture of that compound with the sesquicyanide (prussian blue), with an aqueous alkali, whereby protoxide or sesquioxide of iron is formed; or by treating protoxide of iron with the aqueous solution of the cyanide of an alkali-metal, in which it dissolves with formation of alkali. The insoluble ferrocyanides are obtained by precipitating a soluble ferrocyanide with the solution of the salt of an earth-metal or a heavy metal: *e.g.* the copper-compound:

The ferrocyanides of the alkali-metals are colourless in the anhydrous, but yellow in the hydrated state; they exert no action on vegetable colours, have a faintly saline and bitter taste, and do not exhibit the violent action of hydrocyanic acid on the animal economy. The ferrocyanides of the earth-metals are white, and among those of the heavy metals, some are white, while others are distinguished by bright colours. Hence the use of alkaline ferrocyanides to discover the presence of titanium, tantalum, molybdenum, uranium, cobalt, nickel, and copper; but antimony, tellurium, platinum, rhodium, and iridium are not precipitated by alkaline ferrocyanides.

Those ferrocyanides which are deprived of all their water by a gentle heat, are decomposed at a higher temperature in the following manner: the cyanide of iron is always converted into carbide of iron, with evolution of nitrogen gas; but the other cyanide which is associated with it, either remains undecomposed, which is the case with cyanide of potassium, or is resolved into nitrogen and a metallic carbide, as with cyanide of lead; or into cyanogen gas and metal, as with cyanide of silver. If, however, the ferrocyanides are not completely dehydrated before being subjected to destructive distillation, they give off hydrocyanic acid, carbonic acid, and ammonia, and leave the two metals combined or mixed with a greater or smaller quantity of carbon. In the circuit of the voltaic battery, the aqueous solutions of the alkaline ferrocyanides yield alkali at the negative pole, and hydrocyanic acid and prussian blue at the positive pole, unless the positive polar wire is of copper, in which case the deposit there formed consists of cyanide of copper (Porrett). When ferrocyanides are heated with oil of vitriol to a temperature much above 100°C ., they give off, with strong

effervescence, sulphurous and carbonic anhydrides, and nitrogen, leaving a compound of sulphuric acid with ammonia, oxide of iron, and the oxide of the other metal (Berzelius). Besides the gases just mentioned, a large quantity of carbonic oxide is evolved, and a small quantity of sulphate of ammonium volatilises (Bunsen, Pogg. Ann. xxxiv. 132). See FERROCYANIDE OF POTASSIUM. The stronger acids withdraw the other metal from ferrocyanides, and thereby separate ferroproussic acid :

A similar effect is produced by sulphydric acid, if the other metal be precipitable from its solutions by that reagent. Many ferrocyanides of heavy metals are decomposed by aqueous alkalis, yielding an alkaline ferrocyanide and a hydrate of the heavy metal :

Neither alkalis nor sulphydric acid decompose the cyanide of iron contained in ferrocyanides.

Most ferrocyanides unite in their entire state with strong sulphuric acid, forming a kind of salt, in which they constitute the base. Their powder soaked in cold oil of vitriol swells up to a pasty compound, with loss of colour, and considerable evolution of heat, and, according to the nature of the metal present, either dissolves completely in a large excess of the acid, or remains almost undissolved, forming a solid compound with it. These compounds remain undecomposed even at temperatures much above 100°C . If a small quantity of water be added to the resulting solutions, *e.g.* by exposing them to the air, they frequently deposit a crystalline compound, which contains less sulphuric acid, and when treated with a larger quantity of water, is resolved either into ferroproussic acid and a compound of sulphuric acid with the other metallic oxide, or into metallic ferrocyanide and dilute sulphuric acid. (Berzelius, Schw. J. xxx. 35.)

FERROCYANIDE OF ALUMINIUM, obtained by saturating ferrocyanide of hydrogen (ferroproussic acid) with alumina, is uncrystallisable, and decomposes by evaporation.

Ferrocyanide of potassium added to an aluminium-salt, even if strongly acidulated, throws down the whole of the aluminium in the form of a white precipitate, which yields by analysis 14.87 per cent. aluminium, and 22.36 iron, and may therefore be represented by the formula $2\text{Al}^2\text{Cy}^3.3\text{FeCy}$, or $(\text{Al}^2)^2.\text{Fe}^3\text{Cy}^9$ (calc. 14.70 aluminium, and 22.53 iron), which is that of a prussian blue (p. 329) in which part of the iron (that which enters as *ferricum*) is replaced by an equivalent quantity of aluminium. (C. Tissier, Compt. rend. xlv. 232.)

FERROCYANIDE OF AMMONIUM, $(\text{NH}^4)^4\text{Fe}^2\text{Cy}^6 + 3\text{aq.}$, is obtained by saturating ferroproussic acid with ammonia, or by decomposing ferrocyanide of lead with carbonate of ammonia, and precipitating the filtered solution with alcohol, as the salt would be decomposed by evaporation. It forms pale yellow, transparent, octahedral crystals of the dimetric system, isomorphous, or rather homœomorphous, with ferrocyanide of potassium. Ordinary combination P. oP. Length of principal axis = 1.789. Inclination of P : P in the terminal edges = $97^\circ 46'$; in the lateral edges = $136^\circ 52'$. They are permanent in the air, very soluble in cold water, insoluble in alcohol.

The solution of this salt mixed with chloride of ammonium and concentrated, yields rhombohedral crystals of *Chloroferrocyanide of ammonium*, $(\text{NH}^4)^4\text{Fe}^2\text{Cy}^6.2\text{NH}^4\text{Cl} + 3\text{aq.}$, which are transparent, with a yellowish colour and glassy lustre, permanent in the air and very soluble in water. The crystals are sometimes rhombohedrons R, sometimes in the form of the next acuter rhombohedron, -2R , sometimes exhibiting the combination R. oR. -2R (*fig.* 360). Length of principal axis for R = 1.0325. Inclination of the faces R : R, forming the terminal edges of the hexagonal pyramid = $96^\circ 52'$; R : oR = $129^\circ 59'$; R : -2R = $126^\circ 59'$; -2R : oR = $112^\circ 45'$. The solution is decomposed by boiling, and deposits cyanide of iron. (Bunsen.)

The analogous compound, *Bromo-ferrrocyanide of ammonium*, $(\text{NH}^4)^4\text{Fe}^2\text{Cy}^6.2\text{NH}^4\text{Br} + 3\text{aq.}$ likewise forms rhombohedral crystals permanent in the air and very soluble in water. They exhibit the same faces as those of the preceding compound, but with different inclinations, the rhombohedron -2R also predominating. Length of principal axis for R = 0.9858. Inclination of R : R in the terminal edges = $98^\circ 49'$; -2R : -2R = $75^\circ 5'$. (Himly and Bunsen, Pogg. Ann. xxxviii. 208.)

Ferrocyanide of Ammonium and Potassium, $\left. \begin{matrix} \text{NH}^4 \\ \text{K}^3 \end{matrix} \right\} \text{Fe}^2\text{Cy}^6$.—Obtained by the action

Fig. 360.

of ammonia on ferricyanide of potassium in presence of reducing agents, such as grape- or milk-sugar:

The ammonia should be poured on a mixture of about 20 pts. ferricyanide of potassium to 1 pt. sugar; the mixture left to stand for some days in a loosely stoppered bottle and frequently shaken; and when its colour has changed to a pure yellow, the salt should be precipitated by alcohol and recrystallised from water, as it is liable to decompose if evaporated in presence of the reducing agent. The salt forms pale yellow square prisms, easily soluble in cold, and still more in hot water. When heated, it gives off hydrocyanic acid and cyanide of ammonium. With metallic salts it yields the same precipitates as ordinary yellow prussiate. Heated with fixed alkalis, it gives off ammonia and yields salts of similar constitution; *e. g.* with soda, the salt $\text{K}^2\text{NaFe}^2\text{Cy}^6$. (Reindel, J. pr. Chem. lxx. 450.)

Another ferrocyanide of ammonium and potassium, $(\text{NH}^4)^2\text{K}^2\text{Fe}^2\text{Cy}^6$, is obtained by decomposing the corresponding barium-salt, $\text{Ba}^2\text{K}^2\text{Fe}^2\text{Cy}^6$, with sulphate of ammonium; or by action of ammonia on ferrocyanide of iron and potassium:

(Reindel, J. pr. Chem. lxxvi. 342.)

FERRICYANIDE OF BARIUM, $\text{Ba}^4\text{Fe}^2\text{Cy}^6 + 6 \text{ aq.}$ —Obtained by saturating ferrous prussic acid with baryta-water or carbonate of barium; by decomposing prussian blue with baryta-water at the boiling heat, filtering at the same temperature and leaving the solution to crystallise; or by decomposing a solution of ferrocyanide of potassium with chloride of barium at the boiling heat, the latter being used in considerable excess (more than 2 at. chloride of barium to 1 at. of the yellow prussiate), and again boiling the crystalline powder which separates on cooling, with chloride of barium. If the chloride of barium is not present in considerable excess, a double ferrocyanide of barium and potassium is produced.

Ferrocyanide of barium may also be produced by the action of ferrous sulphate on cyanide of barium ($6\text{BaCy} + \text{Fe}^2\text{SO}^4 = \text{Ba}^4\text{Fe}^2\text{Cy}^6 + \text{Ba}^2\text{SO}^4$), which, according to Margueritte and De Sourdeval (p. 203), may easily be obtained by passing a current of air over an ignited mixture of charcoal and carbonate of barium. If this process should fulfil the expectations of its authors, ferrocyanide of barium may take the place of the potassium-salt for the preparation of certain ferrocyanides used in the arts, being easily converted into ferroproussic acid by the action of dilute sulphuric acid, into prussian blue by ferric salts, &c.

Ferrocyanide of barium crystallises in flattened, oblique, rectangular, monoclinic prisms, yellow, non-efflorescent, soluble in 584 pts. of cold and 116 pts. of boiling water (Duflos). At 40°C. they give off $\frac{11}{12}$ of their water, and become white and opaque, the remaining $\frac{1}{12}$ not being evolved till the salt begins to decompose. At a red heat, it gives off nitrogen, and leaves a mixture of carbide of iron and carbide of barium, or, if in contact with the air, a mixture of ferric oxide and carbonate of barium. On passing chlorine through the aqueous solution, it becomes turbid, acquires a greenish-yellow colour, deposits a green powder, then becomes brown and dark-red, and is decomposed by evaporation, depositing a bluish-white powder, but no crystals.

Fig. 361.

Ferrocyanide of Barium and Potassium, $(\text{Ba}^2\text{K}^2)\text{Fe}^2\text{Cy}^6 + 3 \text{ aq.}$, is produced by mixing the boiling concentrated solutions of 2 pts. ferrocyanide of potassium and 1 pt. chloride of barium, and crystallises on cooling in small, light-yellow rhombohedrons, truncated by the face *oR*. Length of principal axis = 1.570. Inclination of *R* : *R* in terminal edges = $98^\circ 33'$; *R* : *oR* = $118^\circ 53'$.

The crystals dissolve in 38 pts. of cold and 9.5 pts. of boiling water.

By treating the solution of this salt with soluble sulphates, a number of other double ferrocyanides containing potassium may be obtained; thus, with sulphate of ammonium:

The acid sulphates of the alkali-metals, in presence of an oxidising substance, convert it into ferricyanides of alkali-metal, thus:

(Reindel, J. pr. Chem. lxxvi. 342.)

FERROCYANIDE OF BISMUTH.—Nitrate of bismuth forms with ferrocyanide of potassium a white, yellowish-white, or yellow precipitate, which afterwards turns green. It dissolves in nitric acid, and is precipitated therefrom by water.

FERROCYANIDE OF CADMIUM is a white precipitate soluble in ammonia.

FERROCYANIDE OF CALCIUM, $\text{Ca}^4\text{Fe}^2\text{Cy}^6 + 12 \text{ aq.}$, obtained by boiling prussian blue with milk of lime not in excess, evaporating the filtrate to a syrup, and leaving it to crystallise, forms large flattened rhombic prisms, of a light yellow colour, very bitter and disagreeable taste, very soluble in water, insoluble in alcohol.

Prussian blue, boiled or digested with excess of lime, yields basic compounds, or oxyferrocyanides of calcium, (Gm. vii. 482.)

Ferrocyanide of Calcium and Potassium, $(\text{Ca}^2\text{K}^2)\text{Fe}^2\text{Cy}^6 + 3 \text{ aq.}$, is obtained as a yellowish-white crystalline precipitate on adding ferrocyanide of potassium to a solution of a calcium-salt, not too dilute.

FERROCYANIDE OF CERIUM.—White precipitate.

FERROCYANIDE OF COBALT, $\text{Co}^4\text{Fe}^2\text{Cy}^6$.—Pale blue hydrated precipitate, which, when carefully heated, gives off the greater part of its water, and assumes a dark green colour. If it be then heated to 360°C. , it becomes light green, giving off water and a small quantity of cyanide of ammonium. When more strongly heated in a close vessel, it gives off nitrogen, and leaves a mixture of the carbides of iron and cobalt, which glows when raised to a higher temperature. The compound dissolves easily in strong sulphuric acid, forming a red liquid, which, after some time, deposits *sulphate of ferrocyanide of cobalt*, as a rose-coloured, crystalline powder, which is decomposed by water (Berzelius). Ferrocyanide of cobalt dissolves in ammonia and in carbonate of ammonia (Wittstein), not in sal-ammoniac. (Brett.)

FERROCYANIDES OF COPPER. *Cuprous Ferrocyanide*, $\text{CuCu}^4\text{Fe}^2\text{Cy}^6$.—Ferrocyanide of potassium added to a solution of cuprous chloride in hydrochloric acid, throws down white flakes, which, when exposed to the air, or to the action of chlorine-water, become purple-red, and are converted into cupric ferrocyanide (Proust). Cuprous ferrocyanide is likewise obtained by the action of acids on the following compound (Schulz). It dissolves in ammonia, but not in ammoniacal salts. (Wittstein).

Potassio-cuprous Ferrocyanide, $\text{Cu}^2\text{K}^2\text{Fe}^2\text{Cy}^6 + 3 \text{ aq.} = \frac{\text{Cu}^2}{\text{K}^2}\text{Fe}^2\text{Cy}^6 + 3 \text{ aq.}$ —

When precipitated cupric ferrocyanide is added to a solution of cyanide of potassium, cyanogen is evolved, and a light yellow solution is formed, which, if the cyanide of potassium is not in excess, deposits, first a deep red precipitate, and after filtration, small square prismatic crystals, of a dark red-brown colour, and having the composition indicated by the above formula. This compound is more easily obtained by dropping a solution of cupric sulphate into a mixture of cyanide and ferrocyanide of potassium, then heating the liquid and leaving it to itself. The crystals give off water at 100°C. and turn black; they are insoluble in water, ether, and alcohol, but soluble in cyanide of potassium. Boiling water decomposes them, with formation of ferrocyanide of potassium. Acids also decompose them, separating white cuprous ferrocyanide. (C. Schulz, J. pr. Chem. lxxviii. 257.)

Cyanide of Potassium, Cuprosium and Ferrosium, $(\text{K}^3\text{Cu}^2\text{Fe}^2)\text{Cy}^7 + 4 \text{ aq.}$ —A liquid consisting of cyanide of potassium and sulphate of copper containing iron, which had been used for coppering by electrolysis, and had stood for a long time in an imperfectly closed vessel, was found to have deposited brown-red octahedral crystals, resembling chrome-alum, and agreeing in composition with the above formula. The same salt was obtained, in the form of a chocolate-coloured powder, by boiling cuprous cyanide with solution of ferrocyanide of potassium, and leaving the liquid to cool. (Bolley and Moldenhauer, Ann. Ch. Pharm. cvi. 228.)

According to Moldenhauer's analysis, the crystals contain 4 at. water; according to W. J. Wonfor (Chem. Soc. J. xv. 357), they contain 5 at. water, and have the form of the cubo-octahedron (fig. 176, p. 124).

[For Kuhn's experiments on the action of ferrocyanide and ferricyanide of potassium on the oxides, sulphides, and cyanides of copper, see Ann. Ch. Pharm. lxxxvii. 127.]

Cupric Ferrocyanide, $\text{Cu}^2\text{Fe}^2\text{Cy}^6$.—Ferrocyanide of potassium added to excess of a cupric salt forms a dark purple-red precipitate. The liquids, if concentrated, solidify in a magma when stirred; if more dilute, they yield thick flakes; and if very dilute, the mixture assumes a beautiful red colour. This precipitate, even when a large excess of copper-salt is used, carries down with it a large quantity of ferrocyanide of potassium, which cannot be removed by washing. If, therefore, the precipitate be suspended in water, and decomposed by sulphuretted hydrogen—which takes a long time—a strongly acid liquid is obtained which, like ferroprussic acid, deposits prussian blue on exposure to the air, and forms a blue precipitate with

ferric salts, but is not precipitated by ether, except on addition of hydrochloric acid. It contains $\text{H}^1\text{KFe}^3\text{Cy}^{12}$ (Williamson, Ann. Ch. Pharm. lvii. 245). According to Rammelsberg (Pogg. Ann. lxxiv. 65), acetate or sulphate of copper mixed with ferropurssic acid yields pure ferrocyanide of copper, which, after drying over sulphuric acid, contains $\text{Cu}^1\text{Fe}^2\text{Cy}^6 + 7 \text{ aq.}$; according to Monthiers, however, it contains $\text{Cu}^1\text{Fe}^2\text{Cy}^6 + 9 \text{ aq.}$

The salt gives up only a part of its water when gently heated, and at a stronger heat evolves hydrocyanate of ammonia as well as water (Vauquelin), also carbonate of ammonia and nitrogen gas (Berzelius). The residue, if more strongly heated in a retort, exhibits a faint glow, and appears afterwards to be composed of 1 at. bicarbide of iron and 2 at. monocarbide of copper (Berzelius). Aqueous potash decomposes the salt, producing ferrocyanide of potassium and hydrated cupric oxide (Ittner). In oil of vitriol, which dissolves but little of it, the salt assumes a greenish yellow-white colour; but on subsequent immersion in water, which withdraws the sulphuric acid, it resumes its dark red colour (Berzelius). It is insoluble in water and in acids, which do not decompose it; also insoluble in ammoniacal salts. (Brett, Wittstein.) It dissolves, however, in aqueous ammonia, forming a colourless solution, which, on evaporation leaves the cupric ferrocyanide with its original colour. This reaction affords the means of detecting extremely small quantities of copper, even when associated with other metals. (Warington. See p. 56.)

Diammonio-cupric Ferrocyanide, $4\text{NH}^3\text{Cu}^1\text{Fe}^2\text{Cy}^6 + \text{aq.}$, or *Ferrocyanide of Cuprammonium*, $(\text{NH}^3\text{Cu})^4\text{Fe}^2\text{Cy}^6 + \text{aq.}$ —Produced by adding ferrocyanide of potassium to a solution of nitrate of cuprammonium (or of any cupric salt containing sufficient ammonia to form a clear solution). It is a pale yellow crystalline precipitate, soluble in free ammonia, insoluble in water or alcohol. Dilute acids withdraw the ammonia, leaving red-brown cupric ferrocyanide, (Monthiers, J. Pharm. [3] xi. 249; Bunsen, Pogg. Ann. xxxiv. 134.)

Octammonio-cupric Ferrocyanide, $8\text{NH}^3\text{Cu}^1\text{Fe}^2\text{Cy}^6$, or *Ferrocyanide of Ammo-cuprammonium*, $[\text{N.H}^2(\text{NH}^1)\text{Cu}]^4\text{Fe}^2\text{Cy}^6$.—Cupric ferrocyanide, or the preceding ammonio-compound in the moist state, absorbs ammoniacal gas, assuming a green colour and being converted into the octammonio-compound. The latter is very unstable, turning yellow and giving off half its ammonia on exposure to the air. (Monthiers.)

Potassio-cupric Ferrocyanide, $\text{Cu}^2\text{K}^2\text{Fe}^2\text{Cy}^6$.—Produced, according to Mosander, by adding a cupric salt, drop by drop, to excess of ferrocyanide of potassium. [According to Rammelsberg, however, (Pogg. Ann. lxxiv. 65), the precipitate thus formed contains water and is composed according to the improbable formula $\text{Cu}^1\text{Fe}^2\text{Cy}^6.\text{K}^2\text{Fe}^2\text{Cy}^4 + 2 \text{ aq.}$ When, on the other hand, the ferrocyanide is dropt into excess of the cupric salt, the precipitate has the composition $2(\text{Cu}^2\text{K}^2\text{Fe}^2\text{Cy}^6 \text{ aq.}) + 9(\text{Cu}^1\text{Fe}^2\text{Cy}^6 \text{ 7 aq.})$ Jahresber. d. Chem. 1847–8.]

The compound $\text{Cu}^2\text{K}^2\text{Fe}^2\text{Cy}^6$ also constitutes the dark red precipitate mentioned as produced in the preparation of potassio-cuprous cyanide, when a comparatively small quantity of cyanide of potassium is used. (Schulz.)

The corresponding *sodium* and *ammonium* compounds are obtained in like manner. The latter, $\text{Cu}^2(\text{NH}^1)^2\text{Fe}^2\text{Cy}^6$, is a scarlet crystalline body, which turns brown on drying. (Schulz.)

Ferrocyanide of Ethyl, $(\text{C}^2\text{H}^5)^1\text{Fe}^2\text{Cy}^6$.—When hydrochloric acid gas is passed into a well cooled alcoholic solution of ferropurssic acid, colourless crystals are obtained which, after drying for a certain time over lime, consist of $(\text{C}^2\text{H}^5)^1\text{Fe}^2\text{Cy}^6 + 2\text{C}^2\text{H}^5\text{Cl} + 6 \text{ aq.}$ Their concentrated alcoholic solution, mixed with ether, deposits nacreous crystals of pure ferrocyanide of ethyl, $(\text{C}^2\text{H}^5)^1\text{Fe}^2\text{Cy}^6 + 6 \text{ aq.}$ Both compounds become anhydrous by continued exposure over lime. The corresponding *methyl* and *amyl*-compounds appear also to exist. (H. Buff, Ann. Ch. Pharm. xci. 253.)

Ferrocyanide of Hydrogen. *Ferropurssic* or *Hydroferrocyanic acid*, $\text{H}^1\text{Fe}^2\text{Cy}^6 = 4\text{HCy}.2\text{FeCy}$. *Ferruretted Chyazic acid*. *Eisenblausäure*, *Wasserstoffeisencyanür*, *Ferrocyanwasserstoffsäure*. This acid, discovered by Porrett (Phil. Trans. 1814, p. 527), is obtained by decomposing ferrocyanide of barium with sulphuric acid, ferrocyanide of potassium with tartaric acid, ferrocyanide of lead or copper with sulphydric acid, or prussian blue with very strong hydrochloric acid;

A good method of preparing it is to dissolve ferrocyanide of potassium in a small quantity of water, boil the solution to expel the air, leave it to cool in a stoppered bottle, then mix it with strong hydrochloric acid, also freed from air, and shake up the liquid with ether. The ferropurssic acid is then precipitated in thin white scales, which may be collected on a filter, washed with ether-alcohol, pressed, and dried in vacuo over sulphuric acid (Posselt, Ann. Ch. Pharm. xlii. 163). It is better to separate the

acid from its solution by precipitation with ether than by evaporation, as the solution decomposes when exposed to the air. If the aqueous solution of ferrocyanide of potassium be mixed, first with ether, and then with hydrochloric acid, the ferroproussic acid separates perfectly white, and may be dried without becoming coloured. It may then be further purified by pressure, solution in alcohol, and precipitation with ether (Dollfus). Kuhlmann prepares ferroproussic acid on the large scale by decomposing ferrocyanide of barium with an equivalent quantity of sulphuric acid. The clarified solution is preserved in well closed stone-ware jars and sent in that state into the market.

Ferroproussic acid crystallises in white grains or small interlaced needles: larger crystals are deposited from an alcoholic solution covered with a layer of ether. It is easily soluble in water and alcohol, insoluble in ether. When exposed to the air, it absorbs oxygen, even at ordinary temperatures, and more quickly when heated, hydrocyanic acid being set free and prussian blue, $\text{Fe}^{\text{I}}\text{Cy}^{\text{I}8}$, deposited:

(Reiman and Carius, Ann. Ch. Pharm. cxiii. 39.)

This reaction is applied to the production of prussian blue in calico-printing. The pattern is printed with a mixture of ferrocyanide of potassium with tartaric acid, or with sulphuric acid and alum, and exposed to the action of a hot steam-bath. In this treatment, ferroproussic acid is first set free, and then decomposed in the manner just explained.

Ferroproussic acid is a strong acid, having a sour taste, reddening litmus, and decomposing carbonates and acetates without the aid of heat: it even decomposes tartrates and oxalates. With most metallic salts it acts in the same manner as ferrocyanide of potassium. Heated with mercuric oxide, it yields cyanide of mercury and protocyanide of iron:

but the ferrous cyanide is immediately oxidised by the excess of mercuric oxide, with separation of metallic mercury.

Ferroproussic acid is tetrabasic, as appears from the constitution of some of the double ferrocyanides; e. g. $\text{K}^3(\text{NH}^{\text{I}})\text{Fe}^{\text{I}}\text{Cy}^{\text{I}6}$, and from the relations between the ferro- and ferricyanides (p. 222).

FERROCYANIDE OF IRON. FERRIC FERROCYANIDE, $\text{Fe}^{\text{I}}\text{Cy}^{\text{I}9} + 9\text{aq.}$, or rather $\text{Fe}^{\text{I}}\text{Cy}^{\text{I}8} + 18\text{aq.} = (\text{Ffe}^{\text{III}})\text{Fe}^{\text{I}}\text{Cy}^{\text{I}8} + 18\text{aq.} = \text{fe}^{\text{I}}\text{Fe}^{\text{I}}\text{Cy}^{\text{I}6} + 6\text{aq.}$ *—This is one of the compounds designated by the common name of Prussian blue. It is obtained in the pure state by precipitating ferroproussic acid with a ferric salt:

The same precipitate is formed by adding ferrocyanide of potassium to a ferric salt, the latter being in excess; it always carries down with it a certain quantity of the alkaline ferrocyanide, which, however, may be removed by digestion with the ferric salt and subsequent washing. If, on the contrary, the ferric salt be added to excess of the alkaline ferrocyanide, a much larger quantity of the latter is carried down with the precipitate, and cannot be completely separated by any amount of washing (p. 229).

The pure ferric ferrocyanide obtained as above is sometimes called *Paris blue*.

Ferric ferrocyanide is likewise produced by the following reactions

a. By precipitating a ferroso-ferric salt with cyanide of potassium:

if the iron-solution contains a larger proportion of ferric salt, the excess of the latter does not appear to alter the character of the precipitate; but if the ferrous salt is in excess, the precipitate will have a different character, approaching to the composition of ferrous ferricyanide, or Turnbull's blue. (See FERRICYANIDES.)

b. By mixing hydrocyanic acid, first with potash, then with a ferroso-ferric salt, and then with excess of hydrochloric acid. In this case, ferrocyanide of potassium is first formed, and this with the ferric salt present forms prussian blue. This is one of the chief tests for hydrocyanic acid (p. 218).

c. By immersing recently precipitated ferroso-ferric hydrate in hydrocyanic acid.

d. By immersing ferrous cyanide in a solution of a ferric salt, which is thereby reduced to a ferrous salt:

* $\text{Ffe} = \text{Fe}^2 = 56$; $\text{fe} = \frac{2}{3}\text{Fe} = 18\frac{2}{3}$.

c. By the action of air, chlorine-water, or other oxidising agents, on ferrous cyanide :

or, on ferrocyanide of hydrogen :

or, on ferrocyanide of iron and potassium (the white precipitate formed by adding ferrocyanide of potassium to a ferrous salt), probably thus :

It is chiefly by this last reaction that prussian blue is prepared on the large scale, ferrocyanide of potassium being first precipitated by ferrous sulphate, and the resulting white or light blue precipitate either left to oxidise by contact with the air, or subjected to the action of nitric acid, chlorine, hypochlorites, chromic acid, &c. The product, however, is not pure ferric ferrocyanide: for it is certain that another and simpler reaction takes place at the same time, by which the ferrocyanide of iron and potassium is converted, by the abstraction of 1 at. potassium, into ferricyanide of iron and potassium, $\text{K} \left\{ \text{Fe}^2\text{Cy}^6 \right\}$, which also possesses a fine deep blue colour. Commercial prussian blue is therefore generally a mixture of this compound with ferric ferrocyanide, Fe^3Cy^6 , the one or the other predominating according to the manner in which the process is conducted. (See PRUSSIAN BLUE.)

Ferric ferrocyanide forms, when dry, a dark blue mass, having a strong coppery lustre and conchoidal fracture. It cannot be dehydrated by heat, as it is thereby decomposed, giving off hydrocyanic acid and leaving ferric oxide. Heated in contact with the air, it takes fire and burns like tinder, leaving ferric oxide.

It is insoluble in water, alcohol, ether, and oils, and is neither dissolved nor decomposed by dilute mineral acids. It dissolves with violet colour in *tartrate of ammonia*, and with blue colour in *oxalic acid*. This latter solution may be used as a blue ink; it is prepared by triturating prussian blue with 1 or 2 pts. of crystallised oxalic acid and a small quantity of cold water till it forms a thick paste, which may be dissolved in a larger quantity of water.

Immersed in cold strong *sulphuric acid*, it is converted into a white pasty mass, without evolving hydrocyanic acid or giving up iron; the addition of water, alcohol, or even ether, restores the blue colour without contact with the air (Robiquet). The white pasty mass does not dissolve in excess of sulphuric acid; when dried in vacuo on a porous tile, it leaves a white pasty amorphous powder called *sulphate of prussian blue*, which is immediately decomposed by water into prussian blue and dilute sulphuric acid. (Berzelius.)

Strong nitric or sulphuric acid heated with ferric ferrocyanide decomposes it by oxidation. Strong hydrochloric acid gradually decomposes it, abstracting the iron in the form of ferric chloride, and the residue, if continually treated with fresh quantities of acid, ultimately consists of ferrocyanide of hydrogen :

Chlorine-water converts ferric ferrocyanide into a green compound, which turns blue in contact with ferrous or stannous chloride. Ferric ferrocyanide boiled with *mercuric oxide* yields cyanide of mercury and ferroso-ferric oxide :

The *fixed alkalis*, and *magnesia*, in presence of water, decompose ferric ferrocyanide, especially with aid of heat, forming an alkaline ferrocyanide and ferric hydrate :

The *carbonates of potassium and sodium* act in a similar manner, but less powerfully. *Ammonia* at first unites with ferric ferrocyanide, but afterwards decomposes it, forming a greyish-brown basic compound, which again yields prussian blue when treated with acids. *Lime* also boiled with ferric ferrocyanide forms a similar basic compound, but of a light yellow colour.

Aqueous *sulphydric acid* decomposes ferric ferrocyanide, forming ferrous cyanide and ferroproussic acid, with separation of sulphur :

Iron or tin filings placed in contact with it under water, withdraw part of the

cyanogen and convert it into white ferrous cyanide. *Cuprous chloride* also turns it white. Boiled with a *polysulphide of potassium*, it yields, according to Porrett, sulphocyanate of potassium, a sulphide of iron being probably formed at the same time; *e.g.* $\text{Fe}^{14}\text{Cy}^{18} + 9\text{K}^2\text{S}^3 = 18\text{KCyS} + \text{Fe}^{14}\text{S}^9$.

Soluble Prussian blue.—When ferric chloride is added to excess of ferrocyanide of potassium, a dark-blue precipitate is formed, which is insoluble in the saline liquid, but gradually dissolves during washing, the water acquiring a blue colour, which becomes deeper as the soluble salts are removed. This precipitate contains potassium, which, indeed, is found both in the wash-waters and in the residue, even after the washing has been continued long enough to dissolve out a considerable portion of the precipitate. This is the soluble prussian blue of Berzelius and Robiquet; it is usually regarded as ferric ferrocyanide, retaining a certain and sometimes a considerable quantity of yellow prussiate, which is gradually dissolved out during the washing, and renders the precipitate also soluble (Gm. vii. 440). Kekulé, however (*Lehrbuch d. org. Chem.* i. 327), considers it improbable that this should be the case, seeing that a larger quantity of the yellow prussiate renders the precipitate insoluble. He considers it more probable that the precipitate consists of ferricyanide of iron and potassium ($\text{KFe}^3\text{Fe}^2\text{Cy}^6$). The greatest degree of solubility is said to be obtained by precipitating 1 at. ferrocyanide of potassium with a solution of ferric iodide containing 1 at. or rather more of iodine. (Wagner's *Jahresbericht d. Chem. Technologie*, 1858, iv. p. 194.)

Ammonio-ferric Ferrocyanide, $6\text{NH}^3\text{Fe}^{14}\text{Cy}^{18} + 9\text{H}^2\text{O}$, or *Ferrocyanide of ferricum* and *ferricammonium* $2 \left(\text{NH}^3_{\text{Fe}} \right\} \text{FeCy}^3) + 3\text{H}^2\text{O}$.—This, according to Monthiers (J. Pharm. [3] ix. 26), is the first product of the action of ammonia on ferric ferrocyanide, the ultimate products being, as already observed, ferric oxide and ferrocyanide of ammonium. The best mode of preparing it is to pour an excess of ammonia into a solution of protochloride of iron, and throw the whole on a filter resting in a funnel, the neck of which dips into a solution of ferrocyanide of potassium. As soon as the two liquids mix, a perfectly white precipitate is formed, which turns blue in contact with the air. This precipitate is digested with tartrate of ammonia, to remove the ferric oxide likewise produced in the reaction, the whole being kept for some hours at a temperature of 60° to 80°C ., and the precipitate then washed with distilled water. The first product formed is white *cyanide of ferrosammonium*:

and this when exposed to the air, takes up oxygen, gives off ammonia, and is converted into ammonio-ferric ferrocyanide and ferric oxide:

It is a blue powder with a tinge of violet. It begins to give off prussic acid at 100°C ., but retains its colour up to 160° , below which temperature no ammonia is evolved. It is altogether more stable than ferric ferrocyanide, not being attacked by tartrate of ammonium either at ordinary or at higher temperatures. (Monthiers.)

Potassio-ferrous Ferrocyanide, $\text{K}^2\text{Fe}^4\text{Cy}^6 = \frac{\text{K}^2}{\text{Fe}^2} \left\} \text{Fe}^2\text{Cy}^6$.—This is the white (or yellow) insoluble substance formed when ferrocyanide of potassium is distilled with dilute sulphuric acid for the preparation of hydrocyanic acid (Everitt, Phil. Mag. [3] vi. 97):

It is also produced on adding ferrocyanide of potassium to a solution of a ferrous salt

the reaction consisting simply in an interchange between 2 at. iron (ferrosium), and 2 at. potassium. If the ferrous salt is quite free from ferric salts, and the air is completely excluded, the precipitate is white, but it quickly turns blue in contact with the air. The solution of ferrous sulphite and hyposulphite obtained by immersing clean iron wire in aqueous sulphurous acid contained in a closed vessel, gives with ferrocyanide of potassium a perfectly white precipitate.

By the action of the air, nitric acid, and other oxidising agents, potassio-ferrous ferrocyanide is converted partly into ferricyanide of iron and potassium (Williamson), partly into ferric ferrocyanide. (See p. 228.)

FERROCYANIDE OF LEAD, $\text{Pb}^4\text{Fe}^2\text{Cy}^6 + 3 \text{aq.}$, is obtained as a white precipitate on mixing the solutions of nitrate of lead and ferrocyanide of potassium. It gives off all

its water when gently heated. The anhydrous salt ignited in a close vessel gives off nitrogen, and leaves a mixture of carbide of lead and carbide of iron, which burns like tinder when gently heated in contact with the air. The hydrated salt suddenly exposed to a strong heat, gives off water, carbonic acid, and cyanide of ammonium. The salt is decomposed by dilute sulphuric acid, and by aqueous sulphydric acid, yielding ferroproussic acid. Heated in sulphydric acid gas, it is resolved into sulphide of lead, sulphide of iron and hydrocyanic acid (Berzelius). It is insoluble in water, partially soluble in hot aqueous ammonia, perfectly soluble in a hot solution of chloride or succinate of ammonium, insoluble in other ammoniacal salts. (Wittstein.)

FERROCYANIDE OF MAGNESIUM, $\text{Mg}^4\text{Fe}^2\text{Cy}^6 + 12 \text{ aq.}$, is obtained in the form of small, pale yellow, stellate needles, permanent in the air, by saturating ferroproussic acid with carbonate of magnesium, and evaporating the filtrate.

Ferrocyanide of Magnesium and Ammonium is obtained in an impure state by adding ferrocyanide of potassium, or of calcium, to a solution of a magnesium-salt containing sal-ammoniac and free ammonia. On boiling the liquid, the double salt is deposited in the form of a white powder, which does not decompose at 100°C .

Ferrocyanide of Magnesium and Potassium, $(\text{Mg}^2\text{K}^2)\text{Fe}^2\text{Cy}^6$, is obtained as a white granular precipitate on adding ferrocyanide of potassium in excess to a not very dilute solution of a magnesium-salt.

FERROCYANIDE OF MANGANESE.—White precipitate, soluble in hydrochloric acid. When a solution of a manganous salt is poured into excess of ferrocyanide of potassium, the precipitate contains both manganese and potassium.

MERCURIC FERROCYANIDE.—White precipitate obtained by adding ferrocyanide of potassium to solution of mercuric chloride.

Ammonio-mercuric Ferrocyanide, $2\text{NH}^3(\text{Hg}^{\prime\prime})^2\text{Fe}^2\text{Cy}^6 + \text{aq.}$, or *Ferrocyanide of Mercury and Mercurammonium*, $\left. \begin{smallmatrix} \text{N}^2\text{H}^6\text{Hg}^{\prime\prime} \\ \text{Hg}^{\prime\prime} \end{smallmatrix} \right\} \text{Fe}^2\text{Cy}^6 + \text{aq.}$, is obtained by dissolving nitrate of mercurammonium (ammonio-mercuric nitrate) in a moderately strong solution of nitrate of ammonium containing free ammonia and cooled by ice, and precipitating with ferrocyanide of potassium. It forms wine-yellow rhomboidal prisms, which give off their ammonia on exposure to the air. They are decomposed by water, yielding cyanide of mercury, ferric oxide, and ammonia. If the solution of nitrate of ammonia used in the preparation is too strong or too hot, mercury is reduced, and if it is too dilute, the product is immediately decomposed by the water present. (Bunsen, Pogg. Ann. xxxiv. 139.)

FERROCYANIDES OF MOLYBDENUM.—Ferrocyanide of potassium forms with molybdous salts, a dark-brown precipitate soluble in excess of the reagent and in ammonia; with molybdic salts, also a dark brown precipitate, insoluble in excess of the alkaline ferrocyanide, but soluble with decomposition in ammonia; with solutions of molybdic acid in the stronger acids, it forms a red-brown precipitate, soluble in excess of the ferrocyanide, and in ammonia, with formation of ferrocyanide and molybdate of ammonium. (Berzelius.)

FERROCYANIDE OF NICKEL, $\text{Ni}^4\text{Fe}^2\text{Cy}^6$.—Precipitated in pale apple-green flocks, soluble with red colour in ammonia, insoluble in ammoniacal salts. When thus prepared, it always retains ferrocyanide of potassium, which cannot be removed by washing. It may, however, be obtained quite pure by decomposing the following compound with boiling water.

Ammonio-ferrocyanide of Nickel, $10\text{NH}^3.\text{Ni}^4\text{Fe}^2\text{Cy}^6 + 4 \text{ aq.}$ —A solution of recently precipitated ferrocyanide of nickel in excess of ammonia deposits this compound, after a short time, in a multitude of very delicate violet-coloured needles. The same compound is obtained by adding ferrocyanide of potassium to a nickel-salt containing a large excess of ammonia. In the moist state, it is decomposed by mere exposure to the air, giving off ammonia and water and leaving ferrocyanide of nickel; but after drying, it bears a heat of 100° — 150°C . without decomposing. Boiling with water also decomposes it, the ammonia dissolving and ferrocyanide of nickel remaining. (Reynoso, Ann. Ch. Phys. [3] xxx. 252.)

Ferrocyanide of Nickel-ammonium, $(\text{NH}^3\text{Ni})^4.\text{Fe}^2\text{Cy}^6 + 4 \text{ aq.}$, is obtained as a greenish white precipitate on adding ferrocyanide of potassium to a solution of nitrate of nickel-ammonium. It is insoluble in water and more stable than the preceding. (Reynoso.)

FERROCYANIDE OF POTASSIUM. $\text{K}^4\text{Fe}^2\text{Cy}^6 = 4\text{KCy}.2\text{FeCy}$. *Prussiate of Potash*, *Ferroproussiate of Potash*, *Yellow Prussiate of Potash*, *Yellow Prussiate*, *Blood-lyc-salt*, *Blutlaugensalz*, *Kaliumeisencyanür*. (Gentele, Dingl. polytechn. J. lxi.

289; lxxvi. 352; xciv. 197; cxvii. 414.—Liebig, Ann. Ch. Pharm. xxxviii. 20. Habich, Dingl. cxl. 371.—Wagner's Jahresber. d. Chem. Technologie, 1856, p. 111.—Brunquell, Dingl. cxl. 374; cxli. 47; Wagner's Jahresber. 1856, p. 102.—Karmrodt, Dingl. cxlvi. 294; Wagner's Jahresber. 1857, p. 139.—Nöllner, Ann. Ch. Pharm. cxviii. 8; Wagner's Jahresber. 1858, p. 175.—R. Hofmann, Dingl. cli. 63; Wagner's Jahresber. 1858, p. 179.—Graeger, Polyt. Centralhalle, 1858, pp. 25, 33, 49; Wagner's Jahresber. 1858, p. 183.—Handwörterbuch der Chemie, 2^{te} Aufl. ii. [2] 184.—Gm. vii. 453.)

This important salt was first prepared about the middle of the last century by Macquer, who obtained it by the action of alkali on prussian blue, and called it *Phlogisticated alkali*. Sage, and afterwards Bergmann, showed that it might be prepared in the dry way. The iron contained in it was at first regarded as an impurity, till Berthollet showed that it was an essential constituent. The salt is now manufactured on a very large scale, and used for the preparation of cyanide and cyanate of potassium, prussic acid, prussian blue, and other cyanogen-compounds; also in dyeing and calico printing, for the direct formation of prussian blue on tissues.

Formation.—Ferrocyanide of potassium is formed on bringing together the following substances:

1. Protoxide of iron with aqueous cyanide of potassium.—2. Ferroproussic acid with hydrate or carbonate of potassium.—3. Ferrous hydrate with cyanide of potassium, potash being formed at the same time:

4. Ferrous cyanide with aqueous potash:

5. Ferric ferrocyanide or ferrous ferriocyanide with aqueous potash, ferric oxide being separated in the first case (p. 228), and ferroso-ferric oxide in the second (p. 202).—6. By the action of potash on various ferrocyanides (p. 223).—7. By bringing metallic iron in contact with aqueous cyanide of potassium, the action taking place slowly at ordinary temperatures, quickly at the boiling heat. If the air is excluded, hydrogen is evolved:

but if the air has access to the liquid, oxygen is absorbed and no hydrogen is evolved:

8. Sulphide of iron with aqueous cyanide of potassium, sulphide of potassium being formed at the same time:

9. Any soluble ferrous salt with aqueous cyanide of potassium:

Preparation.—1. *On the small scale*, pure ferrocyanide of potassium is easily obtained by adding pure Prussian blue (ferric ferrocyanide) to boiling aqueous potash, as long as its blue colour changes to brown, then filtering, and evaporating the liquid to the crystallising point. If commercial Prussian blue is used, the salt obtained will probably be contaminated with carbonate, sulphate, and other salts of potassium, and with green *prussiate of potash* (p. 235). It may be purified by picking out the crystals and recrystallising them several times, or, according to Berzelius, by heating the salt, first gently till it effloresces, afterwards to the melting point; dissolving it in water, which then leaves charcoal and carbide of iron undissolved; adding acetic acid to convert the carbonate and cyanide of potassium in the solution into acetate; precipitating the sulphuric acid present with solution of acetate of barium, added gradually and not in excess; then filtering, evaporating, precipitating the ferrocyanide of potassium by alcohol, and twice recrystallising it from hot water.

2. *On the large scale*, ferrocyanide of potassium is prepared by adding animal matters, such as horn, feathers, dried blood, leather-clippings, &c., mixed with iron filings, to fused carbonate of potassium (pearl-ash), lixiviating the fused mass with water, then filtering and crystallising by evaporation. The animal matter contains nitrogen and carbon, the latter in larger proportion than is required to form cyanogen with the nitrogen: hence when these substances are fused with carbonate of potassium, the excess of carbon reduces potassium from the carbonate, and the potassium thus set free unites with the cyanogen formed from the nitrogen and the remainder of the carbon, producing cyanide of potassium, which is converted into ferrocyanide in the subsequent lixiviation. It was formerly supposed that the cyanide of potassium is converted into

ferrocyanide during the fusion, by the action of the iron present in the fused mass, and that, in the lixiviation, the ferrocyanide is simply dissolved out. This, however, is impossible, inasmuch as the ferrocyanide is decomposed at the temperature to which the mass is exposed, into cyanide of potassium, carbide of iron, and nitrogen (p. 199). Moreover, Liebig has shown that if the fused mass, soon after cooling, be lixiviated with aqueous alcohol (brandy), nothing but cyanide of potassium is dissolved out, and the residual mass treated with water no longer yields any ferrocyanide. The ferrocyanide obtained when the fused mass is treated with water in the usual way, does not exist ready formed in the mass, but is produced by the mutual action of the cyanide of potassium and the metallic iron existing therein; moreover the product is considerably increased by adding, during the lixiviation, more metallic iron, or sulphide of iron, or a soluble ferrous salt (p. 231). This view has indeed been called in question by Runge (Pogg. Ann. lxi. 96) and others, who have found that the melted mass, when treated with brandy, yields but little cyanide of potassium, but afterwards yields the usual quantity of ferrocyanide when lixiviated with water. These results were probably due to the use of alcohol of too great strength, which dissolves cyanide of potassium but slowly, or to the melted mass having been left for some time in contact with the air, in which case the highly deliquescent cyanide of potassium would absorb water, and ferrocyanide would be gradually formed. Liebig's view has been confirmed by the recent experiments of Nöllner and R. Hoffmann, who find that when the fused mass is left to cool slowly, pure cyanide of potassium often separates out of it. Hoffmann has also shown, that when pure cyanide of potassium mixed with iron is treated with acetic acid and alcohol, it is completely decomposed, without formation of ferrocyanide, and that the ferrocyanide itself is not decomposed by acetic acid and alcohol; now when the fused mass obtained in the manufacturing process is pulverised and heated with acetic acid and alcohol, it behaves like a mixture of iron and cyanide of potassium, and the residue treated with water no longer yields ferrocyanide of potassium.

The manufacture of ferrocyanide of potassium (yellow prussiate) consists of three stages: *a.* The preparation of the melted mass, technically called "metal;" *b.* The lixiviation; *c.* The crystallisation.

a. The "metal" is prepared by melting animal matters with pearlash, generally with addition of iron, sometimes, though less advantageously, without it. The animal substances used are horn, woollen rags, dried blood, carcasses of animals, hairs, feathers, leather-clippings, old shoes, &c.; they are sometimes used in their original state, sometimes subjected to a previous dry distillation, the ammonia thereby evolved being condensed in hydrochloric or sulphuric acid, and thus obtained as a secondary product, and the residual azotised charcoal used for the preparation of the cyanide. Those substances are of course the most eligible which contain the largest proportion of nitrogen: in this respect, the several kinds of animal matter differ considerably, as shown by the following table given by Karmrodt.

100 parts of horn.	.	.	.	contain 15 to 17 p. c. nitrogen.
" dried blood	.	.	.	15 " 17 "
" woollen rags	.	.	.	10 " 16 "
" sheep-shearings.	.	.	.	16 " 17 "
" calves' hair	.	.	.	15 " 17 "
" bristles	.	.	.	9 " 10 "
" feathers	.	.	.	" 17 "
" hide-clippings	.	.	.	4 " 5 "
" old shoes	.	.	.	6 " 7 "
" charcoal from horn, accord-				
ing to the heat to which				
it has been subjected	.	.	.	2 " 7 "
" charcoal from rags	.	.	.	2 " 12 "

According to Boussingault and Payen, horn contains 14.3, air-dried muscular flesh 13.4, and woollen rags 16.0 p. c. nitrogen. According to Nöllner, old leather often contains not more than 1 to 2 p. c. nitrogen, whereas well preserved leather contains from 6 to 12 p. c.

The charcoal obtained by the carbonisation of animal substances contains nitrogen, but less in proportion as it has been more strongly heated; at the same time, however, the quantity of charcoal obtained is less. 100 parts of rags carbonised at a certain temperature, yielded 75 pts. charcoal containing 12 p. c. nitrogen, whereas the same rags charred at a stronger heat yielded 25 pts. charcoal containing only 1.25 to 2 p. c. nitrogen. It is important, therefore, not to heat the animal substances too strongly, and to stop the distillation at such a point that the yield of charcoal shall be from 50 to 70 p. c.

It is important that the animal substances used should not yield much ash, as this,

besides thickening the mass, will decompose a portion of the potash, converting it into soluble salts which will mix with the ferrocyanide: the animal substances should, therefore, be well-cleaned, especially from sand, before calcination (1 pt. of sand will decompose 2 pts. of pearl-ash).

The *potassium* for the preparation is supplied in the form of carbonate (pearl-ash). It is not necessary to use perfectly pure carbonate of potassium; indeed a certain proportion of sulphate is said to act beneficially, by forming sulphide of iron. According to Brunnuell and Hoffmann, however, it is always injurious, as it converts a portion of the cyanide of potassium into sulphide, cyanate, and sulphocyanate.

In localities where potash from plant-ashes is too dear, an impure carbonate is sometimes prepared from the sulphate by ignition with coal and carbonate of lime, just as, in the ordinary method of soda-making. The sulphate of potassium used for this purpose may be obtained from the mother-liquor of sea-water, and of the ashes of kelp and varechs. (See *POTASH*.) Bramwell uses, instead of carbonate of potassium, the sulphide obtained by igniting sulphate of potassium with charcoal. It is fused with animal matter and an equivalent quantity of iron, which is thereby converted into sulphide.

The addition of *iron* in the melting process might appear at first sight to be unnecessary, inasmuch as the conversion of the cyanide of potassium into ferrocyanide takes place only in the lixiviation. It is, however, required for two reasons: first, because the sulphate of potassium, which is almost always present, is converted, by ignition with charcoal, into sulphide and bisulphide of potassium, and the latter, if no iron is present, converts a portion of the cyanide of potassium into sulphocyanate, which is not converted into ferrocyanide in the subsequent lixiviation, and consequently occasions a loss of cyanogen; and, secondly, because the bisulphide of potassium exerts a very rapid corroding action on the iron pot in which the materials are fused. Now, when iron is added in the form of filings, turnings, &c., it easily decomposes the alkaline sulphides, thereby preventing the formation of sulphocyanate of potassium, and is itself converted into sulphide of iron, which is easily transformed into ferrocyanide by the action of the aqueous cyanide. The iron is usually added in the form of filings, turnings, or smithy scales (black oxide), sometimes also in the form of spathic iron (native ferrous carbonate).

For calcining the mixture, pear-shaped iron pots were originally, and are still frequently, used; they are built into the furnace in a slanting direction, and in such a manner that the flame can play all round them. The contents are stirred with a flat iron bar, or scoop, introduced through an aperture in the lid.*

A more complete arrangement, now adopted in the larger English works, consists of a set of iron melting pots of nearly hemispherical shape, set in brickwork, and each heated by a separate fire and circular flue. The pots are closed by iron lids having apertures for introducing the animal matters, the aperture being immediately closed by a slide after each addition. Through the lid of each pot there passes a vertical spindle, carrying a set of blades or arms for mixing the materials, and set in motion by a driving shaft worked by steam power. The pots being completely closed during the melting, the atmosphere within them is maintained in a deoxidising condition, and thus the formation of cyanates is prevented.†

As iron pots heated from below cannot be raised to the high temperature which is most favourable to the success of the process without subjecting them to very rapid wear, the calcination is frequently performed, especially in Germany, in a reverberatory furnace, on the hearth of which is placed a cast-iron pan 4 or 5 feet wide, 4 or 5 inches deep, and several inches thick on the sides and bottom. The interior dimensions of the furnace should not be larger than is necessary for convenient manipulation, and the arch should be very flat. The mass in the pan is stirred by a thick iron bar, or crook, suspended by a chain and passing through an aperture in the side of the furnace; with this arrangement, the stirring is much more easily performed than with the old-fashioned pots. The furnaces are so arranged that when the potash has once been brought into the fused state, the doors of the fire-place may be closed, and no fresh firing is required during the introduction of the animal matters: this prevents the access of air to the melting mass which would oxidise it, and lead to the formation of cyanate of potassium, which would entail loss of cyanogen. Ordinary reverberatory furnaces with fire-brick hearths cannot be used for the fusion, because the hearth would be strongly attacked by the melting potash, and a large quantity of silicate of potassium would be formed.

The fuel used is either wood or coal. When the process is performed in a rever-

* A figure of the arrangement is given in the new edition of *Ure's Dictionary of Arts, Manufactures, and Mines*, vol. iii. p. 480.

† For a figure and full description of this arrangement, see *Knapp's Chemical Technology*, edited by Richardson and Watts, vol. i. part 4.

beratory furnace the fuel should be very dry; for if aqueous vapour comes in contact with the heated mass, a considerable quantity of the cyanide will be decomposed, yielding carbonate of potassium, ammonia, carbonic anhydride, and free hydrogen:

Quite recently the use of gas-generators with a blast of air has been introduced into the manufacture of ferrocyanide of potassium; it presents many advantages, in particular that of facilitating the regulation of the temperature and the admission of oxygen, so as to produce at pleasure either, an ordinary, a neutral, or a reducing flame. According to Hoffmann, it is advisable, at the beginning of the process, to burn the flame-gases completely by the admission of a sufficient quantity of oxygen, so as to produce a very high temperature, which materially facilitates and expedites the process, at the same time that the excess of carbon in the animal matters, and the combustible gas evolved from the melting mass, prevents the oxygen from coming in contact with the metal, and thereby converting the cyanide of potassium into cyanate.

The melting process is conducted as follows. The pearl-ash (2 to 5 cwt. according to the dimensions of the furnace), or a mixture of 1 pt. pearlash and 2 to 4 pts. *blue salt* or *blue potash* obtained in a preceding operation (*vid. inf.*), is melted in the iron vessel (which takes about two hours), and heated to bright redness, so that the mass may not be too much cooled by the introduction of the animal matters. These, or an equivalent quantity of animal coal mixed with 6 to 8 per cent. iron, are then added in successive portions, first at shorter, afterwards at longer intervals. For every 100 pts. of pearlash, from 100 to 125 parts of fresh animal substances are taken, often a mixture of several kinds of animal matter containing different proportions of nitrogen, horn and rags for example. Sometimes a smaller quantity of uncharred animal matter is taken, and the amount made up with animal coal; the latter is seldom used alone. Each addition of animal matter causes a violent reaction and evolution of combustible gases, viz. carbonic oxide and hydrocarbons, together with water and carbonic acid, and the mass becomes thickened, less by the admixture of solid matter than by the fall of temperature resulting from the abundant formation of gas; active stirring must therefore be resorted to, in order to mix the materials well together and accelerate the decomposition. After a while, the mass gradually becomes hotter and more fluid, and carbonic oxide is evolved in consequence of the reduction of potassium. After this reaction has gone on for $1\frac{1}{2}$ to 2 hours more, the decomposition is complete. The pasty mass is then ladled out into small cast iron dishes of about 2 inches diameter, and the furnace is again heated and filled with potash. In this manner, from 4 to 6 melting operations may be performed in 24 hours. The higher the temperature of the furnace, up to a certain point, the more quickly does the reaction take place, and the more abundant generally speaking is the product. If the heat is too low, the reduction of the potassium does not take place fast enough; and if it is too high, the cyanide and other potassium-salts volatilise and condense in the flues. A loss of product may arise from the decomposing action of aqueous vapour evolved from the animal matters: hence, according to Habich, it is best to dry these substances previously by means of over-heated steam, continuing the action till a slight evolution of ammonia begins, and substances like horn and rags are rendered friable.

b. Lixiviation.—The metal, which in a well conducted process, should yield about 16 per cent. of ferrocyanide, is broken into lumps when cold, and thrown into large iron pans filled with cold water, mixed with the weak lyes of former operations. The liquid is then heated to 80° or 90° C. (176° to 194° F.), and constantly stirred to dissolve the metal as quickly as possible, because a portion of the cyanide of potassium is decomposed during the lixiviation into ammonia and formate of potassium (p. 198), and the amount thus lost increases as the operation is protracted. According to Brunquell, the metal should be macerated for 24 hours in water of 50° to 60° C. (122° to 140° F.), and then boiled, in which case no decomposition takes place. According to Hoffmann, the ammonia evolved is not actually formed during the lixiviation but is previously enclosed within the pores of the metal, and, dissolving in the cold water, is evolved when the liquid is heated.

As soon as the lye has attained a density of 1.16 to 1.22 (20° to 26° Baumé), it is left to clarify without further heating; the clear solution is decanted from the insoluble residue, and transferred to the evaporating pans, which are usually heated by the waste heat of the melting furnaces. It is then brought to a density of 1.27 (32° Baumé), and run off into the crystallising vessels, where it deposits a crude salt, containing, according to Hoffmann, about $\frac{1}{2}$ of pure ferrocyanide of potassium.

c. Crystallisation.—The crude salt obtained as above mentioned is dissolved in warm water, so as to form a solution of specific gravity 1.27 (32° Baumé), and this solution, after clarification, is transferred to the crystallising vessels. These are sometimes made of wood, but the salt crystallised in such vessels generally has a green

colour arising from a decomposition, produced, according to Gentele, by the tannin of the wood. On this account, cast-iron crystallisers are more generally preferred. The liquor is left to crystallise slowly, the crystallisation often going on for weeks in large vessels; the mother-liquor is drawn off, and if not too impure, is used to dissolve fresh quantities of crude salt; after being used two or three times for this purpose, it serves for the preparation of *blue-salt*.

The ferrocyanide is deposited in crusts in the crystallising vessels; but by suspending lumps of the solid salt in the solution by threads, it may be obtained in long bunches of crystals (*Krystaltrauben*), and by suspending these in fresh lyes, they may be obtained of great size. The salt thus obtained may be further purified by recrystallisation; 100 pts. of crude salt yield about 90 pts., or if pure materials have been used, 97 pts. of pure ferrocyanide of potassium.

The *green salt* above mentioned may be purified by recrystallisation, with addition of a small quantity of an oxidising agent, such as arsenious acid, or better, of ferricyanide of potassium (red prussiate). According to Hoffmann, the green colouring sometimes arises from the presence of sulphide of iron and potassium.

Commercial yellow prussiate often contains sulphate of potassium, which indeed may be present in considerable quantity without altering the appearance of the salt. This impurity is not easily removed by recrystallisation. The best mode of purification is to decompose the sulphate with chloride or acetate of barium, separate the resulting chloride or acetate of potassium by repeatedly crystallising the filtered solution, or by precipitating it with alcohol, then wash the precipitate with alcohol, and recrystallise from water. On the large scale, the sulphate may be completely separated by evaporating the solution to specific gravity 1·31 (35° Bm.), whereupon the greater part of the sulphate crystallises out, then drawing off the clear liquor, diluting it to specific gravity 1·26 (30° Bm.), and leaving it to cool: it then deposits pure ferrocyanide of potassium. A further portion may be obtained in like manner from the mother-liquors. For technical use, however, the sulphate of potassium is not directly injurious, but merely objectionable in so far as its presence diminishes the proportion of ferrocyanide.

Treatment of the residucs.—The mother-liquor of the crude salt concentrated to a density of 1·33 to 1·38 (30° to 40° Bm.) deposits, on standing, nearly all the remaining ferrocyanide in the form of a fine-grained powder. The last mother-liquor contains a considerable quantity of carbonate of potassium, together with hydrate, chloride, sulphocyanate and silicate of potassium. When concentrated to a specific gravity of 1·45 (45° Bm.), it deposits the greater part of the silicate, chloride, &c., of potassium, and the mother-liquor still remaining, which contains the greater part of the carbonate, is evaporated to dryness and calcined in reverberatory furnaces provided with iron pans like the melting furnaces. The dry residue, called *blue-salt*, or *blue-potash* (*Blausalz*, or *Blaukali*), which contains from 70 to 80 per cent. of carbonate of potassium, is used, instead of potashes, or mixed with it, in subsequent melting operations.

According to analyses by Brunnequell (1), and Hoffmann (2, 3, 4 and 5), slightly calcined blue salt contains in 100 pts.:

	1.	2.	3.	4.	5.
Carbonate of potassium	71·9	71·0	82·4	75·1	44·1
Silicate	11·9	9·5	7·6	8·8	22·8
Sulphide	4·3	1·4	3·8	8·3	8·7
Chloride, sulphocyanate, phosphate and sulphate of potassium	8·2	13·0	7·1	10·1	26·7
Insoluble matter	1·6				
Water and loss	2·1				

Analysis 1 is from a melting with crude potash of 75 per cent.; 2 is blue salt from a melting conducted in the ordinary way with pearl-ash; 3, with pearl-ash of better quality; 4, from a melting made with blue salt; 5, with impure potash. The last three analyses show clearly the rapid increase of the impurity of the blue-salt when impure materials are used, and the necessity of purifying it; since, when the proportion of silica increases, part of the potash is rendered insoluble and remains in the deposit, being thus lost to the process.

The *insoluble residue* or *deposit* which remains in the lixiviation of the metal, varies in quantity and composition according to the nature and proportions of the animal matters and the alkali used in the preparation; it also contains matter carried over from the fuel. Karmrodt obtained from 100 pts. of *metal* the following quantities of ash, each being the mean of 10 analyses:

By the use of . . . Rags	Horn	Hair	Leather	Charcoal (bad)
Insoluble salt . . . 28·3	1·8	23·0	35·1	38·7

The composition of three samples of insoluble residue is shown in the following table:

Potash (K_2O)	12.2	16.7	10.2
Lime	16.2	18.4	19.6
Magnesia	2.1	1.3	1.0
Alumina	4.8	10.2	14.2
Iron, with sesquioxide	16.1	2.1	3.1
Manganese	0.4	0.06	0.7
Copper	trace	0.4	0.02
Silica	21.1	29.7	26.4
Sulphuric acid (SO_3)	1.2	0.2	1.8
Phosphoric acid (P_2O_5)	10.4	6.4	4.9
Charcoal	6.1	4.2	9.2
Sulphur, chlorine, cyanogen, and loss	9.4	10.34	8.88
	<u>100.0</u>	<u>100.00</u>	<u>100.00</u>

The following analyses of insoluble residues from the prussiate of potash manufacture, are by Dr. Richardson of Newcastle.

	Fresh residue.	Old residue.
Sulphate of potassium with traces of sulphate of calcium, and of the chlorides of sodium and magnesium	9.06	3.21
Phosphates of calcium, magnesium, and iron	13.74	6.24
Sesquioxide of iron	13.34	19.58
Lime and Magnesia	5.08	7.23
Sand and Silica	23.97	29.24
Charcoal and Moisture	34.81	34.50
	<u>100.00</u>	<u>100.00</u>

The sample of old refuse was taken from a heap near the manufactory, which had lain exposed for a long time to the weather.

Hoffmann found in 100 pts. of dried residue which had been thoroughly lixiviated with cold water, from 20 to 30 pts. of silica in combination with alkali, which, if calculated as carbonate of potassium, amounted to between 20 and 30 pts. A considerable quantity of this alkali appears to be soda, and as the whole of the soda contained in the pearl-ash passes into this insoluble residue, Hoffmann suggests that a quantity of soda equivalent to the potash found in the residue might be added in the melting without diminishing the amount of ferrocyanide of potassium obtained.

The large amount of potash in the insoluble residue, together with the phosphoric acid and the decomposable silicates, renders it well adapted for the preparation of artificial manures. It may also be used for the manufacture of alum by moistening and heating it with strong sulphuric acid, and adding sulphate of alumina. Or, again, the alkali may be extracted from it as carbonate by igniting it with an equal weight of carbonate of lime and lixiviating (Karmarodt); according to Hoffmann, however, this treatment does not extract from the residue a larger amount of alkaline carbonate than simple calcination and lixiviation, or boiling with milk of lime, by which he finds that two-thirds of the whole amount of potash may be extracted. Hoffmann is of opinion that the whole of the potash might be thus extracted from the residues in the soluble form, if they could first be freed from silica. Whether it is more profitable to extract the potash from these residues and use it in subsequent operations, or to apply the residues to the preparation of manure, must depend on local circumstances.

The manufacture of ferrocyanide of potassium is still very imperfect in an economical point of view. Besides the loss of potash in the insoluble residue, there is a very large loss of nitrogen, first, because the greater portion of that element contained in the animal matter used is not converted into cyanogen at all, and secondly, because part of the cyanide of potassium in the metal is lost by decomposition, and another portion remains in the mother-liquor, so that out of 100 parts of ferrocyanide, which ought to be obtained from the metal, about $\frac{1}{25}$ is lost when pure materials are used, and about $\frac{1}{2}$ when the materials are impure.

During the year 1847, a series of experiments was undertaken by Messrs. Lee and Richardson*, to ascertain how far it was possible to prevent the loss of nitrogen in the present mode of manufacturing prussiate of potash.

The experiments were on a large laboratory scale, and the fusions were conducted in

* Communicated by Dr. Richardson.

gun-barrels. Several preliminary experiments were made with the ordinary mixture in the usual method, to enable the authors to acquire a familiarity with the nature and character of the operations.

In the subsequent experiments the same mixture of materials was always employed.

Pure horn, carefully and finely rasped, was mixed with pure potashes and clean iron filings. A small quantity of water was added to assist in making an intimate mixture, which was carefully and thoroughly dried and then reduced to a fine powder. This mixture was composed of:

Horn	16·00
Potashes	17·72
Iron	3·00
Moisture	3·28—40 oz.

The potash-charcoal was made by soaking 13 oz. of wood-charcoal with a solution of 4 oz. of potashes, and then carefully dried.

The gun-barrel was partially filled with the first mixture and exposed to a red heat in a distinct furnace. In the first and second series of experiments, the gases generated in the retort were passed through the potash-charcoal, which was kept at a red heat in another iron tube in connection with the retort-tube. In the third series of experiments, the gases were passed through hydrochloric acid. In the fourth series, the gases were passed through the red-hot potash-charcoal, and afterwards successively through hydrochloric acid and a solution of potash. In the last series, the gases escaping were collected and analysed.

In each case the prussiate was carefully extracted and crystallised. The ammonia was estimated in the usual manner, and in the tabulated results which follow, the equivalent of this ammonia is calculated in crystallised prussiate of potash.

The theoretical yield of prussiate was 382·50 and the actual quantities obtained and calculated were as follows, from the

	1.	2.	3.	4.
Retort	101·97	135·46	146·93	141·08
Tube	68·25	63·54	.	71·00
Acid	140·24	58·80
Potash	2·75
Total	170·22	199·00	287·17	273·63
Loss	212·28	183·50	95·33	108·87
	382·50	382·50	382·50	382·50
Produce per cent.	44·5	52·2	75·1	71·5

The gas evolved from the fourth experiment was collected after all the air had been expelled from the apparatus, and consisted of:

Hydrogen	46·00
Carburetted hydrogen	14·66
Carbonic oxide	25·34
Nitrogen	14·00
	100·00

Hence it appears that a considerable portion of the nitrogen of the organic matter is lost in a form which cannot be recovered in any shape available for manufacture of a commercial article.

From experiments on the proportion of the nitrogen of animal matter which is actually rendered available in the production of yellow prussiate, Karmrodt has obtained the results given in the following table:

<i>Animal substances used.</i>	<i>Proportion of Nitrogen converted into Cyanogen.</i>
Woollen rags	1/6
Horn	1/5
Leather-cuttings	1/3
Cow-hair	1/7
Horn-charcoal (50 pts. charcoal from 100 pts. horn)	4/7
Rag-charcoal (75 pts. charcoal from 100 pts. rags)	1/3

From the analysis of well-fused "metal" from a factory of yellow prussiate, Karmrodt obtained the following results:

<i>Substance used.</i>	<i>Nitrogen converted into Cyanogen.</i>
Dried blood	1/6
Leather-cuttings	1/5
Horn	1/8
Woollen rags	1/9

The greater part of the nitrogen thus lost to the process goes off in the form of ammoniacal salts; the quantity of these salts increasing as the temperature of the mass becomes lower: hence a too rapid addition of the animal matters diminishes the quantity of cyanide obtained; on the other hand, the product is increased by keeping the melted mass at a very high temperature.

Numerous attempts have been made to render available the ammonia given off in the process. With this view the animal substances were formerly subjected to dry distillation, in the first instance, to obtain ammoniacal salts, and only the residual azotised charcoal was used for the preparation of yellow prussiate. Now, however, that ammoniacal salts can be obtained so cheaply from other sources, as from the ammoniacal liquor of the gas-works, in England, and from sewage water in Paris, this mode of saving the nitrogen can scarcely be made to pay; and, according to the general experience of manufacturers, the amount of cyanide obtained is not so great when the animal matters have been previously distilled, as when they are used in their original state.

Another mode of utilising the ammonia evolved in the process, is to pass it over an ignited mixture of charcoal or coke and potash, and thus convert it into cyanogen (see page 198). There can be no doubt of the possibility of producing cyanogen in this manner, and several patents have been taken out for performing it on the large scale*, but it does not appear that any of them have yet been profitably worked. Brunnequell suggests to pass the gases evolved by the dry distillation of animal substances through a red-hot tube of fire-clay filled with lumps of charcoal about the size of a nut, in order to convert the ammonia into cyanide of ammonium, pass the vapour of this salt, together with undecomposed carbonate of ammonium, into a moderately dilute solution of protosulphate of iron,—and boil the resulting precipitate, containing protocyanide of iron, with carbonate of potassium, to convert it into yellow prussiate. This process would certainly have the advantage of avoiding the contamination of the product with silica and the ash of the animal substances.

Another source of loss in the ordinary process is that a certain portion (from $\frac{1}{50}$ to $\frac{1}{15}$) of the cyanide of potassium in the crude lye obtained by lixiviating the metal, is not converted into ferrocyanide, even by prolonged digestion with sulphide or oxide of iron. The best mode of proceeding, according to Hoffmann, is to draw off the first liquor into a large cistern containing a considerable quantity of carbonate of iron: the cyanide of potassium will then be completely converted into ferrocyanide in the course of twenty-four hours.

If the metal contains much sulphur and not enough iron to take up the whole of it, a portion of the cyanide of potassium will be converted into sulphocyanate during the lixiviation of the metal with warm water. Hoffmann finds that the sulphocyanate is easily desulphurised by metallic iron on the small scale, but not in the manufacturing process. Scale-oxide of iron added to the metal at the end of the melting process, easily decomposes the sulphocyanate, but forms cyanate of potassium instead of cyanide. Habich desulphurises the solution with native carbonate of iron, previously freed from the carbonates of lime and magnesia by digestion with sesquichloride of iron. The complete conversion of the sulphocyanate into cyanide, would increase the quantity of yellow prussiate obtained from a given quantity of raw material from 100 to 116 pts.

As animal matters are very valuable for the preparation of manures, various attempts have been made to obtain the nitrogen required for the production of ferrocyanides from other and cheaper sources, especially from the air. That cyanides can be formed by passing atmospheric nitrogen over carbon impregnated with potash, has been satisfactorily proved by several experiments, especially by those of Fownes and of Bunsen (p. 198); and it has also been found possible to carry out this mode of formation on the manufacturing scale. Possoz and Boissière first established a manufactory for this purpose at Grenelle near Paris, in 1845, but afterwards transferred their operations to Newcastle, where fuel could be obtained at a much smaller cost. Their process, improved by Mr. Bramwell of Newcastle, consisted in passing a current of air over charcoal powder saturated with carbonate of potassium, and heated to whiteness for ten hours in wide earthen cylinders placed in an upright position.† The charcoal was

* For a description of Berry's process (patented) see *Ure's Dictionary of Arts, Manufactures, and Mines*, vol. iii.

† For a description and drawing of the apparatus, see *London Journal of Arts*, 1845, p. 380; *Reper-tory of Patent Inventions*, 1847, p. 280; also *Graham's Elements of Chemistry*, 2nd ed. vol. i. p. 387.

afterwards mixed with pulverised native carbonate of iron and lixiviated. The factory was in operation for two years, during which it produced 1000 kilogrammes (about a ton) of yellow prussiate daily. It was, however, not found to work profitably, and was ultimately abandoned, chiefly, it appears, on account of the large expenditure of fuel, and because the cylinders, whether of fire-clay or iron, were unable to withstand the intense heat to which they were exposed.

Mr. Spencer, of the Commercial Road, London, patented a process in 1837, for making use of the waste lime and lime-liquor of gas-works for the preparation of yellow prussiate and prussian blue. This gas-lime certainly contains cyanides, but the proportion appears to be too small to yield a profitable result.

The alteration which appears to present the greatest hope of improvement in the manufacture of ferrocyanide is the substitution of baryta for potash. Margueritte and De Sourdeval have shown that cyanide of barium is easily formed by passing a current of air over an intimate mixture of charcoal and baryta at a bright red heat. The baryta, not being fusible, forms with the charcoal a porous mass which the nitrogen can easily penetrate, and thus an immense number of points of contact between the carbon and nitrogen are at once obtained, whereas carbonate of potassium fuses, and the nitrogen can act only on its surface. Equally favourable results are said to have been obtained by passing the ammoniacal vapours obtained by the distillation of animal substances over a mixture of charcoal and baryta.

Another process, recently introduced by Gélis (Rép. Chim. app. 1862, p. 370), consists in forming sulphocyanate of potassium by distilling a mixture of disulphide of carbon and sulphhydrate of ammonium with sulphide of potassium, and converting the sulphocyanate into yellow prussiate by heating it to dull redness with metallic iron. (See SULPHOCYANATES.)

Properties of Ferrocyanide of Potassium.—The pure salt crystallises with 3 at. water, $K^1Fe^2Cy^6 + 3H^2O$, in truncated pyramids belonging to the dimetric or quadratic system. Ordinary form P. oP (like fig. 362), sometimes also with P ∞ and $\infty P\infty$. The crystals are often reduced to the tabular form by predominance of the face oP. Length of principal axis = 1.768. Inclination of P : P in the terminal edges = $97^\circ 56'$; in the lateral edges = $136^\circ 24'$. They are generally lemon-yellow, turbid, or translucent, sometimes amber-yellow, or orange-yellow and quite transparent; transparent crystals appear to be formed especially by the cooling of large masses of the solution. The crystallised salt has a specific gravity of 1.83. It is permanent in the air at ordinary temperatures. The water of crystallisation begins to escape at $60^\circ C.$ ($140^\circ F.$), but is not given off completely even at $100^\circ C.$, unless the salt is reduced to powder and stirred for some time in contact with the air. The anhydrous salt is a white powder. The crystals contain exactly so much water (12.77 per cent. = 3 at.) that they may be regarded as *anhydrous hydrocyanate of ferrous oxide and potash* ($K^1Fe^2Cy^6 + 3H^2O = 2K^2O.Fe^2O.6HCy$). Ferrocyanide of potassium is inodorous, has a sweetish, saline, rather bitter taste, a neutral reaction, and is not poisonous.

The crystallised salt dissolves in 2 pts. boiling and 4 pts. cold water, forming a pale yellow solution. According to Michel and Kraft (Ann. Ch. Phys. [3] xli. 471), a litre of the solution saturated at $15^\circ C.$ (which has a specific gravity of 1.144) contains 258.77 grms. salt, and 885.34 grms. water. The salt is insoluble in alcohol, and is precipitated by alcohol from its aqueous solution in yellowish-white pearly scales.

Decompositions.—1. Ferrocyanide of potassium heated in a close vessel melts at little above a red heat, giving off nitrogen and leaving a mixture of cyanide of potassium and carbide of iron. If, however, it contains moisture, it likewise evolves carbonic acid, ammonia, and prussic acid. When the salt is heated with a sufficient quantity of hydrate or carbonate of potassium, no nitrogen is evolved, but the residue contains the whole of the cyanogen in the form of cyanide and cyanate of potassium, mixed with metallic iron, which sinks to the bottom of the melted mass. On this reaction is founded the preparation of the impure salt called "Liebig's cyanide of potassium," which is largely employed for galvanic gilding.

2. Both the crystals and the solution decompose slowly when exposed to light, giving off hydrocyanic acid, depositing ferric oxide or prussian blue, and acquiring an alkaline reaction. The solution is also slowly decomposed by boiling in an open vessel, ammonia being given off and the liquid becoming alkaline.

3. Oxygen, in its ordinary state, does not alter ferrocyanide of potassium at ordinary temperatures; but in an atmosphere containing ozone, as for example in a bottle containing moist phosphorus, the salt is gradually converted, from without inwards, into

Fig. 362.

ferri-cyanide (red prussiate). The same transformation takes place when a solution of the salt is subjected to the action of the *electric current*, ferri-cyanide of potassium being formed at the positive pole, while hydrogen and potash are eliminated at the negative pole.

4. The salt *heated to redness in contact with the air* is converted into cyanate of potassium; also when ignited with reducible *metallic oxides*, such as the oxides of lead and iron, peroxide of manganese, &c. In fact, fused ferrocyanide of potassium reacts with oxides and sulphides just like the cyanide, inasmuch as it is converted into cyanide by fusion.

5. The aqueous solution is converted by finely divided *peroxide of lead* into ferri-cyanide of potassium, slowly in the cold, more quickly when heated, completely in a few hours at the boiling heat: the other products of the reaction are carbonate of potassium and basic carbonate of lead. The same transformation is produced, though less easily, by finely divided *peroxide of manganese*; on the addition of a dilute acid, it takes place quickly. *Pernmanganate of potassium* converts ferrocyanide of potassium chiefly into ferri-cyanide, together with a small quantity of nitrate.

6. *Chlorine* converts either the pulverised salt or the solution into ferri-cyanide of potassium:

Bromine acts in a similar manner. (Smee.)

7. *Iodine* dissolves abundantly in a warm solution of ferrocyanide of potassium, if only a sufficient quantity is added to form an olive-green solution. An iodo-ferri-cyanide of potassium, $\text{KI.K}^2\text{Fe}^2\text{Cy}^6$, is deposited on cooling, in the form of a golden-yellow crystalline powder having a silky lustre. (Preuss, Ann. Ch. Pharm. xxix. 323.)

8. Strong *nitric acid* heated with ferrocyanide of potassium decomposes it completely, giving off cyanogen, nitrogen, nitric oxide, and carbonic acid, and forming ferric oxide and nitrate of potassium. Moderately strong nitric acid dissolves it, forming a coffee-coloured solution, which contains nitro-ferri-cyanide or nitro-prusside of potassium (p. 250).

9. Aqueous *chloric* and *iodic acids* are said to convert the ferrocyanide into ferri-cyanide, with evolution of chlorine or iodine.

10. *Chromic acid* and soluble chromates convert the ferrocyanide into ferri-cyanide. (Schönbein, J. pr. Chem. xx. 145.)

11. The ferrocyanide melted with *sulphur* is converted into sulphocyanate of potassium, mixed, according to the temperature, with proto-cyanide of iron, sulphocyanate of iron or mellone-compounds. (See SULPHOCYANATES.)

12. Fused in like manner with *selenium*, it yields selenocyanate of potassium (*q. v.*)

13. Heated with *strong sulphuric acid*, it gives off carbonic oxide, and leaves a residue of sulphate of potassium, sulphate of ammonium, and ferrous sulphate:

When the acid is first poured on the pulverised salt, the mass becomes hot and gives off a small quantity of prussic acid. On applying heat, the white pasty mass dissolves and gives off abundance of carbonic oxide, which is pure, excepting that it has a slight garlic odour; no hydrocyanic acid passes over with it, but only a trace of formic acid; finally also a small quantity of sulphurous anhydride is evolved; but if the heat be continued after all the carbonic oxide has passed over, large quantities of sulphurous anhydride are evolved and the ferrous sulphate is converted into ferric sulphate, which unites with the sulphate of potassium, forming an iron-alum, $\text{K}(\text{Fe}^2)^{1/2}\text{SO}^4$. (Fownes, Phil. Mag. [3] xxiv. 21; see also Grimm and Ramdohr, Ann. Ch. Pharm. xeviii. 127.)

14. The *stronger acids* added in the state of dilute solution, and not in too great excess, to a solution of ferrocyanide of potassium, produce no apparent alteration; but subsequent treatment with ether shows that ferroprussic acid has been separated (p. 226). The mixture becomes turbid when heated; boils below 100°C .; gives off half the cyanogen of the ferrocyanide in the form of hydrocyanic acid; deposits the white or yellow powder of ferrocyanide of iron and potassium, $\text{K}^2\text{Fe}^4\text{Cy}^6$; and then contains in solution a compound of the acting acid with three-fourths of the potassium. Supposing that the ferrocyanide of potassium is not completely decomposed in the cold—which, though not certain, may be assumed as true when only 3 at. sulphuric acid are used—the equation will be:

But, if the ferrocyanide of potassium is completely decomposed at the commencement, without the aid of heat, into ferroprussic acid and a potassium-salt, we must suppose

that the ferroproussic acid, when resolved by heat into hydrocyanic acid and $\text{H}^2\text{Fe}^{\text{I}}\text{Cy}^6$ again takes up 2 at. potassium from the potassium-salt produced:

According to calculation, 211.4 parts (1 at.) of crystallised ferrocyanide of potassium, yield 40.5 pts. ($1\frac{1}{2}$ at.) or 19 per cent. of hydrocyanic acid.

15. Ferrocyanide of potassium boiled with *mercuric oxide* is gradually decomposed, with formation of mercuric cyanide, which remains in solution, together with carbonate of potassium formed by absorption of carbonic acid from the air, while ferric hydrate produced by absorption of atmospheric oxygen, is deposited (Vauquelin):

If the quantity of mercuric oxide is not sufficient for complete decomposition, the liquid deposits pale yellow rhombic tablets, probably a double salt of cyanide of mercury with ferrocyanide of potassium (Preuss, Ann. Ch. Pharm. xxix. 324). When 1 pt. ferrocyanide of potassium is boiled with 2.5 pts. *mercuric sulphate* and 8 pts. water, cyanide of mercury is formed, together with sulphate of potassium and ferric sulphate, and metallic mercury is precipitated, together with a small quantity of a greenish-white powder:

The ferrocyanide boiled with *mercuric nitrate* or *chloride*, forms a double salt, $\text{K}^2\text{Hg}^{\text{O}}\text{Cy}^4 + 2\text{aq.}$, which crystallises in white micaceous laminæ (Desfosses). The hot solution of the ferrocyanide takes up a large quantity of *mercuric iodide*, and on cooling deposits a double salt which crystallises in laminæ. (Preuss.)

16. When the solution of the ferrocyanide is boiled with *nitrate of silver*, a dirty blue precipitate of ferrous cyanide is produced, while cyanide of silver and potassium remains in solution:

A similar reaction takes place with chloride of silver (Gerh. i. 327):

17. When the solution of ferrocyanide of potassium is boiled with a few drops of *sesquichloride of iron*, a certain quantity of ferricyanide of potassium is formed, so that the liquid yields a deep blue precipitate with ferrous salts:

A small quantity of ferricyanide is also formed on boiling the ferrocyanide with a large excess of prussian blue. (Williamson, Ann. Ch. Pharm. lvii. 238.)

18. When ferrocyanide of potassium is heated with *sal-ammoniac*, either dry or in solution, cyanide of ammonium volatilises, while chloride of potassium and chloride of iron remain (Duflos, Schw. J. lxx. 106. Bineau, Ann. Ch. Phys. lxxvii. 231.)

19. The aqueous solution of ferrocyanide of potassium forms with the salts of most of the *earth-metals* and *heavy-metals*, precipitates consisting of ferrocyanides of those metals, *e.g.*:

the precipitate generally carries down with it a small quantity of the alkaline ferrocyanide, which is difficult to remove by washing. The colours of many of those precipitates are very characteristic, and render ferrocyanide of potassium a valuable reagent for the detection of metals in solution. The colours exhibited by the most important metals are given in the following table.

Reactions of Ferrocyanide of Potassium with Metallic Solutions.

Salts of Aluminium	.	White precipitate (after some time only).
„ Antimony	.	White.
„ Bismuth	.	White, insoluble in hydrochloric acid.
„ Cadmium	.	White, soluble in hydrochloric acid.
„ Chromium	.	No precipitate.
„ Cobalt	.	Yellowish-green, turning grey after a while; insoluble in hydrochloric acid.
„ Copper (cupric)	.	Red-brown, insoluble in hydrochloric acid.
„ Gold	.	Emerald-green coloration; no precipitate.
„ Iron: (ferrous)	.	White precipitate, quickly turning blue in contact with the air; insoluble in hydrochloric acid.
(ferric)	.	Deep-blue, insoluble in hydrochloric acid.

Salts of Lead . . .	White.
„ Magnesium . . .	White (only in concentrated solutions).
„ Manganese . . .	White, soluble in hydrochloric acid.
„ Mercury (mercurous) . . .	White, gelatinous.
„ „ (mercuric) . . .	White, becoming blue after a while, from formation of prussian blue.
„ Molybdenum . . .	Brown. (See page 230.)
„ Nickel . . .	White, with greenish tinge, insoluble in hydrochloric acid.
„ Silver . . .	White.
„ Tin (stannous and stannic) . . .	White, gelatinous.
„ Uranium (uranous) . . .	Light-brown.
„ „ (uranic) . . .	Red-brown.
„ Zinc . . .	White, gelatinous, insoluble in hydrochloric acid.

The solutions to which the reagent is applied should be moderately acidulated: too great an excess of acid is likely to decompose the ferrocyanide of potassium, and thus mask the reaction; and in alkaline liquids the precipitates are not produced at all.

The presence of iron in ferrocyanide of potassium is not exhibited either by caustic alkalis, or by sulphide of ammonium.

Estimation of Ferrocyanide of Potassium.—The amount of this salt contained in a solution, may be determined by means of *permanganate of potassium*, which, when added to an acidulated solution of the ferrocyanide (containing therefore ferroprussic acid in the free state) converts it into ferricyanide:

The solution of permanganate is graduated by means of a standard solution of ferrocyanide of potassium containing 20 grammes of the pure crystallised salt in a litre; of this solution 10 cub. cents. are diluted with 250 cub. cents. water; the liquid is acidulated with hydrochloric acid; and the solution of permanganate is then added till the yellow colour of the liquid changes to the yellowish-red of the ferricyanide. As the solution of permanganate changes very rapidly, this mode of graduation (which is very quickly executed) must be repeated before each series of determinations.

To apply the method to the estimation of an impure sample of yellow prussiate, 5 grammes of the salt are dissolved in 250 cc. water, and 10 cc. of the solution are treated with the solution of permanganate whose strength has just been determined. If, for example, 80 burette-divisions of the permanganate solution are required to decompose 10 cc. of the solution of pure ferrocyanide, and only 70 divisions for 10 cc.

of the solution of the given sample, that sample will contain $\frac{70}{80}$ or 87·5 per cent. of pure crystallised ferrocyanide (De Haen, Ann. Ch. Pharm, xc, 160). Slater (Chem. Gaz, 1855, p. 460) graduates the solution of permanganate by adding it to the normal solution of ferrocyanide till the last drop no longer produces any green coloration.

This method will not, however, give accurate results, if the yellow prussiate is contaminated with any substance which can likewise exert a reducing action on the permanganate. If such are present, or suspected, the salt must be first precipitated as prussian blue (ferric ferrocyanide), and, after careful washing, reconverted into ferrocyanide of potassium by pure potash. This purified salt may then be treated by the method just described (Hoffmann.)

Brunnquell estimates the amount of ferrocyanide of potassium in a sample by the quantity of a ferric salt required to precipitate a given quantity of it. The standard ferric solution is prepared by dissolving 83·70 grm. of pure crystallised ferrous sulphate in water, and boiling the solution with nitric acid till it is completely oxidised, and diluting to a litre. 100 cc. of this solution will precipitate exactly 10 grm. of pure crystallised yellow prussiate in the form of hydrated ferric ferrocyanide;

taking into account the small quantity of the yellow prussiate which is carried down with the precipitate.

To apply this solution in estimating the value of a sample of “metal” (p. 232), 10 grm. of the metal are dissolved in water; a few drops of the standard ferric solution are added from a burette, then a small quantity of dilute nitric acid, till the precipitate, which is brown at first, turns blue; the test-liquid is then added as long as prussian blue continues to form. To know when the reaction is complete, a drop of the liquid is let fall on filtering paper, and the colourless circle which forms round the blue spot is tested with ferric solution diluted for the purpose; and the addition of the iron

solution to the liquid under examination is continued till the sample on the filtering paper is turned brown on addition of the iron-salt (from formation of sulphocyanate of iron), or, till it turns blue on addition of yellow prussiate, showing that it contains a slight excess of ferric salt (Brunnquell, *Polyt. Centralb.* 1853, p. 771; *Handw. d. Chem.* 2^o Aufl. ii. [2] 205).

FERRICYANIDE OF SILVER, $\text{Ag}^1\text{Fe}^2\text{Cy}^6$.—White precipitate, turning bluish when exposed to the air; soluble in ammonia, insoluble in ammoniacal salts. When heated, it glows, gives off cyanogen and nitrogen, and leaves carbide of iron mixed with metallic silver. Nitric acid converts it into the orange-yellow ferricyanide, $\text{Ag}^3\text{Fe}^2\text{Cy}^6$ (Glassford and Napier). Strong sulphuric acid also decomposes it, forming sulphate of silver. Other acids, even hydrochloric acid, exert no decomposing action. Cyanide of potassium converts it into argentocyanide and ferrocyanide of potassium; $\text{Ag}^1\text{Fe}^2\text{Cy}^6 + 8\text{KCy} = 4\text{KAgCy}^2 + \text{K}^1\text{Fe}^2\text{Cy}^6$. (Glassford and Napier, *Phil. Mag.* [3] xxv. 71.)

FERRICYANIDE OF SODIUM, $\text{Na}^1\text{Fe}^2\text{Cy}^6 + 12\text{H}^2\text{O}$.—Usually obtained by adding prussian blue to caustic soda as long as the blue colour changes to brown, then filtering and crystallising. The crystals are pale yellow, transparent, oblique rhombic prisms, efflorescing in warm air, soluble in $4\frac{1}{2}$ pts. cold water, insoluble in alcohol.

The crystals belong to the monoclinic system. Dominant faces ∞P . [$\infty\text{P}\infty$]. $\infty\text{P}\infty$. [$\text{P}\infty$]. Inclination of ∞P : $\infty\text{P} = 99^\circ 40'$; ∞P : [$\infty\text{P}\infty$] = $139^\circ 50'$; ∞P : $\infty\text{P}\infty = 130^\circ 10'$; [$\text{P}\infty$]: [$\infty\text{P}\infty$] = $127^\circ 56'$; ∞P : [$\text{P}\infty$] = $118^\circ 33'$. The faces [$\infty\text{P}\infty$] are often much developed. (Bunsen, *Pogg. Ann.* xxxvi. 413).

As soda is very much cheaper than potash, it has been proposed to prepare ferrocyanide of sodium on the manufacturing scale by fusing carbonate of sodium with animal matter and iron. The sodium-salt is, however, much more difficult to crystallise than ferrocyanide of potassium, and would therefore be scarcely separable from the very impure lyes obtained by lixiviating the metal. The preparation of ferrocyanide of sodium, might, however, succeed by Brunnquell's process (p. 238). But, as already observed, the most promising substitute for the ordinary yellow prussiate appears to be the ferrocyanide of barium (pp. 224, 239).

Ferrocyanide of Sodium and Potassium, $\text{NaK}^3\text{Fe}^2\text{Cy}^6 + \frac{7}{2}\text{aq}$.—Obtained by treating a mixture of ferricyanide of potassium and grape-sugar with caustic soda, or by boiling a solution of the corresponding ammonium salt $(\text{NH}^4)\text{K}^3\text{Fe}^2\text{Cy}^6$, with caustic soda; it may be purified by precipitating with alcohol and recrystallising. It forms rhombic or nearly square prisms, having a glassy lustre and easily soluble in water: they do not give off their water below 200°C . Chlorine appears to convert the salt in sodio-potassic ferricyanide, $\text{NaK}^2\text{Fe}^2\text{Cy}^6$. (Reindel, *J. pr. Chem.* lxx. 450.)

FERRICYANIDES OF TIN. }
FERRICYANIDES OF URANIUM. } See p. 242.

FERRICYANIDE OF ZINC, $\text{Zn}^1\text{Fe}^2\text{Cy}^6 + 3\text{aq}$, is precipitated as a white powder, on mixing the solution of a zinc-salt with ferrocyanide of potassium; also, according to Jonas, by digesting metallic zinc with pulverised prussian blue mixed with hydrochloric acid; hydrogen is thus evolved, and the mixture gradually loses its blue colour, but the reaction is not complete for some days.

Ammonio-ferrocyanide of Zinc, $3\text{NH}^3.\text{Zn}^1\text{Fe}^2\text{Cy}^6 + \text{aq}$, or *Ferrocyanide of Zinc and Diammo-zincammonium*, $\overbrace{\text{NAm}^2\text{ZnH}}^{\text{Zn}^3}\text{Fe}^2\text{Cy}^6 + \text{aq}$.—Obtained as a crystalline precipitate on adding ferrocyanide of potassium to a dilute solution of a zinc-salt supersaturated with ammonia. (Bunsen, *Pogg. Ann.* xxxiv. 136; Monthiers, *J. Pharm.* [3] xi. 253.)

Ferricyanides or Ferridcyanides.

These salts, discovered by Leopold Gmelin, differ from the ferrocyanides only in containing 1 at. metal less with the same quantity of iron and cyanogen, and are consequently produced from the ferrocyanides by the action of oxidising (metal-abstracting) agents, chlorine, chromic acid, peroxides, &c.:

On the other hand, ferricyanides are converted into ferrocyanides by the action of reducing (metal-adding) agents; thus ferricyanide of potassium is converted by grape-sugar in presence of potash into ferrocyanide of potassium, and in presence of soda or

ammonia, into the double ferrocyanide of potassium and sodium or ammonium (pp. 224, 243). The conversion of a ferrocyanide into a ferricyanide is therefore precisely analogous to that of protochloride of iron into sesquichloride, the iron, as in other cases of oxidation, being altered in such a manner, that whereas in the ferrocyanides 2 at. iron are equivalent to 2 at. hydrogen, in the ferricyanides 2 at. iron are equivalent to 3 at. hydrogen.

The relations between the ferro- and ferricyanides may perhaps be most clearly seen by expressing their composition in equivalent instead of atomic formulæ:

Ferrocyanide of potassium	$K^4Fe^2Cy^6$
Ferricyanide of potassium	$K^3Fe^3Cy^6$
Ferrocyanide of iron and potassium	$(K^2Fe^2)Fe^2Cy^6$
Ferricyanide of iron and potassium	$(KFe^2)Fe^3Cy^6$

The equivalent formulæ of the simple ferricyanides, such as $K^3Fe^3Cy^6$, are divisible by 3 and may be reduced to $MfeCy^2$ or $MCy.feCy$.

The ferricyanides may also be regarded as containing the compound radicle, *ferric- or ferrid-cyanogen*, $Fe^3Cy^6 = Cfdy$: *e. g.* $K^3Fe^3Cy^6 = K^3Cfdy$.

The ferrocyanides of the alkali-metals are easily soluble in water and crystallise well; both crystals and solutions have a fine red colour. The ferricyanides of the alkaline earth-metals are also soluble in water; most of the others are insoluble or difficultly soluble, and may be formed by precipitation.

Reactions of soluble Ferricyanides with Metallic Salts.

Salts of Aluminium	No precipitate.
„ Antimony	No precipitate.
„ Cadmium	Yellow precipitate, soluble in acids, ammonia, and ammoniacal salts.
„ Bismuth	Light brown, insoluble in hydrochloric acid.
„ Chromium	No precipitate.
„ Cobalt	Dark brown-red, insoluble in hydrochloric acid.
„ Copper (cupric)	Yellowish-green, insoluble in hydrochloric acid.
„ Gold	No precipitate.
„ Iron (ferrous)	Dark blue, insoluble in acids.
„ „ (ferric)	No precipitate, the liquid merely becoming a little darker.
„ Lead	No precipitate.
„ Magnesium	No precipitate.
„ Manganese	Brown precipitate, insoluble in acids.
„ Mercury (mercurous)	Red-brown, turning white after some time.
„ „ (mercuric)	No precipitate.
„ Nickel	Yellowish-green, insoluble in hydrochloric acid.
„ Tin (stannous)	White, soluble in hydrochloric acid.
„ „ (stannic)	No precipitate.
„ Uranium (uranic)	No precipitate.
„ Zinc	Orange precipitate, soluble in hydrochloric acid.

FERRICYANIDE OF AMMONIUM, $(NH^4)^3Fe^3Cy^6 + 3 aq.$, obtained by the action of chlorine on the ferrocyanide, forms oblique rhombic prisms, of a fine red colour, permanent in the air, very soluble in water.

FERRICYANIDE OF COPPER.—Yellowish-green precipitate, soluble in ammonia; and always retaining a small quantity of the alkaline ferricyanide used to precipitate it.

FERRICYANIDE OF HYDROGEN, or FERRIPRUSSIC ACID, $H^3Fe^3Cy^6 = 3HCy.fe^3Cy^3$, is obtained by decomposing ferricyanide of lead with an exactly equivalent quantity of dilute sulphuric acid, and evaporating the filtrate at a gentle heat. It forms brownish needles, easily decomposed by a stronger heat; reddens litmus strongly, and has a rough sourish taste. The solution gives a dark blue precipitate with ferrous salts, and alters the colour of ferric chloride to a lighter brown. (Gm. vii. 448.)

FERRICYANIDE OF IRON.—*a. Ferrous Ferricyanide*, $Fe^2Cy^6 + x aq. = Fe^3.fe^3Cy^6 + x aq. = Fe^3fe^3Cy^6 + x aq.$ —This compound, commonly called *Turnbull's blue*, is obtained by precipitating a ferrous salt with ferricyanide of potassium:

A portion of the alkaline ferrocyanide goes down with the precipitate, but may be

removed, according to Williamson, by digesting the precipitate for some time with excess of protochloride of iron, and then washing with boiling water.

Ferrous ferricyanide, when dry, is of a deep blue colour, more delicate than that of ordinary prussian blue, with a tinge of copper-red; it cannot, however, be dried completely without partial decomposition, attended with evolution of hydrocyanic acid. When heated in contact with the air, it is converted into a mixture of ferric oxide and ferric ferrocyanide (p. 227):

Heated with aqueous potash or carbonate of potassium, it is converted into ferricyanide of potassium and ferroso-ferric hydrate:

This reaction distinguishes it from ferric ferrocyanide, which yields ferric hydrate when treated with aqueous alkalis.

Turnbull's blue is occasionally used by the calico-printer, who mixes it with perchloride of tin, and prints the mixture, which is in a great measure soluble, upon Turkey-red cloth, raising the blue colour afterwards by passing the cloth through a solution of bleaching powder containing excess of lime. The chief object of that operation is indeed different, namely to discharge the red and produce white patterns where tartaric acid is printed on the cloth; but it has also the effect incidentally of precipitating the blue pigment and stannic oxide together on the cloth, by neutralising the acid of the stannic chloride. (*Graham's Elements*, 2nd edition, vol. ii. p. 40.)

b. *Ferroso-ferric Ferricyanide*, $\text{Fe}^{\text{e}}\text{Cy}^{\text{e}} + x\text{aq.} = (\text{Fe}^{\text{e}})^{\text{e}}\text{Cy}^{\text{e}} + x\text{aq.}$ —This compound, often called *Prussian green*, is produced by the action of chlorine in excess on aqueous ferro- or ferri-cyanide of potassium; also by leaving the ferrocyanide for some time in contact with aqueous acids, especially in hot solutions (Pelouze). To obtain it pure, chlorine in excess is passed into a solution of yellow or red prussiate; the liquid is heated to boiling; and the precipitate is boiled with strong hydrochloric acid to extract oxide of iron and decompose any prussian blue that may have been formed at the same time, this treatment being continued till the liquor is no longer turned blue on addition of water (Pelouze, *Ann. Ch. Phys.*, [2] lxxix. 40). Williamson appears to have obtained the same compound by the action of nitric acid on ferrocyanide of iron and potassium (p. 229).

Prussian green, heated to 180°C ., gives off cyanogen, with a little hydrocyanic acid, and is converted in a short time into a violet-blue compound; by prolonged contact with the air it is converted into prussian blue. Potash decomposes it, separating ferric hydrate, and forming a solution of yellow and red prussiate:

Potassio-ferrous Ferricyanide, $\text{KFe}^{\text{e}}\text{Cy}^{\text{e}} = (\text{KFe}^{\text{e}})^{\text{e}}\text{Cy}^{\text{e}}$. (Williamson *Ann. Ch. Pharm.* lvii. 228.)—This compound, which may also be regarded as *potassio-ferric ferrocyanide*, $(\text{KFe}^{\text{e}})^{\text{e}}\text{Fe}^{\text{e}}\text{Cy}^{\text{e}}$, is produced by the action of oxidising agents on potassio-ferrous ferrocyanide, $(\text{K}^{\text{e}}\text{Fe}^{\text{e}})^{\text{e}}\text{Fe}^{\text{e}}\text{Cy}^{\text{e}}$ (p. 229). To prepare it, 1 pt. of the white compound is digested in a basin with 1 pt. nitric acid and 20 pts. water, the liquid being constantly stirred. As the temperature approaches the boiling-point, the compound begins to turn blue and nitric oxide is evolved; as soon as this evolution of gas becomes rapid, the basin must be removed from the fire; the gas, however, continues to escape till the solid compound has assumed a deep blue colour. If the colour be not deep enough, the compound must be again heated with fresh nitric acid, till a sample decomposed by caustic potash no longer leaves ferroso-ferric but pure ferric oxide. The product is then to be washed till the wash-water no longer leaves a residue of nitre on evaporation. If the action of the nitric acid has been too strong, the resulting blue compound, when treated with potash, yields the red instead of the yellow prussiate, and is then useless.

When dry, it exhibits a very beautiful violet colour, with scarcely any coppery lustre. The recently precipitated compound, suspended in water, appears green by transmitted light.

By further boiling with nitric acid, this blue compound is converted into a dark green substance, which appears to be identical with Pelouze's prussian green. It is decomposed by aqueous potash, yielding ferrocyanide of potassium and ferric hydrate:

Potassio-ferrous ferricyanide digested with solution of ferrocyanide of potassium,

converts the latter into ferricyanide, and is itself converted into white potassio-ferrous ferrocyanide :

FERRICYANIDE OF LEAD, obtained by mixing nitrate of lead with ferricyanide of potassium, forms dark red-brown crystals, grouped like cocks' combs: they are slightly soluble in cold water, rather more in hot water.

FERRICYANIDE OF MAGNESIUM.—Obtained by treating the ferrocyanide with chlorine. Very soluble, uncrystallisable.

FERRICYANIDE OF NICKEL.—Yellowish green precipitate, insoluble in hydrochloric acid.

On adding ferricyanide of potassium to an ammoniacal solution of nitrate of nickel, a precipitate is formed of a fine yellow colour, soluble in excess of ammonia, and having the composition of an *ammonio-ferricyanide of nickel*, $2\text{NH}^3.\text{Ni}^3\text{Fe}^2\text{Cy}^6 + \frac{1}{2}\text{aq.}$, or *ferricyanide of nickel and nickel-ammonium*, $\left(\text{NH}^3\text{Ni}\right)^2 \left\{ \text{Fe}^2\text{Cy}^6 + \frac{1}{2}\text{aq.} \right\}$.

FERRICYANIDE OF POTASSIUM, $\text{K}^3\text{Fe}^2\text{Cy}^6 = 3\text{KCy.Fe}^2\text{Cy}^3$. *Ferridcyanide of Potassium, Red prussiate of Potash.* (*Roth's Cyaneisenkalium, rothes Blutlaugensalz, Kaliumeisencyanid, Ferridcyanikalium.*)—This beautiful salt, which was discovered by Leopold Gmelin (Schw. J. xxxiv. 325; *Handbook*, vii. 468), is obtained by the action of oxidising agents on ferrocyanide of potassium. It is usually prepared by passing washed chlorine gas (with constant agitation, to ensure uniformity of action) through a cold solution of the yellow prussiate, till a sample tested with a ferric salt, no longer forms a dark blue precipitate, but a clear brown mixture. The liquid is then evaporated till it crystallises, and the crystals are purified by repeated crystallisation from hot water. Larger crystals are obtained by hot evaporation than by cooling from a rapidly boiled solution. The mother-liquor contains scarcely anything but chloride of potassium.

If the passage of the chlorine into the liquid is continued too long, prussian green is produced, which greatly interferes with the crystallisation, and cannot be separated by filtration, as it runs through the filters. To remove it, Posselt (Ann. Ch. Pharm. xlii. 170) evaporates the solution to the crystallising point, then boils it, adding a few drops of caustic potash, just sufficient to decompose the green compound and separate ferric oxide (p. 245), then filters, and leaves the solution to crystallise by slow cooling. An excess of potash must be carefully avoided, as it reconverts the red into yellow prussiate; a certain quantity of the latter is, however, necessarily formed in the decomposition of the prussian green (p. 245).

It is not, however, an easy matter to obtain perfectly pure ferrocyanide of potassium by the preceding process, partly on account of the chloride of potassium necessarily produced, partly on account of the prussian green, the formation of which can scarcely be avoided, both of these substances interfering greatly with the formation of good crystals. A sure way of obtaining a pure salt is to digest the solution of the yellow prussiate with an excess of potassio-ferrous ferricyanide (p. 245), which converts it completely into red prussiate. The liquid, filtered and evaporated, yields at once pure crystals of the red-salt. The pale blue residue on the filter, which consists of white potassio-ferrous ferrocyanide, mixed with the excess of the blue salt used, may be entirely reconverted into the latter by digestion with nitric acid, so that it may be repeatedly used for converting fresh quantities of the yellow prussiate into the red. (Williamson.)

Yellow prussiate may also be converted into red by the action of hypochlorites, by digesting the solution with finely pulverised peroxide of lead or manganese, by ozone, or by placing it in the circuit of the voltaic battery (p. 240).

For manufacturing purposes, the chlorine process is invariably used, the yellow prussiate being treated with chlorine, either in the dry or in the wet way. In the dry way, red prussiate is prepared by spreading the pulverised yellow salt on shelves in a chamber into which chlorine is passed, just as in the manufacture of bleaching powder. In this manner, a bluish-green powder is obtained, which is a mixture of the ferricyanide with chloride of potassium, likewise containing either decomposition-products of the former, or unaltered yellow prussiate.

The wet method of decomposition, which is more frequently practised, is exactly similar to the laboratory process above described. The last mother-liquors, which contain chiefly chloride of potassium with a small quantity of red (and sometimes also yellow) prussiate, are either evaporated to dryness and sold as "blue powder" for dyeing wool blue; or they are precipitated with solution of ferrous sulphate, the precipitate being sold as prussian or Turnbull's blue.

Properties.—Ferricyanide of potassium forms prismatic crystals of a fine blood-red

colour, sometimes very large. According to Kopp (*Krystallographic*, p. 311), they belong to the monoclinic system, the ordinary combination being $\infty P . \infty P \infty . + P . -P$ (fig. 363). Ratio of axes $a : b : c = 0.7457 : 1 : 0.5985$. Inclination of $b : c = 72^{\circ} 27'$; angle $\infty P : \infty P$ in the clinodagonal section = $76^{\circ} 4'$; $+P : +P = 105^{\circ} 4'$; $-P : -P = 119^{\circ} 28'$. Twin-crystals sometimes occur, united by the face $\infty P \infty$ (fig. 364), and having very much the aspect of rhombic prisms. Schabus, indeed (Wien. Akad. Ber. 1850, p. 582), regards the crystals of ferricyanide of potassium as rhombic or trimetric, having their axes in the ratio $1.2418 : 1.6706 : 1$, and ordinarily exhibiting the combination $\infty P . \infty P \infty . P . \bar{P}2 . \frac{3}{2}P\frac{3}{2}$; he attributes their monoclinic aspect to the occurrence of the face $\bar{P}2$ in combination with $\frac{3}{2}P\frac{3}{2}$ on the one side of the brachydiagonal principal section, and with ∞P and $\infty \bar{P} \infty$ on the other.

Fig. 363.

Fig. 364.

The crystals are anhydrous, and have a specific gravity of 1.800 (Schabus), 1.845 (Wallace). The salt has a saline, slightly astringent taste, neutral reaction, and yields an orange-yellow powder. It dissolves easily in water, the concentrated solution having a brownish-yellow, and the dilute solution a lemon-yellow colour.

One part of the salt dissolves :

at	4.4° C.	in 3.03 pts. water,	forming a solution of specific gravity	1.151
„	10.0	„	2.73	1.164
„	15.6	„	2.54	1.178
„	37.8	„	1.70	1.225
„	100.0	„	1.29	1.250
„	104.0	„	1.22	1.265

The concentrated solution boils at $104^{\circ} \text{C}.$; it is precipitated by alcohol, but the salt is not quite insoluble in alcohol.

Decompositions.—1. The crystals heated in a close vessel decrepitate loudly, and give off cyanogen with a small quantity of nitrogen, leaving a residue containing cyanide and ferrocyanide of potassium, prussian blue, a mass resembling paracyanogen, charcoal, and iron. In the flame of a candle, the salt burns with sparks.—2. It becomes incandescent when heated with *oxide of copper*, and detonates sharply when heated with nitrate of ammonia.—3. The aqueous solution is permanent in the dark, but decomposes in *sunlight*, also when boiled for a considerable time, being converted into yellow-prussiate.—4. When the salt is *electrolysed*, yellow prussiate is formed at the negative pole.—5. *Chlorine* in excess decomposes red prussiate, chloride of cyanogen and hydrocyanic acid being evolved, whilst the liquid acquires a dark red colour, and on standing in an open vessel, or more quickly on boiling or on addition of an alkali, deposits prussian green.—6. *Bromine* acts in the same manner as chlorine (Sme e).—7. *Nitric acid* forms with the crystals, gradually, even at ordinary temperatures, a brown solution like that which it produces with the yellow ferrocyanide (p. 240); it deposits crystals of nitre, and contains nitroferricyanide of potassium (Playfair).—8. The pulverised crystals heated with strong *sulphuric acid* become pale yellow, and impart that colour to the acid; at a higher temperature, the mass becomes bluish-white and tough; at a still higher temperature, it swells up and evolves combustible gases; and, finally, at a red heat, leaves a residue of potassio-ferric sulphate.—Sulphuric acid forms with the aqueous solution a green precipitate, which consists of Fe^{Cy^3} [?] mixed with a small quantity of cyanide of potassium, and turns blue when boiled with excess of sulphuric acid, part of the cyanogen being thereby converted into ammonia (Williamson, Ann. Ch. Pharm. lvii. 243).—9. The aqueous solution of the red salt boiled with *hydrochloric acid*, deposits ferrous ferricyanide, the reaction being probably attended with evolution of cyanogen :

10. *Ferrous salts*, added in equivalent quantity or in excess to a solution of red prussiate, form a precipitate of ferrous ferricyanide :

but on adding to the boiling solution of the red salt, a quantity of protochloride of iron not sufficient for complete precipitation, the yellow ferrocyanide is formed, and ferric ferrocyanide is precipitated (Liebig, Ann. Ch. Pharm. lvii. 237):

11. When the aqueous solution of ferricyanide of potassium is boiled with *mercuric oxide*, the whole of the iron is precipitated in the form of pulverulent ferric oxide, to which small quantities of potassium and cyanogen tenaciously adhere (Gmelin):

12. *Potash* does not act on the solution at ordinary temperatures, or even at higher temperatures, unless the liquid be boiled down to a high state of concentration; in that case the red prussiate is converted into the yellow prussiate and cyanide of potassium, with evolution of cyanogen (not of oxygen) and precipitation of ferric oxide (Boudault).

13. Many *heavy metallic oxides*, in presence of potash, convert the dissolved red prussiate into the yellow prussiate, the red salt taking up potassium, and the oxygen of the potash bringing the heavy metal to a higher state of oxidation (Boudault, J. Pharm. [3] vii. 437); *e.g.*

The action may be produced by adding to the solution of the red salt either the hydrated oxide, together with potash, or a mixture of the salt of the heavy metal with excess of potash.—A solution of *chromic oxide* in potash boiled with the solution of the red salt, yields chromate and ferrocyanide of potassium.—*Hydrated manganous oxide* with potash, or a manganous salt with excess of potash, yields peroxide of manganese, even at ordinary temperatures; if the potash is in large excess, the peroxide produced is crystalline; but if the manganous oxide is in larger proportion, brown-red manganoso-manganic oxide is produced.—*Protoxide of lead* dissolved in potash, or a lead-salt supersaturated with potash, yields a precipitate of brown peroxide of lead, which is generally crystalline, or of red lead, if the lead-oxide is present in larger proportion.—*Stannous salts* also convert the red salt mixed with potash into the yellow salt.—But the *protoxides of cobalt and nickel* are not brought to a higher state of oxidation, even by boiling with a mixture of potash and the red salt.—*Silver and gold salts*, on the other hand, exhibit a different reaction with potash and the red prussiate; for they yield, on boiling, a precipitate of ferric oxide, while ferrocyanide of potassium and cyanide of silver and potassium, or cyanide of gold and potassium, remain in solution. 14.—*Sulphydric acid* decomposes the red prussiate dissolved in water into yellow prussiate, ferroprussic acid, and sulphur (Williamson, Ann. Ch. Pharm. lvii. 237):

15. *Selenydric acid* and *phosphoretted hydrogen* likewise impart to the solution of the red prussiate the property of forming a blue precipitate with ferric salts; and the same change is produced, though more slowly, by *tellurhydric acid*, *arsenetted hydrogen*, and *antimonetted hydrogen* gases (Schönbein).—16. *Ammonia* converts the aqueous solution of ferricyanide of potassium into ferrocyanide of potassium and ferrocyanide of ammonium, with evolution of nitrogen (Monthiers, J. Pharm. [3] xi. 254):

17. Many other deoxidising agents likewise impart to the aqueous solution of ferricyanide of potassium the property of forming a blue precipitate with ferric salts. The deoxidising agents which produce these effects are: *Phosphorus*, which acts but slowly;—*phosphorous acid* and the *hypophosphites*;—*sulphurous acid*, which is thereby converted into sulphuric acid, and *sulphites*, which are transformed into sulphates;—*nitric oxide gas*, and even *fuming nitric acid*, whereas nitrous oxide exerts no reducing action.

18. Similar effects are likewise produced by various metals: *viz. arsenic, antimony, tin, bismuth, lead, iron* and *zinc*, more slowly by *copper, cadmium, mercury* and *silver*. According to Schönbein, iron and zinc, immersed in the aqueous solution of red prussiate in a close vessel, often remain bright for weeks, whereas, in contact with the air, the liquid becomes lighter in colour, and ferrocyanide of potassium is formed, together with an insoluble ferrocyanide.

19. The reduction of red to yellow prussiate is likewise produced by many *organic substances*, *e.g.* by formic, acetic, citric, tartaric, and uric acids, creosote, cinchonine, and morphine, not by quinine or strychnine (Boudault). Ether, alcohol, and sugar do not easily reduce the aqueous solution of the red prussiate alone, but much more quickly on addition of a ferric salt, in which case prussian blue is precipitated. Oxalic

acid is not oxidised by the aqueous solution of red prussiate; indeed, its presence actually prevents the reduction which would otherwise be effected by nitric oxide, sulphydric acid, uric acid, or sugar. (Schönbein.)

All these reductions take place much more quickly in an alkaline than in a neutral solution of the red prussiate. In the alkaline solution, sulphur and phosphorus, and their lower oxides, are quickly converted into sulphuric and phosphoric acid respectively; iodine into iodic acid; iodide and sulphide of potassium also reduce the red prussiate to the yellow; oxalic acid is converted into carbonic acid; cyanide of potassium into cyanate; sugar, gum, starch, alcohol, and even paper, into carbonic acid and water. Indigo is bleached by it, a reaction which has been applied by Mercer (Phil. Mag. [3] xxxi. 126) in calico-printing. Cotton dyed with indigo and saturated with red prussiate is instantly bleached on immersion in potash-ley.

Ferrieyanide of potassium forms, with the solutions of many of the *heavy metals*, precipitates which exhibit very characteristic colours (p. 244); hence this salt, as well as the yellow prussiate, is a valuable reagent in chemical analysis. In dyeing and calico-printing, it is used, either alone or mixed with ferrous salts, for the production of blue colours on wool and cotton; for this purpose the so-called "blue powder," obtained by evaporating the mother-liquors of red prussiate is often made available.

Estimation of Ferrieyanide of Potassium.—Ordinary red prussiate is generally contaminated with chloride of potassium and with yellow prussiate, the latter being recognisable by the blue precipitate which it forms with ferric salts. For determining the proportion of real ferrieyanide in a commercial sample of red prussiate, the following methods may be used:

1. Brunnequell converts the ferrieyanide of potassium into ferrocyanide, and estimates the latter by a standard ferric solution in the manner already described (p. 242). 7.99 grms. of the red prussiate are dissolved in water; and the liquid is boiled with addition of a few grms. of sulphite or hyposulphite of sodium, filtered, if a precipitate forms, and tested with the graduated ferric solution, 1 cc. of which corresponds to 1 per cent. of ferrieyanide of potassium.

2. De Haen mixes 10 cc. of a solution of a red prussiate containing 20 grms. in a litre, with 5 to 8 cc. of strong potash-ley, and heats the liquid, after addition of 0.5 gm. finely pulverised protoxide of lead, which is thereby converted into peroxide. After dilution with water, filtering, and acidulation with hydrochloric acid, a graduated solution of *permanganate of potassium* (see p. 242) is added till the liquid becomes clear and of a decided reddish-yellow colour. If the sample of red prussiate originally contained yellow prussiate, the proportion of the latter is determined in a second sample by heating with the permanganate solution without addition of oxide of lead.

3. Ferrieyanide of potassium mixed with *iodide of potassium and hydrochloric acid* yields ferroproussic acid, chloride of potassium, and free iodine:

Consequently 1 at., or 127 pts., iodine corresponds to 1 at., or 329 pts., ferrieyanide of potassium. To apply this reaction volumetrically, 10 cc. of a solution of red prussiate (containing from 0.2 to 0.4 grms. of the salt) are mixed with 10 cc. of a solution of iodide of potassium (containing 1 gm. of the iodide), and strong hydrochloric acid is added as long as the solution is thereby rendered darker in colour by separation of iodine. The free iodine is then estimated by Bunsen's method with sulphurous acid (see ANALYSIS, VOLUMETRIC, i. 265). Lenssen (Ann. Ch. Pharm. xci. 240.)

4. Wallace (Chem. Soc. Qu. J. vii. 77) determines the amount of ferrieyanide by the quantity of *stannous chloride* required to convert it into ferrocyanide of potassium or ferroproussic acid. The reaction is as follows:

100 grains of pure ferrieyanide of potassium are dissolved in $1\frac{1}{2}$ oz. water and $\frac{3}{4}$ oz. strong hydrochloric acid, and solution of stannous chloride (of specific gravity 1.046) is added till the liquid exhibits a decided violet or blue without any shade of green colour. By treating the sample of red prussiate to be examined with the solution of stannous chloride thus standardised, the amount of pure ferrocyanide contained in it is determined.—5. Greater exactness appears to be attained by the following process given by Leesching (Jahresber. d. Chem. 1853, 681), in which an alkaline solution of the ferrieyanide is mixed with a solution of *sulpharsenate of sodium*, till the liquid becomes nearly colourless and the precipitated sulphur is perfectly white. The reaction is expressed by the equation:

According to this equation, 100 pts. ferrieyanide of potassium decompose 20.6 pts.

crystallised sulpharsenate of sodium, $2\text{Na}^3\text{AsS}^4 + 15\text{aq.}$ 100 grains of the ferricyanide are dissolved in 2 oz. of water, and to this solution is gradually added a standard solution containing 20 grains (more exactly 20.6 grains) of sulpharsenate of sodium and 40 to 60 grains dry carbonate of potassium or sodium in 200 burette-divisions*, so that one division of this solution corresponds to $\frac{1}{4}$ per cent. ferricyanide of potassium. The standard solution is gradually added till the liquid has become quite white, and a few drops of it no longer destroy the red colour of a decoction of cochineal. (Handw. d. Chem. 2^{te} Aufl. ii. [2] 212.)

Ferricyanide of Potassium and Barium, $\text{KBa}^2\text{Fe}^2\text{Cy}^6 + 3\text{aq.}$, is obtained by passing chlorine into a solution of ferrocyanide of potassium and barium, expelling the excess of chlorine by heat, adding a little alcohol, separating the resulting blue precipitate by filtration, and leaving the filtrate to evaporate. The first crystals deposited from the solution (larger than those of ferri-cyanide of potassium, which afterwards separate) consist of ferricyanide of potassium and barium; they are short hexagonal prisms, of a deep red colour, and permanent in the air. (Laurent, Compt. chim. 1849, p. 324.)

FERRICYANIDE OF SODIUM, $\text{Na}^3\text{Fe}^2\text{Cy}^6 + \text{aq.}$, prepared, like the potassium-salt, by the action of chlorine on the ferrocyanide, forms ruby-coloured right four-sided prisms, which deliquesce when exposed to the air, dissolve in 5.3 pts. of cold, and 1.25 pts. boiling water. (Kramer, J. Pharm. xv. 98; Bette, Ann. Ch. Pharm. xxiii. 117.)

Ferricyanide of Sodium and Potassium, $\text{Na}^3\text{K}^3\text{Fe}^4\text{Cy}^{12}$, is deposited from a mixture of the solutions of ferricyanide of potassium and ferri-cyanide of sodium, in fine cubic crystals of a garnet-red colour. The solution once also deposited large black-brown hydrated crystals, containing 6 at. water, and having the form of hexagonal prisms, with angles of 120° ; but on redissolving them in water, the solution yielded the cubic anhydrous crystals. The hydrated crystals give off their water at a temperature somewhat above 100°C. , decrepitating and falling to powder at the same time. (Laurent, loc. cit.)

Nitro-ferricyanides.

Nitroprussides, Nitroprussiates. (Playfair, Phil. Mag. [3] xxxvi. 197, 271, 348. —Gerhardt, Compt. chim. 1850, p. 147; *Traité*, i. 344. —Kyd, Ann. Ch. Pharm. lxxiv. 340.)—These compounds, discovered by Playfair in 1850, are produced by the action of nitric acid on the ferro- or ferri-cyanides of the alkali-metals, or by that of nitric oxide on ferro- or ferri-cyanide of hydrogen. Their composition is not yet established with certainty. Playfair represented them by the general formula $\text{M}^2.\text{Fe}^5\text{Cy}^{12}(\text{NO})^3$, or $\text{M}^{10}.\text{Fe}^{10}\text{Cy}^{24}(\text{N}^2\text{O})^3$, in which the cyanogen is supposed to be partly replaced by nitrous oxide; but the formula most generally received is that proposed by Gerhardt, viz. $\text{M}^2.\text{Fe}^2\text{Cy}^5(\text{NO})$, in which 1 at. cyanogen in Fe^2Cy^6 is supposed to be replaced by nitric oxide. According to this formula, the formation of nitro-ferricyanide of hydrogen by the action of nitric oxide on *ferricyanide of hydrogen* is represented by the equation,

When nitric oxide is passed into a warm aqueous solution of *ferrocyanide of hydrogen* (or of ferrocyanide of potassium mixed with a sufficient quantity of an acid to convert it into ferroproussic acid), the gas is rapidly absorbed,—the ferrocyanide is converted into ferricyanide:

the change being indicated by the deep blue precipitate which the liquid then gives with ferrous salts,—and afterwards the ferricyanide is converted into nitro-ferricyanide as above, the liquid giving, with ferrous salts, precipitates of a paler and paler colour, and ultimately of a clear salmon tint. It then contains nitro-ferricyanide of hydrogen (nitroprussic acid), which will yield the nitro-ferricyanides of the different metals by neutralisation.

When nitric acid is added to a solution of *ferrocyanide of potassium*, this salt is first converted into ferricyanide by abstraction of 1 at. potassium (p. 243), and the nitric acid is at the same time reduced to nitric oxide, which, however, does not escape as gas, unless the action is very violent, but is employed in converting the ferricyanide into nitro-ferricyanide as above. The action is accompanied by evolution of hydro-cyanic acid and nitrogen, as shown by the equations above given, also of carbonic acid,

* Or 5 grms. of ferricyanide are dissolved in 50 cc. water, and to the liquid is added a standard solution containing in 200 burette-divisions 1.03 gr sulpharsenate of sodium, and 2 or 3 grms. carbonate of potassium or sodium.

cyanogen, and an extremely pungent vapour, probably cyanic acid, these latter being secondary products, resulting from the action of the nitric acid on the hydrocyanic acid.—[Respecting the formation of nitroferri cyanides from the so-called *nitro-sulphurets of iron*, see Roussin (Ann. Ch. Phys. [3] lii. 285).]

Preparation.—The nitroferri cyanides of potassium and sodium are obtained as follows: 422 gr. (2 at.) pulverised ferrocyanide of potassium is mixed with 5 at. commercial nitric acid diluted with its own bulk of water (the strength being determined by an alkalimetric process). One-fifth of this quantity (1 at.) of acid is actually sufficient to transform the ferrocyanide into nitroferri cyanide, but the use of the larger quantity is found to give the best results. The acid is poured all at once upon the ferrocyanide, the cold produced by the mixing being sufficient to moderate the action. The mixture first assumes a milky appearance; but after a little while the salt dissolves, forming a coffee-coloured solution, and the gases above-mentioned are disengaged in abundance. When the salt is completely dissolved, the solution is found to contain ferri cyanide (red prussiate) of potassium, mixed with nitroferri cyanide and nitrate of the same base. It is then immediately decanted into a large flask, and heated over the water-bath; it continues to evolve gas, and, after a while, no longer yields a dark blue precipitate with ferrous salts, but a dark green or slate-coloured precipitate. It is then removed from the fire, and left to crystallise, whereupon it yields a large quantity of crystals of nitre, and more or less of oxamide. The strongly coloured mother-liquid is then neutralised with carbonate of potassium or sodium, according to the salt to be prepared, and the solution is boiled, whereupon it generally deposits a green or brown precipitate, which must be separated by filtration. The liquid then contains nothing but nitroferri cyanide and nitrate of potassium or sodium. The nitrates being the least soluble, are first crystallised out; and the remaining liquid, on further evaporation, yields crystals of the nitroferri cyanide. The sodium-salt crystallises most easily.

The insoluble nitroferri cyanides, those of iron, copper, silver, zinc, &c., are obtained by precipitating the solution of the potassium or sodium salt, with solutions of the respective metals; and the ammonium, barium, calcium, and magnesium salts, which are soluble, by decomposing the iron or copper salt with a solution of caustic ammonia, baryta, or lime. (Playfair.)

Properties and Reactions.—The nitroferri cyanides are in general strongly coloured. The ammonium, potassium, sodium, barium, calcium, and lead salts, are of a dark red or ruby colour; they dissolve easily in water, forming red solutions, from which they are not precipitated by alcohol. The soluble salts crystallise with facility. The copper, iron, cobalt, nickel, zinc, and silver salts, are nearly or quite insoluble in water.

The following are the most characteristic reactions of soluble nitroferri cyanides.

With the Sulphides of the Al-

kali-metals . . .	Splendid but transient purple colour.
„ Sulphydric acid . . .	Formation of prussian blue, together with a ferrocyanide and a peculiar compound.
„ Neutral Lead-salts . . .	No change.
„ Basic „ . . .	White precipitate, after some time, from strong solutions.
„ Mercuric salts . . .	No change.
„ Stannous and Stannic salts . . .	No change.
„ Zinc-salts. . . .	Light salmon-coloured precipitate.
„ Cupric salts	Light green precipitate.
„ Cobalt-salts	Flesh-coloured precipitate.
„ Ferrous salts	Salmon-coloured precipitate.
„ Ferric salts	No change.
„ Caustic alkalis	Red coloration, changing to orange.

The most characteristic reaction of the nitroferri cyanides is the splendid purple colour which they exhibit with *alkaline sulphides*: it is extremely delicate, and serves to detect the minutest portion either of a sulphide or of a nitroferri cyanide. Oppenheim (J. pr. Chem. lxxxi. 305) recommends it for the detection of small quantities of free alkalis or alkaline earths in solution, a few bubbles of sulphydric acid gas being passed through the liquid, and then a few drops of solution of nitroferri cyanide of sodium added. The purple colour is not, however, permanent, the compound being quickly resolved into other products, including hydrocyanic acid, ammonia, nitrogen, oxide of iron, a ferrocyanide, a sulphocyanate, and perhaps a nitrate. The purple compounds may be isolated by operating with alcoholic solutions; it is then blue, and appears to be simply a compound of nitroferri cyanide and sulphide.

The soluble nitroferri cyanides are decomposed by *sulphydric acid* gas, yielding oxide of iron, prussian blue, sulphur, a ferrocyanide, and a peculiar sulphur-compound.

The nitroferri-cyanides are decomposed by boiling with *alkalis*, yielding oxide of iron, free nitrogen, a ferrocyanide, and perhaps a nitrite. An excess of ammonia gradually decomposes them, even in the cold, nitrogen being evolved, and a black uncrystallisable substance finally remaining.

Nitroferri-cyanides are not sensibly affected by *sulphurous acid*, *sulphites*, or *hypo-sulphites*: but they are decomposed by boiling with strong *sulphuric acid*, the liquid during the decomposition exhibiting the peculiar purple colour which indicates the presence of a sulphide. *Chlorine* exerts no action on the nitroferri-cyanides. *Prussian blue* dissolves in the solutions of certain nitroferri-cyanides, with a fine blue colour.

Some of the nitroferri-cyanides are very permanent, their solutions undergoing no change either by exposure to the air, or by the action of heat. Several, on the contrary, especially the nitroferri-cyanides of hydrogen, ammonium, barium, and calcium, undergo partial decomposition when their solutions are long kept, and rapid alteration when boiled, depositing prussian blue or oxide of iron.

Nitroferri-cyanide of Ammonium, $(\text{NH}_4)^2\text{Fe}^2\text{Cy}^5(\text{NO}) + \text{aq.}$, is very unstable, depositing prussian blue when boiled, and then yielding by concentration rhombic crystals of a slightly altered salt. Dominant faces, $\infty\text{P} \cdot \infty\bar{\text{P}}\infty \cdot \bar{\text{P}}\infty \cdot \text{oP}$. Inclination of $\infty\text{P} : \infty\text{P} = 91^\circ 56'$; $\bar{\text{P}}\infty : \infty\bar{\text{P}}\infty$ in the macrodiagonal principal section = $69^\circ 45'$. (Miller: see *Playfair's Memoir*.)

Nitroferri-cyanide of Barium, $\text{Ba}^2\text{Fe}^2\text{Cy}^5(\text{NO}) + 2 \text{aq.}$, crystallises in vacuo in fine octahedral crystals of a dark red colour. The crystals belong to the dimetric system, exhibiting the dominant faces $\text{P} \cdot \text{oP} \cdot \infty\text{P}\infty$. Inclination of $\text{P} : \text{P}$ in the terminal edges = $120^\circ 30'$; $\text{P} : \text{oP} = 135^\circ 25'$ (Miller). Concentrated solutions sometimes yield flattened prisms which appear to be another hydrate. This salt is very soluble in water; the solution when boiled deposits a brown precipitate. The crystallised salt dried in vacuo gives off from 14.9 to 15.2 p. c. water at 100°C .

Nitroferri-cyanide of Calcium, $\text{Ca}^2\text{Fe}^2\text{Cy}^5(\text{NO}) + x \text{aq.}$, forms shining dark red monoclinic prisms, with the dominant faces $\infty\text{P} \cdot \infty\text{P}\infty \cdot \text{oP}$. Inclination of $\infty\text{P}\infty : \text{oP} = 82^\circ$; $\infty\text{P} : \infty\text{P}$ in the orthodiagonal principal section = 140° . (Miller.)

The *copper-salt* is a pale green precipitate insoluble in water, and acquiring a slate colour when exposed to light in the moist state.

Nitroferri-cyanide of Hydrogen or *Nitroprussic acid*, $\text{H}^2\text{Fe}^2\text{Cy}^5(\text{NO}) + \text{aq.}$, is obtained by decomposing the silver-salt with an equivalent quantity of hydrochloric acid, or the barium-salt with an equivalent quantity of sulphuric acid. The red strongly acid solution yields, by evaporation in vacuo, dark red, very deliquescent, oblique prisms, part of the acid, however, decomposing at the same time, with formation of hydrocyanic acid and oxide of iron. The aqueous solution is not precipitated by ether.

Nitroferri-cyanide of Iron (ferrous) is a salmon-coloured precipitate, nearly insoluble in pure water, more soluble in water acidulated with nitric acid. It is decomposed by caustic alkalis, with separation of oxide of iron and formation of a soluble nitroferri-cyanide, a dark-coloured basic iron-salt being, however, formed previous to complete decomposition. After drying at 32°C . it loses about 20 per cent. more water when heated to 100° .

Nitroferri-cyanide of Potassium, $\text{K}^2\text{Fe}^2\text{Cy}^5(\text{NO})$, forms dark red oblique prisms, more soluble than the sodium-salt, and less easy to crystallise. The crystals are monoclinic. Dominant faces $\infty\text{P} \cdot [\infty\text{P}\infty] \cdot -\text{P} \cdot -\text{P}\infty \cdot [\frac{1}{2}\text{P}\infty]$. Inclination of $\infty\text{P} : [\infty\text{P}\infty] = 130^\circ 14'$; $-\text{P} : [\infty\text{P}\infty] = 125^\circ 55'$; $-\text{P}\infty : \text{principal axis} = 57^\circ 56'$. The salt is very deliquescent, and acquires a faint green tint when exposed to light. Its solution after a while deposits prussian blue.

On mixing the aqueous solution of this salt with twice its volume of alcohol, and then adding caustic potash, a light yellow curdy precipitate is formed, consisting of a basic salt, $\text{K}^2\text{Fe}^2\text{Cy}^5(\text{NO}) \cdot 2\text{KHO}$.

Nitroferri-cyanide of Silver, $\text{Ag}^2\text{Fe}^2\text{Cy}^5(\text{NO})$, is a flesh-coloured precipitate, insoluble in water, alcohol, and nitric acid.

Nitroferri-cyanide of Sodium, $\text{Na}^2\text{Fe}^2\text{Cy}^5(\text{NO}) + 2 \text{aq.}$, is prepared as described on page 251. The dark red solution which remains after the nitrates of potassium and sodium have crystallised out, yields by evaporation, prismatic crystals, which must be taken out of the liquid, dissolved in water, and left to crystallise by cooling. The object of taking the crystals out of the hot solution, is to obtain them free from nitrates, which are more soluble in hot water than the nitroferri-cyanide.

The crystals are large ruby-coloured prisms, bearing considerable resemblance to ferri-cyanide of potassium crystallised from an alkaline solution. The salt is not deliquescent, dissolves in $2\frac{1}{2}$ pts. of water at 15°C ., and in a smaller quantity of hot water. It does not lose weight at 100°C .

The crystals belong to the trimetric system. Dominant faces, ∞P . $\infty \bar{P}\infty$. $\infty \bar{P}\infty$. $\bar{P}\infty : \bar{P}\infty$. Inclination of $\infty P : \infty P = 105^\circ 17'$; $\bar{P}\infty : \bar{P}\infty$ in the brachydiagonal principal section $= 136^\circ 32'$; $\bar{P}\infty : \bar{P}\infty$ in the macrodiagonal principal section $= 124^\circ 52'$. (Miller.)

A solution of the salt exposed to sunshine becomes coloured, deposits prussian blue, and gives off nitric oxide. (Overbeck, Pogg. Ann. lxxvii. 110.)

CYANIDE OF LEAD. Hydrocyanic acid does not precipitate either the nitrate, the neutral acetate, or the basic acetate of lead. Cyanide of ammonium forms with the neutral acetate a slight yellowish precipitate.

Oxycyanide of Lead. On mixing a solution of basic acetate of lead with ammonia, and then adding hydrocyanic acid, a white precipitate is formed, containing $PbCy.PbHO$, according to Kugler (Ann. Ch. Pharm. lxi. 63),—whose formula does not, however, agree well with his analysis,—and $PbCy.Pb^oO$, according to Erlenmeyer (J. pr. Chem. xlviii. 356).

CYANIDE OF MAGNESIUM. Soluble salt produced by dissolving recently precipitated magnesia in hydrocyanic acid. It is decomposed by the carbonic acid of the air.

CYANIDES OF MANGANESE. (Rammelsberg, Pogg. Ann. xlii. 117.—Haidlen and Fresenius, Ann. Ch. Pharm. xliii. 132.—Balard, Compt. rend. xix. 909.)—Cyanide of potassium forms with manganese salts a bulky reddish-white precipitate, which quickly turns brown in contact with the air. It is decomposed by strong acids, and dissolves in alkaline cyanides, the solutions when exposed to the air being converted into manganecyanides, $R^3Mn^2Cy^6$, salts analogous in composition to the ferricyanides.

Manganecyanide of potassium, $K^3Mn^2Cy^6$, obtained in this manner, forms brown-red anhydrous needles, isomorphous with the ferricyanide. In contact with the air the crystals turn brown, and their aqueous solution becomes turbid and gradually deposits the manganese in the form of a black hydrate, the decomposition being accelerated by dissolving and evaporating several times. Acids decompose the salt, eliminating hydrocyanic acid. Alkalis do not act upon it. Sulphide of ammonium slowly precipitates a portion of the manganese. The crystals are decomposed by water and by alcohol, so that it is necessary to dissolve them in cyanide of potassium. The solution gives, with various metallic salts, precipitates of analogous composition, and for the most part easily decomposable. The precipitate formed with *ferrous salts* has a cobalt-blue colour; those with *zinc* and *cadmium* salts are rose-coloured; with *lead*-salts, brown; with *silver*-salts from neutral solutions, yellowish-brown; in presence of free acid, scarlet, but becoming brown by washing.

CYANIDE OF MERCURY. $HgCy$ or Hg^oCy^2 , according as mercury is regarded as monatomic ($= 100$) or diatomic ($= 200$). This salt, discovered by Scheele (*Opuscula*, ii. 159) is obtained by the action of mercuric sulphate on ferrocyanide of potassium, or of mercuric oxide on hydrocyanic acid, or of the same oxide on prussian blue (p. 228).—1. One part of ferrocyanide of potassium is boiled for a quarter of an hour with 2 pts. mercuric sulphate and 8 pts. water; the deposit is separated by filtration, and the liquid evaporated to the crystallising point (Desfosses, J. Chim. méd. vi. 261). Theoretically, 100 pts. ferrocyanide require 245 pts. mercuric sulphate, and yield 179 pts. mercuric cyanide:

2. Mercuric oxide is digested with dilute hydrocyanic acid, till the odour of the acid is no longer perceptible, and the solution is left to evaporate.—3. Four pts. pulverised prussian blue and 3 pts. mercuric oxide are boiled with 40 pts. water; the liquid is filtered as soon as the solid matter has acquired a light brown colour; the residue is boiled with a fresh quantity of water; the second filtrate added to the former; and the whole evaporated to the crystallising point.

Cyanide of mercury crystallises in forms belonging to the dimetric system, colourless, transparent, permanent in the air, having a nauseous metallic taste, and very poisonous. They are anhydrous. The salt dissolves in 8 pts. of cold water; it is less soluble in hydrated alcohol, quite insoluble in absolute alcohol.

For the primary form P , the length of the principal axis is 0.4596 . The angle $P : P$ in the terminal edges $= 134^\circ 40'$; in the lateral edges $66^\circ 2'$. P is for the most part sphenoidically hemihedral, and the character of the crystals varies considerably, according to the manner in which they are obtained. By spontaneous evaporation, quadratic sphenoids (p. 136), are often obtained, either perfectly developed, or having their lateral edges truncated by the faces $\infty P\infty$ as in *fig.* 368. By rapid cooling prismatic crystals are produced, in which the face $\infty P\infty$ predominates (*figs.* 365, 366).

In *fig. 365*, the prism $\infty P\infty$ is bevelled by the faces $\frac{P}{2}$, which are set alternately on the prismatic edges above and below. In *fig. 366*, the prism exhibits an oblique

Fig. 365.*Fig. 366.*

termination, one only of the two upper faces $\frac{P}{2}$ being distinctly formed, while the other is either very subordinate or not present at all: on the other hand, two faces are present belonging to the pyramid $2P\infty$ (the next acuter to the primary form P); they rest symmetrically on the prismatic faces $\infty P\infty$, and the terminal edge in which two of them would meet is truncated by the faces $\frac{P}{2}$.

A solution of the salt slowly evaporated often yields crystals of different form (*fig. 367*), with faces of the sphenoid $\frac{P}{2}$ resting alternately on the edges of the prism $\infty P\infty$, and faces of the pyramid $2P\infty$ (of which, however, only four are present) resting on the faces of the same prism. The two upper (and likewise the two lower) faces $2P\infty$ are separated from one another by ∞P and by two faces of an obtuser pyramid of

Fig. 367.*Fig. 368.*

the second order, which are rendered dull by deep striation, and likewise rounded, so that they cannot be accurately determined, but appear to belong to $P\infty$. More frequently, however, the crystals obtained by slow evaporation have the form shown in *fig. 368*, the faces $\frac{P}{2}$ predominating, their lateral edges truncated by $\infty P\infty$, and each terminal edge replaced by ∞P and by two faces of the pyramid of the second order, which is probably $P\infty$. (*Kopp's Krystallographie*, p. 150.)

Decompositions.—1. Cyanide of mercury when heated, turns black, softens, and yields, if perfectly dry, nothing but cyanogen gas and mercury; part of the cyanogen is, however, converted into the isomeric compound, paracyanogen, which remains in the form of a black, very light, coaly mass, the quantity thus altered being greater as the heat is stronger; at the same time, a small quantity of cyanide of mercury sublimes undecomposed. If the cyanide of mercury is moist, it yields carbonic acid, ammonia, hydrocyanic acid, and mercury. (Gay-Lussac.)

2. Dry cyanide of mercury is not decomposed by dry *chlorine gas* in the dark; but in strong sunshine it undergoes decomposition, emitting the odour of chloride of cyanogen (Gay-Lussac), and in ten days, yields protochloride of mercury and a yellow oily liquid (Serullas, *Ann. Ch. Phys.* xxxv. 293).—Cyanide of mercury exposed in the moist state to chlorine gas, is converted in the dark into protochloride of mercury and volatile chloride of cyanogen (Serullas):

But in strong sunshine — its temperature rising to 30° or 40° C. — it yields sal-ammoniac, protochloride of mercury, the above-mentioned yellow oil, a small quantity of volatile chloride of cyanogen, and a trace of carbonic acid. If the cyanide of mercury is completely dissolved in water, chlorine in sunshine produces a large quantity of the yellow oil and a small quantity of volatile chloride of cyanogen (Serullas). According to Bouis (Ann. Ch. Phys. [3] xx. 446; Jahresber. d. Chem. 1847—8, 486), a hot saturated solution of cyanide of mercury treated with excess of chlorine in sunshine, is converted into chloride of mercury, hydrochloric acid, and sal-ammoniac, which remain dissolved in the water, together with chloride of cyanogen, carbonic acid, and nitrogen, which escape, and a yellow, oily liquid, to which Bouis assigns the formula C^NCl^4 . A mixture of the aqueous solutions of cyanide of mercury and *chloride of lime*, which is clear at first, begins in a few minutes to emit white fumes, effervescing violently and giving off nitrogen, carbonic acid, and a small quantity of cyanogen; neither cyanic nor cyanuric acid is produced in this reaction (Liebig, Pogg. Ann. xv. 571).—3. *Bromine* at medium temperatures decomposes cyanide of mercury, with great evolution of heat, yielding protobromide of mercury and bromide of cyanogen (Serullas, Ann. Ch. Phys. xxxi. 100).—4. *Iodine*, even when triturated cold with cyanide of mercury, yields protiodide of mercury and iodide of cyanogen. (H. Davy, Porrett.)

5. When cyanide of mercury is distilled with $\frac{1}{5}$ of its weight of *sulphur*, the mass fuses, gives off nitrogen, cyanogen, and vapour of sulphide of carbon; then becomes viscid, swells up, and leaves a black mass insoluble in water; and this, when further heated, yields nitrogen, cyanogen, sulphide of carbon, and cinnabar, while light yellow mercurous sulphocyanate remains, which at a higher temperature partly sublimes in the form of a yellow, sometimes translucent, crystalline mass, but is for the most part resolved into cyanogen gas and cinnabar (Berzelius).—6. Cyanide of mercury, gently heated with *phosphorus*, yields a white sublimate, perhaps a cyanide of phosphorus, having a pungent odour, and decomposed by water into phosphoric and hydrocyanic acids. The preparation of this substance is very difficult, generally giving rise to a violent explosion. (Cenedella, J. Pharm. xxi. 683.)

7. Cyanide of mercury is decomposed when heated with strong *sulphuric acid*, not by dilute sulphuric or by nitric acid. With *hydrochloric*, *hydrobromic*, *hydriodic*, and *sulphuric acids*, it yields hydrocyanic acid and a mercuric compound of the radicle of the acid. An excess of hydrochloric acid, aided by heat, may, however, decompose the resulting hydrocyanic acid into ammonia and formic acid, in which case the residue will consist of mercuric chloride and sal-ammoniac.

8. Cyanide of mercury heated with *sal-ammoniac* yields cyanide of ammonium and mercuric chloride, which unites with the sal-ammoniac if the latter is in excess.—9. With solution of *stannous chloride*, it yields hydrocyanic acid, and a black mixture of stannic oxide and mercury.—10. When shaken up with *iron filings* and dilute sulphuric acid, it yields hydrocyanic acid, metallic mercury, and ferrous sulphate.—11. With aqueous *trisulphide of potassium*, it yields mercuric sulphide and sulphocyanate of potassium:

Aqueous *alkalis* do not decompose cyanide of mercury, even at the boiling heat.

Combinations. a. With *Mercuric oxide*.—Warm aqueous cyanide of mercury dissolves a large quantity of mercuric oxide, forming an alkaline solution, which deposits small needles of oxycyanide of mercury, $Hg''Cy^2.Hg''O$, or $(Hg'')^2.Cy^2O$, sparingly soluble in cold, moderately soluble in boiling water, sparingly in hydrated alcohol.

b. With *Salts*.—Cyanide of mercury combines with a large number of salts, forming definite, soluble, crystalline compounds, which are obtained by evaporating the mixed solutions of the component salts. The greater number of them contain 1 at. $Hg''Cy^2$ (or 2 at. $Hg''Cy$), to 1 at. of the other salt, and these may likewise be obtained by dissolving 1 at. mercuric chloride, iodide, &c., in a solution of potassio-mercuric, sodio-mercuric cyanide, &c. For this reason Geuther (Ann. Ch. Pharm. cvi. 241) regards them as compounds of mercuric chloride, iodide, &c., with double cyanides, *e. g.*, $2(Hg''Cy^2.KCl) = K^2Hg''Cy^4.Hg''Cl^2$. The latter view receives some support from the fact that these double salts are decomposed by the weaker acids, such as arsenious and benzoic acid, with evolution of prussic acid, whereas cyanide of mercury itself is not decomposed by weak acids. The double salts of cyanide of mercury have been investigated chiefly by Brett (Phil. Mag. [3] xii. 235); Poggiale (Compt. rend. xxiii. 762); Caillot (Ann. Ch. Phys. [3] xix. 230); Custer (Arch. Pharm. [2] lvi. 1); Rammelsberg (Pogg. Ann. xlii. 131; lxxxv. 145); Darby (Chem. Soc. Qu. J. i. 23); L. Gmelin (*Handbook*, viii. 17).

1. With *Acetate of Sodium*:

$HgCy^2.2C^2H^3NaO + 7aq.$ Once obtained from the mother-liquor of a solution of the two salts. (Custer.)

2. With *Bromides* :

$\text{HgCy}^2.\text{KBr}$. Nacreous scales soluble in 13·4 pts. water 18°C ., and in less than 1 pt. boiling water. (Caillot, Brett.)

$\text{HgCy}^2.\text{NaBr}$. Long flattened needles, very soluble in water.

$\text{HgCy}^2.\text{BaBr} + 3\text{aq}$. Square tables with a strong lustre, and very soluble. (Caillot.)

$\text{HgCy}^2.\text{SrBr} + 3\text{aq}$. Rhombic tablets, efflorescent and soluble. (Caillot.)

$\text{HgCy}^2.\text{CaBr} + \frac{3}{2}\text{aq}$. Very soluble in water and in alcohol. (Custer.)

3. With *Chlorides* :

$\text{HgCy}^2.\text{NH}^4\text{Cl}$. Silky needles, soluble in water and alcohol. $\text{HgCy}^2.4\text{NH}^4\text{Cl}$. Triangular laminæ which separate from the solution of the preceding salt.

$\text{HgCy}^2.\text{KCl}$. Colourless scales, soluble in water and in alcohol. (L. Gmelin.)

$\text{HgCy}^2.\text{NaCl}$. Silky flattened needles, soluble in water and in alcohol. (Brett, Poggiale.)

$\text{HgCy}^2.\text{BaCl} + 2\text{aq}$. Oblique prisms, very soluble and efflorescent. (Brett.)

$\text{HgCy}^2.\text{SrCl} + 3\text{aq}$. Silky, very soluble needles. (Brett, Poggiale.)

$\text{HgCy}^2.\text{CaCl} + 3\text{aq}$. Efflorescent, very soluble needles. (Brett, Poggiale.)

$\text{HgCy}^2.\text{MgCl} + \text{aq}$. Needles very soluble and slightly deliquescent. (Brett, Poggiale.)

$\text{HgCy}^2.\text{MnCl} + \frac{3}{2}\text{aq}$. Four-sided prisms, very soluble. (Poggiale.)

$\text{HgCy}^2.\text{ZnCl} + 3\text{aq}$. Right prisms, efflorescent and soluble in water. (Poggiale.)

$\text{HgCy}^2.4\text{CoCl} + 4\text{aq}$. Reddish-yellow mammellated groups. (Poggiale.)

$\text{HgCy}^2.2\text{NiCl} + 6\text{aq}$. Greenish blue, deliquescent. (Poggiale.)

$\text{HgCy}^2.\text{HgCl}^2$. Four-sided prisms, permanent in the air. (Liebig, Schw. J. xlix. 253.—Poggiale.)

Stannic chloride appears also to unite with cyanide of mercury, forming a confusedly crystalline compound. *Stannous chloride* decomposes cyanide of mercury (p. 255).

4. With *Chromates* :

$\text{HgCy}^2.\text{KCrO}^2$. Large laminæ of a light yellow colour, very soluble (Poggiale, Caillot and Podevin). It is obtained either by mixing the solutions of equal parts of cyanide of mercury and neutral chromate of potassium (Caillot and Podevin, J. Pharm. xi. 246), or by boiling basic mercuric chromate for some time with an equivalent quantity of potassio-mercuric cyanide (Geuther, Ann. Ch. Pharm. cvi. 241).—Another salt, $3\text{HgCy}^2.4\text{KCrO}^2$, is obtained by mixing the solutions of 1 pt. chromate of potassium and 3 pts. cyanide of mercury, and leaving the mixed solution to evaporate. It then yields, first crystals of cyanide of mercury, then red crystals of the double salt. If only 2 pts of mercuric cyanide are used to 1 pt. chromate, the first deposit of mercuric cyanide is but of small amount. (Darby, Rammelsberg.)

$2(\text{HgCy}^2.\text{AgCrO}^2).\text{Cr}^2\text{O}^3$, or $2\text{HgCy}^2.(\text{Ag}^2\text{O}.2\text{Cr}^2\text{O}^3)$, is obtained in splendid red needles by mixing the solution of the preceding salt with nitrate of silver, as long as a precipitate continues to form, then heating the liquid nearly to the boiling point, adding sufficient nitric acid to dissolve the whole, and leaving the solution to cool. (Darby.)

5. With *Cyanides* :

$\text{HgCy}^2.2\text{KCy} = \text{K}^2\text{Hg}''\text{Cy}^4$, forms regular octahedrons, colourless, permanent in the air, soluble in cold water. (L. Gmelin.)

$3\text{HgCy}^2.\text{K}^4\text{Fe}^2\text{Cy}^6 + 4\text{aq} = \text{K}^4(\text{Hg}''')^2\text{Fe}^2\text{Cy}^{12} + 4\text{aq}$. Pale yellow, rhombic tables, obtained by agitating a moderately concentrated solution of ferricyanide of potassium with metallic mercury; a precipitate of ferric oxide is first formed, mixed with mercury, and the yellowish filtrate yields the double salt by evaporation.

Cyanide of mercury and sodium crystallises in octahedrons. *Cyanide of mercury and zinc* is obtained as a white precipitate on adding a zinc-salt to the solution of cyanide of mercury and potassium. The corresponding *lead-compound* is a white precipitate obtained in like manner.

6. With *Formates* :

$\text{HgCy}^2.2\text{CH}(\text{NH}^4)\text{O}^2$ forms triangular prisms. (Poggiale.)

$\text{HgCy}^2.2\text{CHKO}^2$ forms shining scales. (Winckler, Repert. Pharm. xxxi. 459.)

7. With *Hyposulphites* :

$2\text{HgCy}^2.\text{K}^2\text{S}^2\text{O}^3$. Large prisms, obtained by concentrating in vacuo the mother-liquor of the solution of the two salts in equivalent quantities. (Kessler, Pogg. Ann. lxxiv. 274.)

8. With *Iodides* :

$\text{HgCy}^2.\text{KI}$ forms colourless, nacreous, soluble prisms. (Caillot.)

$\text{HgCy}^2.\text{NaI} + 2\text{aq.}$ Silky prisms, very soluble in water and alcohol, giving off their water of crystallisation at 100°C. Mineral acids decompose them, precipitating mercuric iodide and evolving hydrocyanic acid. (Custer.)

$\text{HgCy}^2.\text{BaI} + 2\text{aq.}$ Square tables. (Custer.)

$\text{HgCy}^2.\text{SrI} + 3\text{aq.}$ Square tables. (Custer.)

$\text{HgCy}^2.\text{CaI} + 3\text{aq.}$ Very soluble silky tufts. (Poggiale.)

9. With Nitrates:

$\text{HgCy}^2.\text{AgNO}^3 + 2\text{aq.}$ Obtained by mixing mercuric nitrate with equivalent quantities of cyanide of silver and cyanide of mercury. It forms long slender needles, which melt above 100°C. , and then detonate. (Geuther.)

Cyanide of mercury forms with *mercuric nitrate*, a compound which crystallises in nacreous scales or colourless prisms.

10. With Sulphates:

$2\text{HgCy}^2.\text{Ag}^2\text{SO}^4 + \text{aq.}$ Colourless crystals obtained like the corresponding nitrate compound. (Geuther.)

11. With Sulphocyanates:

$\text{HgCy}^2.4\text{KCyS.}$ Obtained, by crystallising the two salts together, in large laminæ or needles, colourless, sparingly soluble in cold, very soluble in boiling water. (Böckmann.)

$\text{HgCy}^2.4\text{BaCyS.}$ Nacreous scales. (Böckmann, Ann. Ch. Pharm. xxii. 153.)

$\text{HgCy}^2.4\text{CaCyS.}$ Shining scales. (Böckmann.)

The *magnesium-salt* is a white crystalline powder. (Böckmann.)

Cyanide of mercury also forms definite compounds with *alkaloïds*. (See the several ALKALOÏDS.)

CYANIDE OF METHYL. *Acetonitrile.* $\text{C}^2\text{H}^3\text{N} = \text{CH}^3.\text{CN} = \text{CH}^3.\text{Cy.}$ —This compound is obtained: 1. By distilling dry sulphomethylate of potassium with cyanide of potassium, adding chloride of calcium to the distillate, and distilling again at a gentle heat. The product is contaminated with hydrocyanic acid (Frankland and Kolbe, Chem. Soc. Mem. iii. 386; Ann. Ch. Pharm. lxxv. 288).—2. By the action of cyanide of potassium on sulphate of methyl. The product is contaminated with cyanide and formate of ammonium; the latter impurity imparts to the product an intolerable taste and odour, and a highly poisonous action; it may be removed by boiling with mercuric oxide and then with phosphoric anhydride (Dumas, Malaguti, and Leblanc, Compt. rend. xxv. 474).—3. By distilling a mixture of phosphoric anhydride and crystallised acetate of ammonium:

The product is purified by digestion with a saturated solution of chloride of calcium and rectification over solid chloride of calcium and magnesium (Dumas, Compt. rend. xxxv. 383).—4. By distilling acetamide with phosphoric anhydride, washing the distillate with potash to remove hydrocyanic and acetic acids, and rectifying over phosphoric anhydride (Buckton and Hofmann, Chem. Soc. Qu. J. ix. 242).—5. Cyanide of methyl is found, together with the cyanides of ethyl and tetryl, among the products of the oxidation of gelatin by a mixture of acid chromate of potassium and sulphuric acid. Legumin treated in like manner appears also to yield a small quantity of it. (Fröhde, J. pr. Chem. lxxix. 303.)

Cyanide of methyl is a colourless liquid, which boils at 77°C. (Dumas), between 77° and 78° (Buckton and Hofmann), and mixes in all proportions with water. Vapour-density by experiment = 1.45, by calculation (2 vol.) = 1.42. It has an ethereal odour, somewhat like that of cyanogen, and a rather pungent aromatic taste; burns with a bright reddish-bordered flame. (Buckton and Hofmann.)

Boiled with aqueous *potash*, it gives off ammonia and forms acetate of potassium. *Chromic acid* and boiling *nitric acid* have no action upon it. *Potassium* acts violently upon it even in the cold, cyanide of potassium being formed, with rise of temperature, and a combustible gas evolved consisting of free hydrogen and carburetted hydrogen (Dumas). Heated with *fuming sulphuric acid*, it yields disulphometholic acid and sulphacetic acids:

258 CYANIDE OF NICKEL—CYANIDE OF NITROGEN.

The relative quantities in which these two acids are formed depends upon the temperature. If the materials are mixed so as to avoid heating as much as possible, scarcely any carbonic anhydride is evolved, and the chief product is sulphacetic acid; but if the temperature be considerably raised, carbonic anhydride is rapidly evolved and disulphometholic acid is produced. The latter stage of the reaction appears to consist in the resolution of the acetic acid, $C^2H^4O^2$, into carbonic anhydride and marsh-gas, CH^4 , which then unites with 2 at. SO^3 , forming disulphometholic acid. (Buckton and Hofmann, *loc. cit.*)

Combinations. a. With *Trichloride of Phosphorus*. $C^2H^3N.PCl^3$. (Henke, Ann. Ch. Pharm. cvi. 281.)—This compound, obtained by distilling acetamide with pentachloride of phosphorus, is a colourless, mobile, very pungent liquid, which boils at $72^\circ C.$, and takes fire in contact with a spirit-flame. Its vapour-density is anomalous, being 3.56 at $95^\circ C.$, 3.54 at 87° , and 2.4 at 148° . The medium number represents nearly a condensation to four instead of two volumes ($\frac{41 + 137.5}{4} \times 0.0693 = 3.09$).

The anomaly probably arises, as in other similar cases, from the decomposition of the compound at the temperature at which the vapour-density is determined, into C^2H^3N and PCl^3 , each of which occupies two volumes.

b. With *Metallic Chlorides*.—These compounds are formed by direct combination. The *antimony-compound*, $C^2H^3N.SbCl^3$, the formation of which is attended with great rise of temperature, is white, crystalline, and sublimes without decomposition. The *gold-compound*, $C^2H^3N.AuCl^3$, is a brownish-yellow powder. The *titanium-compound*, $2C^2H^3N.TiCl^4$, forms white, coherent, crystalline crusts, which may be sublimed. The *tin-compound*, $2C^2H^3N.SnCl^4$, is white, crystalline, and sublimes in arborescent formations. (Henke, *loc. cit.*)

c. With *Cyanide of Mercury*. $C^2H^3N.2Hg^{\prime}Cy^2$.—White crystalline mass, with vitreous lustre, produced by exposing pulverised cyanide of mercury to the vapour of cyanide of methyl. The compound gives off its cyanide of methyl when exposed to moist air, or when dried over sulphuric acid. Heated in a tube it turns black, and yields a sublimate of white crystals mixed with mercury. (O. Hesse, Ann. Ch. Pharm. cx. 202.)

Cyanide of Trichloromethyl, or *Chloracetonitrile*, $CCl^3.CN$, is obtained by distilling trichloracetate of ammonium, or trichloracetamide, with phosphoric anhydride. It is a liquid of specific gravity 1.444, boiling at $81^\circ C.$ With boiling potash, it yields ammonia and trichloracetate of potassium. It is violently attacked by potassium. (Dumas, Malaguti, and Leblanc, Compt. rend. xxv. 442.)

CYANIDE OF NICKEL. $NiCy$.—Nickel-salts form with cyanide of potassium a light apple-green precipitate, soluble in excess of cyanide of potassium. It turns brown when dried, giving off 19 per cent. water.

The double cyanides of nickel belong to the less stable class of double cyanides (p. 201), giving off prussic acid when heated with dilute acids.

Cyanide of Nickel and Ammonium is a somewhat unstable compound, obtained by dissolving cyanide of nickel in aqueous cyanide of ammonium, and leaving the solution to evaporate.

Cyanide of Nickel and Barium forms yellow crystals, which give off 20 per cent. water when heated. *Cyanide of Nickel and Calcium* forms yellow hydrated crystals. *Cyanide of Nickel and Cobalt* is a pale red precipitate, producing on mixing the solution of a cobalt-salt with cyanide of nickel and potassium. The corresponding *cupric salt* is an apple-green precipitate. The *ferrous salt* is a white precipitate. The *lead-salt* is a yellow crystalline powder, which separates after a while from a solution of acetate of lead mixed with cyanide of nickel and potassium.

Cyanide of Nickel and Potassium, $K^2Ni^{\prime}Cy^4 + aq$.—Obtained by dissolving cyanide or recently precipitated sulphide of nickel in cyanide of potassium. Crystallises in oblique rhomboidal prisms, having a yellow colour. The aqueous solution yields with dilute acids a precipitate of cyanide of nickel. According to Rammelsberg (Pogg. Ann. xlii. 114) and Balard (Compt. rend. xix. 999) the crystals contain 6.61 per cent. water, which they give off at $200^\circ C.$

Cyanide of Nickel and Sodium, $Na^2Ni^{\prime}Cy^6 + 3aq$., forms yellow hexagonal prisms, which give off their water at $100^\circ C.$

CYANIDE OF NITROGEN is said to be produced when a solution of cyanide of potassium is poured upon chloride of nitrogen. The gas thereby evolved, which explodes in contact with phosphorus, and is said to contain cyanide of nitrogen, is probably nothing but nitrogen containing vapour of chloride of nitrogen. Iodide of nitrogen is dissolved by cyanide of potassium without colour, and probably with for-

mation of iodoform, formate of potassium, and iodide of ammonium. (Millon, Ann. Ch. Phys. [3] lix. 75.)

CYANIDES OF OSMIUM. (Claus, *Beiträge zur Chemie der Platinmetalle*, Dorpat. 1854. — C. A. Martius, *Inauguraldissertation*, Göttingen, 1860; Ann. Ch. Pharm. cxvii. 357; Jahresber. d. Chem. 1860, p. 233.)—The only cyanide of osmium which appears to have been obtained in the free state, is the protocyanide OsCy ; it is separated as a dark violet-coloured precipitate, when an osmiocyanide is boiled for some time with strong hydrochloric acid; also when moist osmiocyanide of hydrogen is exposed to the air.

Protocyanide of osmium unites with the more basic cyanides, forming a class of double salts, the OSMIOCYANIDES, $\text{M}^4\text{Os}^2\text{Cy}^6 = 4\text{MCy} \cdot 2\text{OsCy}$, analogous to the ferrocyanides, and exhibiting somewhat similar reactions with iron-salts. A solution of an osmiocyanide, forms with *ferrous* salts a light blue precipitate quickly becoming darker on exposure to the air, and with *ferric* salts a precipitate of a beautiful violet colour. With *cupric* salts, the soluble osmiocyanides form a red-brown precipitate; with *silver*, *mercurous*, and *lead* salts, white crystalline; and with *zinc* and *cadmium* salts, white gelatinous precipitates.

Osmiocyanide of Barium, $\text{Ba}^4\text{Os}^2\text{Cy}^6 + 3 \text{ aq.}$ is obtained by treating ferric osmiocyanide with baryta-water—which separates ferric hydrate in the same manner as from ferric ferrocyanide—removing the excess of baryta from the filtrate by carbonic acid, and evaporating over sulphuric acid. It forms small rhombic prisms with basal end-faces, transparent, reddish-yellow, easily soluble in water and in aqueous alcohol. They are permanent in the air at ordinary temperatures, but give off all their water between 50° and 60°C. (Martius.)

Osmiocyanide of Barium and Potassium $(\text{Ba}^2\text{K}^2)\text{Os}^2\text{Cy}^6 + 3 \text{ aq.}$ separates from a mixture of the boiling concentrated solutions of 1 pt. chloride of barium and 2 pts. osmiocyanide of potassium, in small light-yellow crystals having the form of acute rhombohedrons with the end-face oR . The salt is efflorescent, dissolves sparingly in cold, freely in boiling water. (Martius.)

Osmiocyanide of Hydrogen, *Hydro-osmiocyanic acid*, *Osmioprussic acid*, $\text{H}^1\text{Os}^2\text{Cy}^6$, is obtained by mixing a cold saturated solution of osmiocyanide of potassium with an equal volume of fuming hydrochloric acid, collecting the precipitated osmioprussic acid on a filter (freed from iron by washing with hydrochloric acid), washing it with strong hydrochloric acid, and crystallising it from alcohol covered with a layer of ether. It forms transparent, colourless, shining, prismatic crystals, belonging to the hexagonal system. They are anhydrous, and permanent in the air when dry, but decompose in the moist state, giving off hydrocyanic acid and leaving protocyanide of osmium. The acid dissolves easily in water and in alcohol, and is precipitated therefrom by a small quantity of ether; it has a sour, metallic, astringent taste, a strong acid reaction, and decomposes carbonates. (Martius.)

Osmiocyanides of Iron. The *ferrous* salt, $\text{Fe}^4\text{Os}^2\text{Cy}^6$, is the light blue precipitate produced by soluble osmiocyanides in ferrous solutions. It quickly becomes darker on exposure to the air, and is converted by nitric acid into a violet compound, probably $\text{Fe}^3\text{Os}^2\text{Cy}^6$, analogous to Turnbull's blue. The same compound is said by Martius to be formed by precipitating osmiocyanide of potassium with a ferric salt; but the precipitate thus formed is more probably *ferric osmiocyanide* $(\text{Fe}^3)^{211}\text{Os}^6\text{Cy}^{18}$, analogous to ferric ferrocyanide (p. 227), the reaction being

It has a splendid violet colour, and, as a test for ferric salts, is even more delicate than ferrocyanide of potassium; it settles down quickly, and is not decomposed by boiling water. In drying, it shrinks up to a brittle mass having the colour of pinchbeck. By boiling with alkalis, it is decomposed like ferric ferrocyanide, with separation of ferric hydrate. (Martius.)

Osmiocyanide of Potassium, $\text{K}^4\text{Os}^2\text{Cy}^6 + 3 \text{ aq.}$ This salt, the analogue of ferrocyanide of potassium, was discovered by Claus. It is most easily obtained by treating osmate of potassium with cyanide of potassium. A solution of 1 pt. osmic acid in a sufficient quantity of strong potash-ley just to give it an alkaline reaction, is mixed with $1\frac{1}{2}$ pt. cyanide of potassium; the dark liquid is carefully evaporated to dryness; and the residue is calcined at a gentle heat in a covered porcelain crucible. The solution of the unfused but whitened mass in a small quantity of water, deposits the salt, after filtration, in rather large crystalline plates, which may be purified by recrystallisation. Metallic osmium is not attacked by cyanide of potassium; but when gently ignited with ferrocyanide of potassium, it is almost entirely dissolved; the osmiocyanide thus

formed cannot, however, be separated from the ferrocyanide, because the two salts crystallise together in all proportions.

Osmiocyanide of potassium crystallises from water as a yellow silky powder, or in yellow quadratic laminae, isomorphous with the ferrocyanide. It is insoluble in alcohol and ether. The anhydrous salt is white, melts when heated to redness in a close vessel, with evolution of gas and separation of metallic osmium; when further heated in contact with the air, it yields osmic acid. With strong *hydrochloric acid* it first yields osmiocyanide of hydrogen, then gives off hydrocyanic acid and deposits protocyanide of osmium. Treated with *dilute nitric acid*, it gives off a large quantity of gas, and forms a solution containing a nitro-osmio-cyanogen compound not yet examined, perhaps analogous to a nitroferriocyanide (p. 250). Fused with *sulphur* it appears to yield a sulphosmio-cyanogen compound. It does not appear to form an osmium-compound analogous to ferricyanide of potassium (Martius.) For the reactions of osmiocyanide of potassium with metallic solutions, see page 259.

CYANIDES OF PALLADIUM. (Berzelius, Pogg. Ann. xiii. 460.—Fehling, Ann. Ch. Pharm. xxxix. 119.—Rammelsberg, Pogg. Ann. xliii. 139).

Palladous Cyanide, PdCy, is obtained as a yellowish-white precipitate on mixing a palladous salt with cyanide of mercury. It dissolves in ammonia, and the solution yields an abundant crop of crystals of cyanide of pallados ammonium, $(\text{NH}_4\text{Pd})\text{Cy}$.

Potassio-palladous cyanide, K_2PdCy_2 , is obtained in rhomboïdal crystals by dissolving palladous cyanide in cyanide of potassium, and evaporating.

Palladic Cyanide, PdCy_2 .—The compound of palladic chloride with chloride of potassium (see PALLADIUM) stirred up with water and mixed with cyanide of mercury, yields a pale rose-coloured flocculent precipitate which gradually decomposes, giving off hydrocyanic acid. (Berzelius.)

CYANIDES OF PLATINUM. (L. Gmelin, *Handbook*, viii. 43.—Döbereiner, Ann. Ch. Pharm. xvii. 250.—Knop, *ibid.* xliii. 111.—Knop and Schnedermann, J. pr. Chem. xxxvii. 461.—Quadrat, Ann. Ch. Pharm. lxiii. 164; lxx. 300.—Gerhardt, Compt. chim. 1850, p. 145; *Traité*, i. 362.—Schafarik, Wien. Akad. Ber. xvii. 57; Gm. x. 506.—Weselsky, J. pr. Chem. lxix. 276; Gm. xii. 499.—Buckton, Chem. Soc. Qu. J. iv. 26.—Hadow, *ibid.* xiii. 106.—C. A. Martius, *Ueber die Cyanverbindungen der Platinmetalle*. Inauguraldissertation, Göttingen, 1860; Ann. Ch. Pharm. cxvii. 357; Jahresber. d. Chem. 1860, p. 230.)

Platinum forms two cyanides, PtCy and PtCy_2 , analogous to the chlorides, and an intermediate compound Pt^2Cy_3 . The last two are known only in combination; the protocyanide is known in the separate state, but has never been obtained quite pure. It forms a numerous class of double salts, the platino cyanides MPtCy_2 or MCy.PtCy , which were discovered by L. Gmelin.

Protocyanide of Platinum, or *Platinous Cyanide*, PtCy.—This compound is obtained: 1. By calcining mercurous platinoocyanide in a retort at a gentle heat (Döbereiner).—2. By calcining a dried mixture of mercuric chloride and platinoocyanide of potassium, as long as any reaction is apparent, extracting the soluble matters with boiling water, and calcining the residue to free it from mercurous chloride (Knop and Schnedermann):

3. By adding strong sulphuric acid to platino-cyanide of potassium, whereby it becomes heated, and dissolving out the soluble salts with water (Knop and Schnedermann).—4. By heating platinoocyanide of ammonium to about 300° C. (Schafarik).—5. By boiling platinoocyanide of hydrogen with nitric acid. (Schafarik.)

Platinous cyanide, according to the manner in which it is prepared, is greenish-yellow or sulphur-yellow in the recent state, and of a rusty colour when dry. By the fourth method, it is obtained in yellow crystals, which are pseudomorphs of the ammonium-salt. It is insoluble in water, acids, and alkalis, but in the moist state it dissolves in the cyanides of the alkali-metals, yielding platinoocyanides. When heated in the air, it burns away, leaving metallic platinum, Schafarik's product (4), yielding the metal in distinct pseudomorphous crystals. The quantity of metallic platinum thus obtained varies considerably, according to the method by which the compound has been prepared. According to Döbereiner, it yields from 78 to 79 p. c., the formula requiring 79.2 p. c. Quadrat, however, found in the compound prepared by Döbereiner's method, only 71.7 p. c., and in that prepared by Knop and Schnedermann's process, only 72.8 p. c. platinum, numbers agreeing approximately with the formula of sesquicyanide of platinum, Pt^2Cy_3 , which requires 71.5 p. c. Schafarik, however, found in the products which he obtained by Knop and Schnedermann's method, and likewise by his own methods (4 and 5), from 75.24 to 77.18 p. c. platinum. On the whole, it is

most probable that the products obtained by these several methods consist essentially of protocyanide of platinum, but contaminated with variable quantities of foreign substances which cannot be removed by washing.

Ammonio-platinous Cyanide, NH^3PtCy . See CYANIDE OF PLATOSAMMONIUM (p. 264).

Platinocyanides. $\text{MPtCy}^2 = \text{MCy.PtCy}$, or rather $\text{M}^2\text{Pt}^2\text{Cy}^4$.—These salts may be regarded as compounds of protocyanide of platinum with a more basic cyanide. Those which are soluble may be obtained by treating protocyanide of platinum with an alkaline cyanide, or the protochloride with excess of an alkaline cyanide, or with an alkaline base and hydrocyanic acid; those which are insoluble are obtained by precipitation. The copper-salt decomposed by sulphydric acid yields platinocyanide of hydrogen, and this, when saturated with bases, likewise yields the several platinocyanides.

The platinocyanides belong to the more stable class of double cyanides (p. 201), exceeding even the ferrocyanides in the force with which they retain the negative metal and disguise it to ordinary tests. Strong nitric and hydrochloric acids, either alone or mixed, extract no platinum from them, even at the boiling heat; they are not decomposed by digestion with mercuric oxide; and strong sulphuric acid at the boiling heat separates the platinum but slowly.

The platinocyanides of the alkali-metals, alkaline-earth-metals, and magnesium, are soluble in water; most of the others are insoluble, or sparingly soluble. The soluble salts crystallise well and are remarkable for the beauty and variety of the colours which the crystals exhibit, whereas the solutions are colourless. The solutions form a small-blue precipitate with mercurous salts, white with mercuric salts, and a flocculent blue precipitate with cupric salts.

Platinocyanide of Ammonium, $(\text{NH}^1)\text{PtCy}^2$.—Obtained by dissolving platinous cyanide (3) in hydrocyanic acid saturated with ammonia (Knop and Schnedermann); by passing dry ammonia-gas over platinocyanide of hydrogen, the latter being kept in excess (Quadrat); by decomposing platinocyanide of potassium with sulphate of ammonium (Quadrat), or by precipitating platinocyanide of barium with a mixture of ammonia and carbonate of ammonium, and slowly evaporating the filtrate (Schafarik). By this last method it is obtained in slender prisms of a deep lemon-yellow colour, exhibiting a splendid blue fluorescence on the surface. These crystals contain 1 at. water ($\text{NH}^1\text{PtCy}^2 + \text{aq.}$), and when placed under a bell-jar, together with caustic lime on which ammonia is dropped, they become white and turbid, and give off half their water. These colourless crystals slowly recover their water and turn yellow when exposed to the air. Both the white and the yellow crystals give off the whole of their water at 150°C ., becoming milk-white and pearly. On dissolving the anhydrous salt in absolute alcohol and evaporating over sulphuric acid, crusts of colourless needles shoot out from the margin of the vessel, and at last coat the entire surface with a network exhibiting a beautiful violet fluorescence; on exposure to the air they rapidly turn yellow. The yellow salt dissolves in about its own weight of water, and in a smaller quantity of alcohol.

Platinocyanide of Barium, BaPtCy^2 .—Prepared: 1. By boiling the copper-salt with caustic baryta, and separating the excess of baryta by a stream of carbonic acid gas (Quadrat).—2. By dissolving platinocyanide of potassium in the smallest possible quantity of water, adding an equivalent quantity of the strongest sulphuric acid (23 pts. acid to 100 pts. potassium-salt), taking care to avoid overheating; then adding 10 vols. alcohol of specific gravity 0.63, mixed with a little ether, and immersing the vessel in cold water, to separate the sulphate of potassium; evaporating the filtrate to one-third; adding water; and saturating it at the boiling heat with carbonate of barium (Schafarik).—3. By triturating 2 pts. protochloride of platinum and 3 pts. carbonate of barium with water, heating the mixture with 10 pts. water nearly to the boiling point, and passing vapour of hydrocyanic acid through the liquid as long as carbonic acid continues to escape.

The salt forms monoclinic crystals, often of considerable size. Ordinary combination $\infty \text{P} . \infty \text{P} \infty . [\infty \text{P} \infty] . [\text{P} \infty]$. Inclination of $\infty \text{P} : \infty \text{P}$ in the clinodiagonal principal section = $99^\circ 42'$; $[\text{P} \infty] : [\text{P} \infty] = 130^\circ 8'$. Ratio of axes, $a : b : c = 2.0861 : 1.8145 : 1$. Inclination of b to $c = 75^\circ 53'$. The crystals appear green when viewed along the principal axis; sulphur-yellow at right angles to it. Specific gravity = 3.054. They contain 15.3 per cent. water (rather more than 2 at.), which they give off at 100°C . Easily soluble in hot water. (Quadrat.)

* This formula is more convenient for expressing the composition of most of the hydrated salts, which, if the smaller formula be used, must be supposed to contain a fractional number of water atoms. The double formula is further recommended by the consideration that the atomic weights of several of the metals, viz. Ba, Sr, Ca, Mg, Mn, Fe, Zn, Pb, and Hg are most probably double of those commonly assigned to them (see CLASSIFICATION, I. 1008, n. 4); thus the formula of platinocyanide of barium is most probably $\text{Ba}^2\text{Pt}^2\text{Cy}^4$, not BaPtCy^2 , the barred symbol Ba standing for the atomic weight 137.2 double of Ba = 68.6.

Platinocyanide of Cadmium, CdPtCy^2 .—Formed as a crystalline precipitate on mixing platinocyanide of potassium with chloride of cadmium. It is anhydrous, yellowish-white with blue iridescence when dry; when heated it glows and leaves a compound of cadmium and platinum. (Martius.)

Platinocyanide of Cadmammonium, $(\text{NH}^3\text{Cd})^2\text{Pt}^2\text{Cy}^4 + \text{aq.}$ —A solution of the preceding salt in ammonia yields this compound in large white needles, which retain their ammonia somewhat tenaciously. (Martius.)

Platinocyanide of Calcium, $\text{Ca}^2\text{Pt}^2\text{Cy}^4 + 5\text{aq.}$ —Obtained like the barium-salt. Slender needles which exhibit a trichroism similar to that of the barium-salt, appearing lemon-yellow and siskin-green by transmitted, and bluish with a diamond lustre by reflected light. They are very soluble in water, and give off 20·44 per cent. water at 140°C. (Quadrat.)

Platinocyanide of Cerium, $\text{Ce}^2\text{Pt}^2\text{Cy}^4 + 6\text{aq.}$ —Obtained by mixing cerous sulphate with platinocyanide of barium; evaporating the filtrate at 100°C. , exhausting the residue with warm alcohol, evaporating again, dissolving in water, and crystallising. Forms fine yellow strongly fluorescent prisms, with azure-blue surface-lustre, and exhibiting a siskin-green tint along the axis. It is permanent in the air, gives off half its water over sulphuric acid, but cannot be completely dehydrated by heat without decomposition. From the alcoholic solution it crystallises in white crystals, which contain less water, but when exposed to the air, or when breathed upon, quickly take up water, and are converted into the yellow salt. (Czudnowicz, J. pr. Chem. lxxx. 16.)

Platinocyanide of Cobalt-ammonium, $(\text{NH}^3\text{Co})\text{PtCy}^2$.—Obtained as a crystalline flesh-coloured powder by precipitating platinocyanide of potassium with chloride of cobalt, dissolved in a mixture of caustic ammonia and carbonate of ammonia. (Knop and Schnedermann.)

Platinocyanide of Cinchonine, $(\text{C}^{20}\text{H}^{24}\text{N}^2\text{O})\text{PtCy}^2$.—Easily soluble, colourless needles, obtained by decomposing the barium-salt with sulphate of cinchonine and evaporating. (Martius.)

Platinocyanide of Copper, CuPtCy^2 .—Precipitated on adding sulphate of copper to a solution of the potassium-salt (Quadrat). It is a green precipitate, which shrinks very much in drying, forming shining sharp-edged fragments. Gives off cyanogen when heated in close vessels, and leaves a black powder, probably consisting of platinum and oxide of copper (Schafarik). It is insoluble in water and acids, but easily soluble in ammonia, the solution yielding by slow evaporation azure-blue crystals of the following salt. (Quadrat.)

Platinocyanide of Cuprammonium, $(\text{NH}^3\text{Cu})^2\text{Pt}^2\text{Cy}^4 + \text{aq.}$ —Obtained as just described, or by mixing platinocyanide of potassium with nitrate of copper dissolved in ammonia. It then separates after a few hours in dark blue needles containing water of crystallisation. At 140°C. it gives off ammonia and turns green. (Knop and Schnedermann.)

Platinocyanide of Ethyl, $\text{C}^4\text{H}^5\text{N}^2\text{Pt} + \text{aq.} = (\text{C}^2\text{H}^3)\text{PtCy}^2 + \text{aq.} = \text{C}^2\text{H}^3\text{Cy.PtCy} + \text{aq.}$ (C. v. Thann, Ann. Ch. Pharm. cvii. 315.)—Prepared by passing dry hydrochloric acid gas into a solution of hydroplatinocyanic acid in absolute alcohol. The gas is rapidly absorbed, the liquid becomes very hot, and solidifies on cooling to a crystalline pulp, composed of small aurora-red needles. The crystals must be quickly filtered and dried with great care over oil of vitriol and caustic potash.

The crystals thus obtained contain 1 at. water, from which they cannot be separated without decomposition. They belong to the trimetric system, and are combinations of a prism with the basic terminal face and a dome. They appear to be isomorphous with platinocyanide of potassium. Under the microscope, the body of the crystal exhibits a brown colour, while the surface varies from azure to dark steel blue.

Hydrated platinocyanide of ethyl is resolved at 100°C. into alcohol and hydroplatinocyanic acid:

It suffers the same decomposition in contact with water. At higher temperatures it is resolved into platinous cyanide, cyanide of ethyl, and water. Aqueous ammonia added in excess to a concentrated alcoholic solution of platinocyanide of ethyl mixed with four or five times its bulk of ether, forms stellate groups of needles consisting of *platinocyanide of diplatamosammonium* (p. 264); and on evaporating the mother-liquor to dryness, dissolving it in alcohol, and leaving the solution to evaporate over oil of vitriol, it first deposits *hydrated platinocyanide of ammonium*, and then yellow needles

probably consisting of *platinocyanide of ethylammonium*. The decomposition may be represented by the equation :

Probably both these reactions go on together; but the cyanide of ethyl appears to be further acted on by the free ammonia, perhaps yielding ethylamine and cyanide of ammonium :

Dry ammonia gas converts platinocyanide of ethyl into platinocyanide of ammonium and ethylamine :

Platinocyanide of Ethylammonium, $\text{C}^2\text{H}^5\text{N}^3\text{Pt} = (\text{N}.\text{H}^2.\text{C}^2\text{H}^5)\text{PtCy}^2$.—The yellow crystals obtained, in the manner above described, by the action of aqueous ammonia on a solution of platinocyanide of ethyl in alcohol and ether, dissolve very readily in water and alcohol; and the solutions evaporated in the air, leave long yellow needles, which, while immersed in the mother-liquor, exhibit a splendid violet iridescence on the surface. (v. Thann.)

Platinocyanide of Hydrogen. Hydroplatinocyanic acid, HPtCy^2 .—Prepared by decomposing the copper-salt suspended in water with sulphydric acid, evaporating the filtrate to dryness, dissolving the residue in a mixture of alcohol and ether, and again evaporating. As thus obtained, it forms hydrated bluish-black prisms, or if the crystallisation has been rapid, greenish-yellow needles with a coppery or golden lustre. They absorb moisture from the air, turning yellow and deliquescent (Quadrat). By decomposing the barium-salt with an equivalent quantity of sulphuric acid, evaporating the filtrate, redissolving in alcohol and ether, and evaporating over sulphuric acid, Weselsky obtained the acid in crystals 7 or 8 lines long, half a line thick, and having a splendid vermilion colour with blue iridescence on the prismatic faces. These crystals absorbed water from the air, and then assumed the ordinary appearance of hydroplatinocyanic acid.

Hydroplatinocyanic acid turns yellow at 100°C ., then white, and may be heated to 140° without decomposing. It is soluble in water and in alcohol; the alcoholic solution is colourless. It decomposes carbonates with effervescence. It absorbs ammonia with rapidity, acquiring a yellow colour. Heated with strong sulphuric acid, it is decomposed, yielding hydrocyanic acid and a yellow substance, probably platinous cyanide (Quadrat). Nitric acid decomposes it, with separation of platinous cyanide. (Schafarik.)

Platinocyanide of Lanthanum, $\text{La}^2\text{Pt}^2\text{Cy}^4 + 6\text{aq}$.—Prepared in the same manner as the cerium-salt (p. 262). Crystallises from the aqueous solution in shining rhombic prisms terminated by a brachydiagonal dome. They exhibit dichroism, being yellow inclining to orange by transmitted light, but having a blue surface lustre. When placed over sulphuric acid they give off 3 at. water and acquire a scarlet colour; in vacuo they give off 5 at. water and acquire a dirty yellow-brown colour. From solution in strong alcohol the salt crystallises with difficulty in colourless crystals, which contain less water, but quickly take up an additional quantity and turn yellow. (Czudnowicz, J. pr. Chem. lxxx. 31.)

Platinocyanide of Lead, PbPtCy^2 .—Yellowish-white crystalline powder obtained by precipitation. When heated it behaves like the cadmium-salt. It is soluble in warm dilute nitric acid, solidifies on cooling to a red crystalline magma of platino-sesquicyanide of lead, $2\text{Pb}^2\text{Pt}^2\text{Cy}^5 + 5\text{aq}$.

Platinocyanide of Magnesium, $\text{Mg}^2\text{Pt}^2\text{Cy}^4$.—Prepared by mixing a solution of the barium-salt with sulphate of magnesium, evaporating the filtrate to dryness, digesting the residue in ether-alcohol, and leaving the solution to evaporate; or by mixing the solution of the potassium-salt with sulphate of magnesium, evaporating to a dry powder, digesting with ether-alcohol, and evaporating (Quadrat). It is thus obtained in fine large square-based prisms, often grouped in rosettes, of a deep red colour by transmitted light; when viewed by reflected light the sides of the prisms exhibit a brilliant beetle-green, and their extremities a deep blue or purple colour. The red crystals contain $\text{Mg}^2\text{Pt}^2\text{Cy}^4 + 7\text{aq}$. Between 50° and 40°C . (86° and 113°F .) they give up 1 at. water, and are reduced to $\text{Mg}^2\text{Pt}^2\text{Cy}^4 + 6\text{aq}$, which has a bright

yellow colour; this hydrate is likewise deposited from solution at the temperature of 160°F. ; also, according to Weselsky, by leaving a solution of the ordinary red and green salt in water, or in absolute alcohol, to crystallise over sulphuric acid. At 212°F. the salt becomes quite white, and then consists of $\text{Mg}^2\text{Pt}^2\text{Cy}^4 + 2\text{aq.}$, and between 300° and 400°F. it gives off the rest of its water and again becomes yellow. If a portion of this yellow anhydrous salt be laid on the red salt in powder, it will soon abstract water from the latter, and a white layer will be formed between two yellow borders, one consisting of the anhydrous, the other of the 6-hydrated salt (Schafarik; Hadow). The salt is very soluble in water, and forms a nearly colourless solution.

Platinocyanide of Magnesium and Potassium, $(\text{MgK})\text{Pt}^2\text{Cy}^4 + 7\text{aq.}$ —Hadow obtained this salt on one occasion, simultaneously with the magnesium salt, by evaporating to dryness a mixture of the solutions of sulphate of magnesium and platinocyanide of potassium, and digesting the residue in weak alcohol (instead of ether-alcohol). The crystals are of a paler red than the preceding, and exhibit a steel-blue lustre by reflected light. Part of the water of crystallisation is given off at 100°C. , the rest at a higher temperature. The salt cannot be recrystallised, except from excess of platinocyanide of magnesium, and even then, sudden cooling or agitation of the saturated solution will cause it to separate into its component salts. (Hadow.)

Platinocyanides of Mercury.—The mercuric salt, $\text{Hg}^2\text{Pt}^2\text{Cy}^4$, is a white precipitate obtained by mixing the solutions of platinocyanide of potassium and mercuric chloride. (Gmelin.)

With mercurous nitrate, platinocyanide of potassium forms a blue precipitate, consisting, according to Rammelsberg's analysis, of $5\text{Hg}^2\text{Pt}^2\text{Cy}^4.2\text{HgNO}^3 + 10\text{aq.}$ This compound is not soluble in cold water acidulated with nitric acid, and cannot be freed from mercurous nitrate by washing. When boiled with water, the blue colour changes through green and yellow to white, being ultimately converted into mercuric platinocyanide, the liquid containing mercurous nitrate. It is likewise reduced to mercuric platinocyanide by heating it in the state of powder to 200° — 250°C. (Döbereiner; Schafarik.) This blue compound is also formed on adding mercuric platinocyanide to mercurous nitrate. (Döbereiner.)

Platinocyanide of Nickelammonium $(\text{NH}^3\text{Ni})\text{PtCy}^2$, produced by adding the potassium-salt to an ammoniacal solution of nitrate of nickel, forms violet needles which yield a pale violet crystalline powder.

Platinocyanide of Platinicum $\text{Pt}^3\text{Cy}^4 = \text{ptPtCy}^2$. [$\text{pt} = \frac{1}{2}\text{Pt} = 49.5$].—This, according to Gerhardt (*Traité* i. 366), is the rational constitution of the yellow compound, commonly called protocyanide of platinum (p. 260). But, as already observed, it is most probable that this compound is essentially the protocyanide more or less impure.

Platinocyanide of Diplatossammonium, $\text{N}^2\text{H}^6\text{Pt}^2\text{Cy}^2 = \left. \begin{matrix} \text{NH}^2\text{Pt}(\text{NH}^4) \\ \text{Pt} \end{matrix} \right\} \text{Cy}^2$.—

Precipitated on adding platinocyanide of potassium to a solution of chloride of diplatossammonium (ammonio-protochloride of platinum: see PLATINUM);—also on adding cyanide of potassium to chloride of diplatossammonium; also when cyanogen gas is passed into a solution of hydrate of diplatossammonium, the reaction depending on the decomposition of water, the elements of which unite with the cyanogen, forming hydrocyanic and cyanic acids, and the hydrocyanic acid forming platinocyanide of diplatossammonium, ammonia, and water:

It is a white crystalline precipitate, nearly insoluble in cold water, but may be crystallised from boiling water, and is then deposited in microscopic hexagonal tables often grouped in stars. Heated in the air, it takes fire and burns like amadou. It dissolves, without decomposition, in potash and in ammonia, also in dilute acids, but is decomposed by strong nitric and sulphuric acids. With nitrate of silver it forms a precipitate of platinocyanide of silver, while nitrate of diplatossammonium remains in solution. (Buckton.)

Cyanide of Platosammonium, NH^3PtCy , a compound isomeric with the preceding, is obtained by digesting chloride of platosammonium with cyanide of silver. The decanted liquid is yellow, and yields, by concentration, slender needles of a pale yellow colour, much more soluble in water and ammonia than the platinocyanide of diplatossammonium. (Buckton.)

Platinocyanide of Potassium, $\text{KPtCy}^2 = \text{KCy.PtCy}$.—This salt, discovered by Leopold Gmelin, is produced by fusing cyanide or ferrocyanide of potassium with platinum: hence platinum crucibles are strongly attacked by alkaline cyanides in a state of fusion.

Preparation. 1. A mixture of equal parts of spongy platinum and ferrocyanide of potassium is heated nearly to redness in a glass or crucible (if the heat applied be insufficient, the ferrocyanide of potassium remains undecomposed, and if it be too great, the platinum-salt is decomposed); the mass is dissolved in water; the filtrate evaporated at a gentle heat; the warm liquid separated by decantation from any crystals of undecomposed ferrocyanide of potassium that may have been formed, then left to cool till the platinum-salt is crystallises; and this salt is purified by pressure between paper and recrystallisation, both from ferrocyanide and from cyanide of potassium (Gmelin).—2. Dichloride of platinum is converted by heat into protochloride; an aqueous solution of cyanide of potassium is completely saturated with the latter; and the filtrate is evaporated and left to crystallise (Knop):

Since a large quantity of platinum-salt remains dissolved in the mother-liquor, which contains the chloride of potassium, it must be evaporated and mixed with sulphuric acid: hydrochloric acid is then evolved, and a yellow gummy precipitate formed, consisting of protocyanide of platinum, which separates almost completely on boiling the liquid with excess of sulphuric acid. The liquid is then diluted with water; the precipitate is thrown on a filter, washed with water, and dissolved while hot in aqueous cyanide of potassium; and the liquid is boiled till the evolution of ammonia (from the cyanate of potassium) ceases, and then brought to the crystallising point. (Knop and Schnedermann).—3. A concentrated solution of dichloride of platinum is added to the aqueous solution of cyanide of potassium, and the mixture is heated till the precipitate consisting of chloroplatinate and the chloroplatinate of potassium is redissolved, then left to crystallise.—4. Chloroplatinate of ammonium stirred up with water containing lumps of caustic potash, is dissolved at 100°C . in a strong aqueous solution of cyanide of potassium; the solution is boiled till it no longer gives off ammonia; and the filtrate is left to crystallise. In this manner the salt is obtained quite pure in needles 2 or $2\frac{1}{2}$ inches long, and a line in thickness. The addition of caustic potash prevents the formation of cyanide of ammonium, and of the double platino-cyanide of ammonium and potassium. (Martius.)

Properties.—Platino-cyanide of potassium forms long rhombic prisms, yellow by transmitted and blue by reflected light. The dominant faces are P and ∞P . Inclination of ∞P : $\infty\text{P} = 97^\circ$; P: $\infty\text{P} = 122^\circ$. The crystals contain water, their formula being $\text{KPtCy}_2 + \frac{3}{2}\text{aq.}$ or rather $\text{K}^2\text{Pt}^2\text{Cy}^4 + 3\text{aq.}$ They effloresce rapidly in the air, becoming opaque and rose-coloured; at 100°C . they give off 12.4 p. c. of water, assuming first a white and then an orange-yellow colour. At a higher temperature, the residue gives off 0.22 p. c. more water (12.62 p. c. in all), again becoming white, and ultimately fusing into a grey and yellow mass, which is very apt to run over the sides of the vessel (Gmelin). The dry salt heated out of contact with the air does not decompose at any temperature between 400° and 600°C . (Knop and Schnedermann). Nitric acid decomposes the salt, forming nitre and a transparent and colourless jelly. Mixed with an equal weight of strong sulphuric acid and with water, and evaporated, it forms a yellow tenacious mass. Dilute sulphuric acid colours it orange-yellow (Gmelin).—It dissolves in strong sulphuric acid without evolution of hydrocyanic acid; the solution heated to the boiling point yields proto-cyanide of platinum in thick yellow flakes, no hydrocyanic acid escaping, but a gas which burns with a blue flame, probably carbonic oxide. If the quantity of water added to the sulphuric acid solution is just sufficient to produce intense heat, the cyanide of platinum still separates out; but if too much water be added, it does not. (Knop and Schnedermann.) Boiled for some time in aqueous solution with *chlorate* or *chromate* of potassium, it is converted into platinidecyanide of potassium. The same effect is produced by *peroxide of lead*, with formation of carbonate of potassium and carbonate of lead. *Chlorine*, *bromine*, and *iodine* first convert it into platinidecyanide, and afterwards into a compound of that salt with chloride, bromide, or iodide of potassium (Martius.) According to Hadow, the compounds thus formed consist of 5 at. platino-cyanide with 1 at. Cl. Br., &c. (p. 266).

Platino-cyanide of potassium dissolves abundantly in warm water, but a considerable portion separates out on cooling.

Quadrat (Ann. Ch. Pharm. lxiii. 167) by adding protochloride of platinum to an aqueous solution of cyanide of potassium, and evaporating the filtrate to the crystallising point, obtained well-defined yellow crystals which he found by analysis to agree with the formula $\text{K}^6\text{Pt}^5\text{Cy}^{11} + \frac{21}{2}\text{aq.}$ or $\text{KCy}.5\text{KPtCy}_2 + \frac{21}{2}\text{aq.}$ and from this salt he obtained, by double decomposition, a number of others said to be of similar constitution, and therefore represented by the general formula $\text{M}^6\text{Pt}^5\text{Cy}^{11}$, or $\text{MCy}.5\text{MPtCy}_2$. These salts Quadrat designates as platino-platinidecyanides. The potassium-salt

prepared by Quadrat's method has, however, been analysed by Gerhardt, Laurent, and Schafarik, who all agree in assigning to it, not the formula given by Quadrat, but the formula of platino-cyanide of potassium, KPtCy^2 . Hence it would appear that Quadrat's platino-platinidecyanides were merely platino-cyanides not quite pure.

Platino-cyanide of potassium, mixed in solution with other soluble platino-cyanides, yields crystalline double salts of analogous composition, and of much brighter and deeper colour than the component salt. *Platino-cyanide of potassium and sodium* ($\text{KNaPt}^2\text{Cy}^4 + 6 \text{ aq.}$, prepared as above or by decomposing platino-cyanide of copper with a solution of the carbonates of potassium and sodium, forms monoclinic crystals ($\infty \text{P} \cdot [\infty \text{P} \infty] \cdot [\text{P} \infty]$) of a bright orange colour by transmitted, and steel-blue by reflected light, with siskin-green fluorescence. The salt ($\text{K SrPt}^2\text{Cy}^4$) forms monoclinic crystals, with yellow body-colour and blue iridescence on the surface. The salts ($\text{KCaPt}^2\text{Cy}^4$) and ($\text{K BaPt}^2\text{Cy}^4$) exhibit a fine deep gold colour. (Martius.)

Platino-cyanide of Silver is a white precipitate, resembling cyanide of silver.—*Platino-cyanide of argent-ammonium* ($\text{NH}^4\text{AgPt}^2\text{Cy}^2$) is obtained by dissolving carbonate of silver in ammonia, and adding a solution of platino-cyanide, or platinosquesquicyanide of potassium. It forms colourless or slightly flesh-coloured needles, insoluble in pure water, but soluble at the boiling heat in strongly ammoniacal water. An ammoniacal solution of nitrate of silver mixed with ammonia yields, after a few hours, needles which appear to be hydrated. (Knop and Schnedermann.)

Platino-cyanide of Sodium, $\text{NaPtCy}^2 + x \text{ aq.}$, obtained by boiling the copper-salt with carbonate of sodium, forms large crystals belonging to the monoclinic system.

Platino-cyanide of Strontium, $\text{Sr}^2\text{Pt}^2\text{Cy}^4 + 5 \text{ aq.}$, prepared by saturating hydro-platino-cyanic acid with carbonate of strontium, or by decomposing the copper-salt with strontia-water, forms sometimes milk-white, sometimes transparent crystals, which, when exposed to the air, acquire a violet tint throughout. When left over sulphuric acid for twenty-four hours, they acquire a splendid purple colour, like that of a solution of permanganate of potassium, and a gold-green metallic surface-lustre, but on exposure to the air for a few days, they completely regain their previous appearance. At 100°C. , the salt becomes turbid throughout, and acquires a deep orange colour, deeper than that of the dry barium-salt, the gold-green surface-lustre being at the same time changed to azure. At 150°C. the salt becomes white and anhydrous, but is so sensitive to moisture, that when breathed upon, it immediately acquires a blackish-purple colour. (Schafarik.)

Platino-cyanide of Zinc-ammonium, ($\text{NH}^4\text{ZnPt}^2\text{Cy}^2$), is obtained in large colourless crystals by adding platino-cyanide of potassium to an ammoniacal solution of chloride of zinc.

Platinidecyanides. *Platinosquesquicyanides.* $\text{M}^2\text{Pt}^2\text{Cy}^5 = 2\text{MCy} \cdot \text{Pt}^2\text{Cy}^3$.—These salts are produced by the action of nitric acid, chlorine, bromine, and other oxidising agents on the platino-cyanides:

They have a peculiar coppery lustre, and are all soluble in water and alcohol, forming colourless solutions, excepting the lithium-salt, the solution of which is yellowish (Weselsky). They give off cyanogen when heated, leaving a residue of platino-cyanide. Like the ferri-cyanides, they separate iodine from iodide of potassium, and exert a bleaching action in presence of alkalis. (Hadow.)

According to Hadow (Chem. Soc. Qu. J. xiii. 106), the composition of the platinidecyanides is not correctly represented by the formula above given. For, as the proportion between the platinum and the basic metal is the same in this formula as in that of the platino-cyanides, it is not easy to see how the platinidecyanides are produced from the platino-cyanides by oxidation. Weselsky's equation supposes that platinum is removed at the same time as the basic metal; but this is regarded by Hadow as inconsistent with the known stability of the platino-cyanides. Moreover, when platinidecyanides are reduced to platino-cyanides by the action of potash, no cyanide of potassium appears to be formed. Hadow concludes, from his own analyses of the platinidecyanides, that they are merely platino-cyanides combined with a certain quantity of chlorine, bromine, nitryl, &c., according to the oxidising agent used in their formation, and accordingly divides them into *chloroplatino-cyanides*, *bromoplatino-cyanides*, &c. The compound $\text{PtCy}^2 \cdot \text{KCl}$ (p. 267) he regards as a *perchloroplatino-cyanide of potassium*, $\text{KPtCy}^2 \cdot \text{Cl}$, in which the platino-cyanide is combined with the maximum quantity of chlorine that it is capable of taking up. Moreover as 6 at. of platino-cyanide of potassium (KPtCy^2)⁶, require 6 at. chlorine to convert them into the perchloro-cyanide, whereas, according to Hadow, the chloroplatino-cyanide requires only 5 at. chlorine to produce the same compound, he concludes that the formula of the chloroplatino-cyanide is $(\text{KPtCy}^2)^6 \cdot \text{Cl}$. On this view

the oxidising action of the salt in presence of potash, without formation of cyanide of potassium is explained by the equation:

The chloroplatinocyanides may also be regarded as compounds of platino-cyanides and perchloroplatinocyanides:

And, in fact, on mixing the concentrated solutions of the platino-cyanide and perchloroplatinocyanide, the copper-coloured needles of the chloroplatinocyanide immediately separate out. On the other hand, on mixing the solution of chloroplatinocyanide of potassium with a zinc-salt, platino-cyanide of zinc is precipitated, and perchloroplatinocyanide of potassium remains in solution.

The corresponding bromine-, nitro-, &c., compounds are similarly constituted with Br, NO₂, &c. in place of Cl. No iodine-compounds of the class appear to exist, but an *oxysulphoplatinocyanide of potassium*, $(\text{KPtCy}^2)^6.\text{SO}^4$, is obtained as a copper-red mass, with moss-like ramifications, on adding peroxide of lead to a solution of platino-cyanide of potassium acidulated with sulphuric acid.

The perchloroplatinocyanides give with *mercurous nitrate* a white, and with *cupric salts* a finely pulverulent blue precipitate, whereas the platino-cyanides give with *mercurous nitrate* a smalt-blue, and with *cupric salts* a flocculent blue precipitate. The perchloroplatinocyanides separate iodine from metallic iodides, and when immersed in a solution of platino-cyanide of potassium immediately become covered with copper-red needles. The chloro- (or bromo-, nitro-, &c.) platino-cyanides exhibit the reactions of the two salts of which they may be made up.

As Hadow's results differ from those of all other chemists who have examined the so-called platinidcyanides, the composition of these salts must for the present be considered doubtful.

Platinidcyanide of Ammonium, $(\text{NH}^1)\text{Pt}^2\text{Cy}^5$, crystallises in needles containing $\frac{5}{2}$ at. water (Knop and Schnedermann). They have a golden yellow metallic lustre, become steel-grey at 150° C. with partial decomposition, and lemon-yellow between 180° and 190°. (Weselsky.)

Platinidcyanide of Lead, $2\text{Pb}^2\text{Pt}^2\text{Cy}^5 + 5\text{aq.}$ —This salt crystallises on cooling from a solution of platino-cyanide of lead in warm dilute nitric acid. It may be obtained pure by gradually adding nitric acid of specific gravity 1.2 to a mixture of the concentrated solutions of platino-cyanide of potassium and acetate of lead, and leaving the mixture to cool. It then often separates in needle-shaped crystals 2 inches long, having a light red-lead colour in the body, and deep azure-blue on the surface. At 40° C. they give off 1 at. water, and assume a vermilion colour; between 50° and 60° they become cherry-red, at a stronger heat flesh-red; and at 200°, perfectly white and anhydrous. (C. F. Martius.)

Platinidcyanide of Lithium, $\text{Li}^2\text{Pt}^2\text{Cy}^5 + 3\text{aq.}$, is very soluble in water and alcohol. (Weselsky.)

Platinidcyanide of Magnesium forms a blackish violet satiny mass of microscopic needles. (Weselsky.)

Platinidcyanide of Potassium, $\text{K}^2\text{Pt}^2\text{Cy}^5 + 3\text{aq.}$ —Obtained by passing chlorine into a warm solution of platino-cyanide of potassium, sufficiently concentrated to deposit crystals on cooling, till small copper-red needles begin to form in it and ultimately convert the liquid into a thick pulp. The passage of the gas is then discontinued, the mass is thrown on a filter and slightly pressed, to facilitate the removal of the mother-liquor, and then subjected to strong pressure between folds of filtering paper. It is purified by recrystallising it several times from the smallest possible quantity of boiling water, slightly acidulated with hydrochloric acid to saturate any cyanate or carbonate of potassium that may be mixed with the salt, and would reduce it to platino-cyanide when heated. (Knop.)

Platinidcyanide of potassium crystallises in beautiful prisms, green by transmitted, and having a coppery metallic lustre by reflected light. Viewed in the mass, it resembles a tissue composed of fine needles of copper. It dissolves easily in water, but is insoluble in alcohol. The solution forms a white precipitate with mercuric salts, deep blue with mercurous salts, greenish blue with cupric salts. (Knop.)

The salt is easily decomposed by heat, giving off cyanogen, then acquiring a brownish-yellow colour, and ultimately melting to a brown mass (Knop). According to Weselsky, it turns dark green at 180° C., and yellow at 200°, without losing its metallic lustre. When left over sulphuric acid in vacuo, it gives off part of its water, turns black, and is afterwards only partially soluble in water. By digestion with potash it is reduced to platino-cyanide. Strong sulphuric acid decomposes it, with separation of a yellowish powder, which gives off cyanogen at a red heat, and leaves a

residue containing platinum and potassium. When digested with cold concentrated hydrochloric acid, it first turns orange-yellow and then white, but resumes its copper colour when heated. (Knop.)

Hadow, as already observed, regards this salt as platinocyanide of potassium united with $\frac{1}{6}$ at. Cl, Br, NO₂, &c., according to the oxidising agent used in its formation, that is to say, as (KPtCy²)⁶Cl, (KPtCy²)⁶Br, &c., or as a compound of chloroplatinocyanide, &c., with perchloroplatinocyanide, &c. (p. 267). He gives as the easiest method of preparing the chlorine or bromine compound, to treat $\frac{1}{6}$ of a concentrated solution of platinocyanide of potassium with excess of chlorine or bromine, and after gently warming it, add to it the remaining $\frac{5}{6}$ of the platinocyanide: the pure salt then separates out after a short time. The crystals of *chloroplatinocyanide of potassium* contain K⁶Pt⁶Cy¹²Cl + $\frac{21}{2}$ H₂O, of which 9 at. go off at 100° C., the rest at 186° (Hadow.)

Compound of Platinic Cyanide with Chloride of Potassium, PtCy².KCl + aq.; according to Hadow, *Perchlorocyanide of Potassium*, KPtCy².Cl + aq.—Obtained by dissolving platinidcyanide of potassium in nitromuriatic acid heated nearly to boiling (Knop and Schnedermann), or by adding permanganate of potassium to a solution of the same salt acidulated with hydrochloric acid (Hadow), and evaporating at the heat of the water-bath. The liquid on cooling deposits the salt in large rhomboidal plates belonging to the triclinic system, very soluble in water and in alcohol, while the mother-liquor retains chloride of potassium.

The salt is very efflorescent. When heated it gives off cyanogen, and if calcined at a gentle heat, leaves a residue of platinocyanide and chloride of potassium; but if more strongly heated, leaves metallic platinum and chloride of potassium. When sulphurous acid gas is passed into the solution and the liquid is then left to evaporate, it deposits crystals of platinidcyanide of potassium mixed with platinocyanide. A similar reduction is effected by zinc and by ammonia. (Knop and Schnedermann.)

CYANIDE OF PHOSPHORUS. See page 255.

CYANIDE OF POTASSIUM. CNK = KCy. This salt is produced by the direct combination of cyanogen and potassium. The metal absorbs cyanogen slowly at ordinary temperature, but when heated, it quickly takes up a volume of the gas equal to the volume of hydrogen which the same quantity of potassium would eliminate from water. Potassium heated in the vapour of hydrocyanic acid is also converted into cyanide, with separation of a quantity of hydrogen equal to that which it would eliminate from water.

The formation of cyanide of potassium by fusing azotised organic matters with carbonate of potassium, by igniting nitrates or nitrites with organic substances, and by passing nitrogen gas or atmospheric air over an ignited mixture of charcoal and carbonate of potassium, has been already mentioned (pp. 198, 238).

Preparation.—Cyanide of potassium is prepared by igniting the ferrocyanide (yellow prussiate) either alone or mixed with carbonate of potassium. The former method, when properly conducted, yields a pure product, the ferrocyanide being resolved by heat into cyanide of potassium, carbide of iron, and nitrogen:

One-third of the cyanogen is, however, resolved into carbon and nitrogen, so that only two-thirds is obtained in the form of cyanide of potassium. The latter method yields a larger product, five-sixths of the cyanogen remaining as cyanide of potassium, but the salt thus obtained is mixed with cyanate and carbonate of potassium:

The presence of these impurities does not, however, interfere with many of the purposes to which cyanide of potassium is applied: hence the process is frequently used.

1. *By simple ignition of the ferrocyanide.* Crystallised yellow prussiate is dehydrated by heating it on an iron plate till it forms a dirty white mass on cooling. It is then pulverised, pressed into an iron crucible, and the crucible with its cover on is subjected to a moderate red heat, till a sample of the fused mass taken out on a glass rod, appears white and exhibits the aspect of porcelain on cooling. The crucible is then taken out of the fire, left at rest till the carbide of iron has settled down to the bottom, and the fused cyanide of potassium is poured out on a marble slab or a plate of polished metal. Care must be taken not to apply too strong a heat, which would partly decompose the cyanide into nitrogen and carbide of potassium, and not to leave the fused mass too long in contact with the carbide of iron, as a certain quantity of ferrocyanide may then be reproduced. (Robiquet, J. Pharm. [3] xvii. 643; Geiger, Ann. Ch. Pharm. i. 44.)

2. *By igniting the ferrocyanide with carbonate of potassium.* An intimate mixture

of 8 pts. anhydrous ferrocyanide and 3 pts. carbonate of potassium (the proportion indicated by the equation above given), is introduced by small portions into a cast-iron crucible previously heated to low redness. After all the material has been added, the crucible is kept in the fire till the melted mass exhibits on cooling the aspect of porcelain, as above mentioned; it is then taken out, left at rest till the metallic iron produced by the decomposition has settled down, and the fused salt is poured out; or it is left to cool, and dissolved out by water or alcohol (F. and E. Rodgers, Phil. Mag. [3] iv. 93.—Liebig, Ann. Ch. Pharm. xli. 285).—The carbonate of potassium used in this preparation must be free from sulphate, which would be reduced by the cyanide to sulphide. An iron crucible is preferable to an earthen one, because the latter is penetrated by the fused salt, and imparts silica to it. (Haidlen and Fresenius, Ann. Ch. Pharm. xliii. 130.)

3. Cyanide of potassium may also be prepared by igniting in a covered crucible a mixture of 10 pts. prussian blue and 13 pts. carbonate of potassium, and exhausting the cooled mass with water or alcohol. Also by throwing cyanide of mercury on carbonate of potassium heated nearly to redness. (F. and E. Rodgers.)

4. The attempts to prepare cyanide of potassium on the manufacturing scale by means of atmospheric nitrogen, have already been described. The salt is often produced in considerable quantity in the blast-furnaces in which iron ores are smelted with coal or coke; hence Bunsen has suggested the construction of a blast-furnace expressly for the production of cyanide of potassium, the furnace being filled with coke or charcoal and potash in alternate layers, the whole intensely heated under the influence of a strong blast, and the cyanide running down into a receiver at the bottom. (*Reports of the British Association*, 1845, p. 185.)

Properties.—Cyanide of potassium crystallises in transparent colourless cubes or forms derived therefrom. It is inodorous when dry, but when exposed to the air in the moist state, it is decomposed by the carbonic acid of the air, and exhales the odour of prussic acid. Its taste is acrid and caustic, somewhat like that of bitter almonds. It is very fusible, melting at a dull red heat to a transparent liquid, which, on cooling, solidifies to a dull opaque mass having the aspect of porcelain. At a white heat it appears to volatilise without decomposition. It has an alkaline reaction, and is intensely poisonous.

Cyanide of potassium is easily soluble in *water* and very deliquescent, so that it must always be kept in tightly closed vessels. It likewise dissolves readily in *hydrated alcohol*, but is insoluble in *absolute alcohol*.

Decompositions.—1. The aqueous solution of cyanide of potassium may be kept unaltered in closed vessels at ordinary temperatures, but when boiled, it is resolved into ammonia and formate of potassium:

The cyanide heated with *hydrate of potassium* likewise yields ammonia and formate of potassium, at first; but the latter compound is resolved, before the heat rises to redness, into hydrogen and carbonate of potassium (Pelouze).—Hence, as Gay-Lussac long ago observed (Ann. Ch. Phys. viii. 440), ammonia is likewise evolved when hot cyanide of potassium is dissolved in water, or cold cyanide of potassium in hot water.

2. When the solution is boiled down in contact with the *air*, hydrocyanic acid is evolved, and there remains more carbonate than formate of potassium. When moist or dissolved cyanide of potassium is exposed to the air at ordinary temperatures, it gradually absorbs carbonic acid, gives off hydrocyanic acid, and is converted into carbonate.

3. Cyanide of potassium detonates violently when heated with *nitrate* or *chlorate* of potassium.

4. Cyanide of potassium under various circumstances takes up 1 at. *oxygen*, and is thereby converted into cyanate. This effect takes place, though very slowly, when the cyanide is fused in contact with the air; more quickly when it is fused with peroxide of manganese, arsenic, antimony, lead, or with the oxides of tin, iron, or copper—in the last case with ignition. The peroxide of manganese is thereby reduced to protoxide, and the other oxides to the metallic state. (Liebig, Ann. Ch. Pharm. xli. 289.)

5. Cyanide of potassium fused with *sulphate of potassium*, yields cyanate and sulphide of potassium (Liebig).—Cyanide of potassium may likewise exert a reducing action in the moist way; thus, from aqueous *alloxan*, after a few hours, it throws down dialurate of potassium. (Liebig.)

6. Cyanide of potassium, fused with *sulphur*, is converted into sulphocyanate (Porrett), and similarly when heated with sulphide of antimony or sulphide of tin, the fused metal separating out (Liebig).—Sulphur does not dissolve in aqueous cyanide of potassium, but *selenium* dissolves readily, even at ordinary temperatures. (Wiggers, Ann. Ch. Pharm. xxix. 319.)

7. Cyanide of potassium boiled with *iodine* takes up a large quantity of that substance, forming first a brown and afterwards a colourless liquid, which solidifies on cooling, and forms a crystalline magma of iodide of cyanogen (Liebig, Ann. Ch. Pharm. l. 355). Probably in this manner: $KCy + I^2 = KI + CyI$. According to Langlois (Ann. Ch. Phys. [3] lx. 220), the crystals consist of a compound of cyanide of potassium with iodide of cyanogen. (See CYANOGEN, IODIDE OF.)

8. Cyanide of potassium takes up *iodide of nitrogen* without any evolution of gas; the colourless solution evaporated in vacuo, yields a crystallo-granular, very deliquescent mass, the solution of which smells of iodoform, and produces a yellow precipitate with corrosive sublimate. (Millon, Ann. Ch. Phys. [2] lxi. 78.)

Cyanide of potassium forms numerous compounds with other metallic cyanides, the description of which is given with those cyanides.

Uses.—Cyanide of potassium is of great use to the experimental chemist, both for its reducing and its solvent powers. As a reducing agent, it is nearly equal in power to potassium itself, and is especially useful in blowpipe reactions. As a solvent, it is much used in analysis for separating metals one from the other, *e.g.* cobalt from nickel (i. 1047), copper from bismuth, cadmium, &c. (p. 62);—also in various processes of volumetric analysis, the estimation of copper, for example (p. 48). It is used in medicine for the same purpose as prussic acid; and by photographers for fixing proofs on moist collodion, and for removing stains of nitrate of silver from the hands, which it does by forming a soluble double cyanide of silver and potassium. This last mode of employing it is, however, very dangerous, as if it comes in contact with a cut or scratched surface, it is apt to produce painful and troublesome sores, and may even give rise to dangerous symptoms of poisoning. The removal of silver stains may be quite as well effected by means of a solution of iodine in iodide of potassium. (See a paper by M. Davanne, *Répertoire de Chimie appliquée*, May 1861, p. 182.)

Cyanide of potassium is extensively used in galvanic gilding and silvering, indeed, the chief consumption of it is for this purpose.

Testing and Valuation.—Commercial cyanide of potassium may contain the following impurities: *Carbonate of Potassium*. This salt remains behind when the cyanide is dissolved in hot alcohol of 36° Bm.—*Chloride*. The salt ignited with 2 pts. of nitre and 10 pts. carbonate of potassium (both free from chloride), then dissolved in water and super-saturated with nitric acid, precipitates nitrate of silver.—*Cyanate*. Contained in the cyanide prepared by Rodgers' process, and separates from the hot solution in laminae. If the portion of the cyanide which is soluble in alcohol of 36° Bm. gives off carbonic acid on addition of acids, and forms a precipitate of carbonate with barium-salts, the presence of cyanate may be inferred (p. 192).—*Ferrocyanide*. Precipitate of prussian blue with a ferric salt (which must be quite free from ferrous salt), after saturation with hydrochloric acid. With sulphate of copper, a precipitate which, on addition of hydrochloric acid, does not turn white, but red.—*Formate*. The salt blackens on ignition. Also on expelling the hydrocyanic acid from the solution by a stream of carbonic acid, evaporating to dryness, exhausting with alcohol, again evaporating and distilling the residue with dilute sulphuric acid, formic acid passes over, and may be recognised by its power of reducing silver and mercury-salts.—*Silicate*. Residue of silica, after supersaturation with hydrochloric acid, evaporation to dryness, and digestion in water.—*Sulphate*. Precipitate with barium-salts after supersaturation with hydrochloric acid.—*Sulphide*. Dirty precipitate with lead-salts.

The proportion of pure cyanide of potassium in a given sample may be estimated by means of a standard solution of nitrate of silver. Since 1 at. cyanide of potassium is required to precipitate 1 at. silver, and 1 at. more cyanide of potassium to redissolve the precipitate as cyanide of silver and potassium, $KAgCy^2$, it follows that 1 at. silver precipitated and redissolved corresponds to 2 at. cyanide; or 108 pts. to $2 \times 65 = 130$ pts. cyanide of potassium. (Glassford and Napier, Phil. Mag. [3] xxv. 58.)

A better method is that proposed by Fordos and Gélis (J. Pharm. [3] xxiii. 48), depending on the reaction of iodine on cyanide of potassium. 5 grammes of the salt under examination are dissolved in water, and the solution is made up with water to half a litre. Of this solution 20 c. c. are introduced into a flask of about 2 litres capacity, together with a litre or $1\frac{1}{2}$ litre of water. On the other hand, an alcoholic solution of iodine is prepared containing 40 grammes in a litre, and this standard liquid is poured from a burette (divided into cubic centimetres) into the solution of the cyanide, till the liquid becomes permanently yellow. The quantity of iodine required to produce this effect is then read off. 254 pts. iodine correspond to 65 pts. cyanide of potassium.

CYANIDE OF PROPYL or TRITYL. $C^4H^7N = C^3H^7.CN$.—Identical with BUTYRONITRILE (i. 698).

CYANIDES OF RHODIUM. The *sesquicyanide*, Rh^2Cy^3 , is precipitated as a fine carmine-coloured powder, on adding strong acetic acid to a solution of potassiorhodic cyanide. It dissolves in cyanide of potassium, and is decomposed by ignition, leaving metallic rhodium difficult to attack with acids. (Martius.)

Potassiorhodic Cyanide, $\text{K}^3\text{Rh}^2\text{Cy}^3 = 3\text{KCy}.\text{Rh}^2\text{Cy}^3$, may be prepared like the corresponding iridium-salt (Claus, p. 323), or by igniting rhodium with ferrocyanide of potassium (Martius). It resembles the iridium-salt, but is distinguished therefrom by its reaction with acetic acid as just mentioned, the iridium-salt when treated in the same manner remaining unaltered. (Claus, Martius.)

CYANIDES OF RUTHENIUM. *Rutheniocyanide of Potassium*, $\text{K}^4\text{Ru}^2\text{Cy}^6 + 3\text{aq.}$, is obtained, like the iridium-salt, by fusing 1 pt. of chlororutheniate of ammonium with $1\frac{1}{2}$ pts. pulverised cyanide of potassium, dissolving the fused mass in boiling water, and leaving the filtrate to cool. It crystallises in small transparent, colourless square tables, having their edges truncated by octahedral faces. It is isomorphous with ferrocyanide of potassium, and crystallises with that salt in all proportions; consequently it cannot be obtained pure by fusing ruthenium or any of its salts with ferrocyanide of potassium. When heated with hydrochloric acid, it gives off prussic acid, and after some time yields a deep violet-blue precipitate, consisting of cyanide of ruthenium mixed with a small quantity of cyanide of potassium. The solution of the salt treated with chlorine gas assumes a brown-yellow colour, quickly changing to dark green; probably a ruthenicyanide of potassium, analogous to the ferricyanide, is formed, but no crystalline compound is obtained.

The reactions of rutheniocyanide of potassium with metallic salts are similar to those of the ferro- and osmiocyanides (pp. 247, 259), viz. a light violet precipitate with *ferrous*, dark violet-blue with *ferric* salts; dirty red-brown with cupric salts; white with *mercurous* nitrate, acetate of *lead*, and sulphate of *zinc*; with *dichloride of platinum* it forms a dark brown solution. (Claus, Jahresb. d. Chem. 1855, p. 446.)

Rutheniocyanide of Hydrogen, $\text{H}^4\text{Ru}^2\text{Cy}^6$, is precipitated by hydrochloric acid and ether from the solution of the potassium-salt, in white nacreous laminae, which have a strongly acid, somewhat astringent taste, dissolve readily in water and in alcohol, and merely acquire a faint bluish colour when exposed to the air. (Claus.)

Ruthenium and osmium are the only metals of the platinum group whose potassiocyanides are converted into hydrogen-salts in the manner just mentioned. (Claus.)

CYANIDE OF SILVER. AgCy .—Obtained by precipitating nitrate of silver with a soluble cyanide. According to Glassford and Napier, the purest product is obtained by using as the precipitant a solution of cyanide of silver and potassium.

Cyanide of silver is a white powder, insoluble in water, very slightly soluble in boiling dilute nitric acid, easily in ammonia. It is easily decomposed by hydrochloric and sulphydric acids. Heated in the dry state, it gives off half its cyanogen, with violent effervescence and a glow extending through the whole mass, and leaves a mixture of metallic silver and paracyanide of silver. (See PARACYANOGEN; also Gm. viii. 27.)

Cyanide of silver dissolves in the aqueous solutions of the cyanides of potassium, sodium, barium, strontium, and calcium, forming double cyanides, MAgCy^2 , whose solutions are not precipitated, either by metallic chlorides or by caustic alkalis, but are decomposed by acids, with separation of cyanide of silver. It dissolves also at the boiling heat, in the chlorides of potassium, sodium, barium, calcium, and magnesium, and in ferro- or ferricyanide of potassium, the solution containing crystallisable cyanide of silver and potassium.

Ammoniocyaniide of Silver, or *Cyanide of Argentammonium*, NH^3AgCy , is formed on pouring a dilute solution of nitrate of silver into a hot mixture of ammonia and prussic acid, and separates on cooling in large colourless plates, which give off all their ammonia when exposed to the air. (Liebig and Redtenbacher, Ann. Ch. Pharm. xxxviii. 129.)

Nitrocyaniide of Silver, $\text{AgNO}^6.2\text{AgCy}$, is a crystalline salt obtained by dissolving recently precipitated cyanide of silver in a moderately concentrated and boiling solution of nitrate of silver.

Cyanide of Silver and Potassium, $\text{AgKCy}^2 = \text{KCy}.\text{AgCy}$, crystallises in colourless octahedrons, hexagonal plates, and rhomboidal prisms, the latter when dried at 100°C . containing $\frac{1}{2}$ at. water ($\text{Ag}^2\text{K}^2\text{Cy}^4 + \text{aq.}$) (Glassford and Napier). It is permanent in the air, soluble in 8 pts. cold and 1 pt. boiling water; dissolves also in boiling alcohol, and crystallises therefrom on cooling (Glassford and Napier). According to S. Baup (Ann. Ch. Phys. [3] liii. 462), the pure salt crystallises on cooling in plumose lamellae, and by slow evaporation in six-sided prisms (the rhomboidal prisms observed by Glassford and Napier consist of a cyanide of silver, potassium, and sodium to be presently noticed). It requires for solution 4 pts.

water at 20° C., and 25 pts. alcohol of 25 per cent. at the same temperature. It does not become coloured by exposure to sunlight, neither does it stain paper and the skin like other silver-salts. The cyanide of silver precipitated from the solution by nitric acid is likewise unalterable by light.

Cyanide of silver and potassium is used for galvanic gilding. When its solution is subjected to the action of the battery, metallic silver is deposited at the negative pole in a compact adhering layer, while at the positive pole, where a strip of silver is placed, a quantity of the metal is continually dissolving equal to that which is deposited at the other pole. The silver-bath may be prepared by dissolving cyanide, chloride, or any other silver-salt in cyanide, ferrocyanide, or ferricyanide of potassium.

Cyanide of Silver and Sodium, NaAgCy^2 , obtained by saturating a solution of cyanide of sodium with cyanide of silver, forms anhydrous laminar crystals, soluble at 20° C. in 5 pts. of water and 24 pts. alcohol of 85 per cent. (Baup.)

Cyanide of Silver, Potassium, and Sodium, $2\text{KAgCy}^2.\text{NaAgCy}^2$, crystallises from the mother-liquor of commercial cyanide of silver and potassium, the sodium being derived from the impure potash used in the preparation of the cyanide of potassium. It crystallises in anhydrous rhomboïdal prisms, being in fact the salt regarded by Glassford and Napier as one of the forms of cyanide of silver and potassium. It dissolves in 4.4 pts. water at 15° C., and in 22 pts. alcohol at 17° C.

The solution of either of the double salts above mentioned forms white precipitates with the salts of *manganese, zinc, cadmium, lead, and mercurium*, greenish with *ferrous* salts, pale red with *cobalt*-salts, bluish-white with *cupric* salts, white with *mercuric* salts, all these precipitates consisting of compounds of cyanide of silver with another metallic cyanide.

CYANIDE OF SODIUM, NaCy , may be obtained by the same methods as cyanide of potassium, but does not form so easily. F. and E. Rodgers calcine 6 to 10 pts. prussian blue with 10 pts. dry carbonate of sodium, and exhaust the ignited mass with boiling alcohol, from which the cyanide of sodium crystallises.

CYANIDE OF STYRYL. *Cyanide of Cinnyl*. $\text{C}^{10}\text{H}^9\text{N} = \text{C}^9\text{H}^8\text{Cy}$.—Obtained by heating iodide of styryl with an alcoholic solution of cyanide of potassium in sealed tubes. On mixing the oily layer of liquid thereby produced with water, and adding chloride of sodium, the cyanide of styryl separates as a yellowish-oil, easily soluble in ether, slightly in alcohol, insoluble in water. When treated with potash, it gives off ammonia and becomes resinised. (Ramdohr, Zeitschr. Ch. Pharm. 1858, p. 113.)

CYANIDE OF TETRYL. *Cyanide of Butyl. Valeronitrile*. $\text{C}^5\text{H}^9\text{N} = \text{C}^4\text{H}^8\text{Cy}$.—This body is produced by dehydrating valerate of ammonium, $\text{C}^5\text{H}^9(\text{NH}^4)\text{O}_2$, or valeramide, $\text{N.H}^2.\text{C}^5\text{H}^9\text{O}$, with anhydrous phosphoric acid (Dumas, Malaguti, and Leblanc, Compt. rend xxv. 658). It was discovered, in 1846, by Schlieper (Ann. Ch. Pharm. lix. 15) among the products of the decomposition of gelatin by chromic acid, and has been found by Guckelberger (*ibid.* lxiv. 72) among the products of the oxidation of casein.

Preparation from Glue.—2 pts. of glue are left to swell up in 50 pts. of water; 15 pts. of sulphuric acid are added; the mixture, after cooling, is poured into a retort containing 8 pts. acid chromate of potassium, and distilled till, towards the end, the liquid, which becomes continually greener, no longer boils quietly but begins to froth strongly. The distillate thus obtained—which is white and turbid, has an acid reaction, and smells strongly of hydrocyanic acid—is rectified over mercuric oxide, which decomposes the formic acid present, with evolution of gas, and retains the hydrocyanic acid in the form of cyanide of mercury; and the liquid which first passes over, mixed with oily drops, is collected apart and several times fractionally rectified *per se*, till the oil which passes over is accompanied by only a small quantity of watery liquid—then at a gentle heat over magnesia, to retain benzoic acid, the receiver being changed as soon as, in place of a transparent colourless oil and a clear watery liquid, a milky liquid, gradually depositing oily drops, begins to pass over. The first oil is dehydrated by means of chloride of calcium, and slowly distilled; the receiver changed at 110° C., because that which passes over at 90° is chiefly valeracetonitrile, while at 110° the mixture of that body with cyanide of tetryl, and from 110° to 140° principally the latter distils over; and this last distillate is subjected to two more distillations, the portion which distils over between 122° and 130° being collected apart in the former, and that which passes over between 124° and 127° in the latter: this latter portion is pure cyanide of tetryl. (Schlieper.)

From Casein.—1 pt. of casein is dissolved in a mixture of 3 pts. sulphuric acid and 6 pts. water contained in a retort; a solution of 2 pts. acid chromate of potassium in 10 pts. water is added (a larger quantity would produce valerianic acid instead of cyanide of tetryl); the reaction which ensues is moderated by the addition of 14 pts. more water (30 pts. in all); the distillate is shaken up and redistilled with mercuric oxide; the

distillate thus obtained is neutralised with chalk, and redistilled; and the neutral distillate is subjected to repeated fractional rectification, whereby there is obtained, first a milky distillate mixed with drops of colourless oil, and ultimately the latter only. When this distillate is further rectified, propylic aldehyde passes over below 120°C ., and between 120° and 140° chiefly cyanide of tetryl, which may be purified by repeated rectification, the first and last portions that pass over being set aside. (Guckelberger.)

Cyanide of tetryl is a transparent, colourless, very thin liquid which refracts light strongly. Specific gravity 0.81 (Schlieper); 0.813 at 15°C . (Guckelberger). It boils at 125° (Schlieper); at 125° to 128° (Guckelberger). Vapour-density = 2.892 (Guckelberger). Smells like bitter almond oil and salicylic acid (Schlieper), and has an aromatic, burning, and bitter taste (Guckelberger). It makes a transient grease-spot upon paper. It dissolves in about four times its volume of water and mixes in all proportions with *alcohol* and *ether*. (Guckelberger.)

Cyanide of tetryl when set on fire, burns with a white luminous flame, and without smoke. In sunshine it is decomposed by *chlorine* or *bromine*, with formation of hydrochloric or hydrobromic acid (Schlieper). With strong *sulphuric acid* (also, according to Guckelberger, when distilled with dilute sulphuric acid), it is resolved into sulphate of ammonia and free valerianic acid (Schlieper):

Nitric acid, hydrochloric acid, and ammonia have no action upon it (Schlieper). With aqueous *fixed alkalis*, it is easily resolved into a valerate of the alkali-metal and free ammonia (Schlieper, Guckelberger). It is decomposed at ordinary temperatures by *potassium*, into cyanide of potassium, hydrogen gas, and a peculiar hydrocarbon. (Dumas, Malaguti, and Leblanc.)

CYANIDE OF THALLIUM. Precipitated, on cautiously adding cyanide of potassium to a solution of a thallium-salt, as a white or light brown powder, easily soluble in excess of the precipitant. (Crookes, Proc. Roy. Soc. xii. 156.)

CYANIDE OF TITANIUM? When the solution of crude platinum ore in aqua-regia is precipitated by cyanide of silver, cyanide of titanium is thrown down, together with the cyanide of palladium and copper. On igniting this precipitate in a retort, cyanide [or impure chloride?] of titanium sublimes in the form of a greyish-white mass, which dissolves readily in water, and is then precipitated white by ammonia, yellowish-red by tincture of galls, and gives a white colour with tin and hydrochloric acid. (Fr. Weiss and Fr. Döbereiner, Ann. Ch. Pharm. xiv. 16.)

Nitrocyanide of Titanium, $\text{TiCy}^2.3\text{Ti}^3\text{N}^2$.—This compound, which was formerly regarded as metallic titanium, occurs as a furnace-product, in the form of beautiful, opaque, copper-coloured crystals in the blast-furnaces in which iron is smelted. Its production appears to be connected with the formation of cyanide of potassium so constantly observed in the iron furnaces; a similar product is in fact obtained by placing a mixture of ferrocyanide of potassium and titanous acid in a well-closed crucible, and exposing it for an hour to a heat sufficient to melt nickel. The result is a brown unfused mass, which, under a magnifying power of 300 diameters, exhibits, besides particles of metallic iron, a network of short copper-coloured prisms having a strong metallic lustre. These crystals, when freed from iron by hydrochloric acid, exhibit all the properties of the crystals found in the blast-furnaces.

When this compound is heated to redness in a porcelain tube, and a continuous current of aqueous vapour passed over it, titanous acid is formed, with evolution of hydrogen gas in considerable quantity (Regnault), and likewise of ammonia and hydrocyanic acid (Wöhler). If the crystals are in their natural state (not pulverised), the titanous acid thus produced maintains the form of rounded cubes; but these, when examined by the microscope, are found to consist of aggregates of crystals, in the form of pointed square-based octahedrons, having a strong lustre and exactly resembling the crystals of native anatase.

The crystals of nitrocyanide of titanium heated in dry *chlorine gas*, yield liquid chloride of titanium, and a crystalline volatile yellow sublimate, consisting of a compound of chloride of titanium with chloride of cyanogen. Mixed in the state of powder with *hydrate of potassium* and fused, they give off ammonia and are converted into titanate of potassium. When the pulverised compound is heated with *oxide of lead*, *copper*, or *mercury*, a lively sparkling flame is emitted, and the oxide is reduced to the metallic state. The heat evolved in this reaction is so great that even copper runs into a globule in the glass tube. (Wöhler, Ann. Ch. Phys. [3] xxix. 166; Chem. Soc. Qu. J. ii. 252.)

CYANIDE OF TIN. Alkaline cyanides added to *stannous salts* throw down stannous hydrate, but retain a small portion of tin in solution. Stannous sulphide

dissolves slightly in boiling cyanide of potassium, and the solution is precipitated by hydrochloric acid.

CYANIDE OF TRITYL. $C^3H^3N = C^3H^3.Cy$. (See BUTYRONITRILE, i. 698).

A compound of this body with trichloride of phosphorus, $C^3H^3N.PCl^3$, is obtained by treating butyramide with pentachloride of phosphorus. It is a colourless, strongly refracting liquid, which is decomposed by water, yielding cyanide of trityl, hydrochloric acid, and phosphorous acid. (Henke, Ann. Ch. Pharm. cvi. 272.)

CYANIDES OF URANIUM. Cyanide of potassium forms with uranic salts a yellow precipitate, soluble in nitric acid and in excess of cyanide of potassium. From uranous salts it merely precipitates uranous oxide.

CYANIDE OF VANADIUM. When hydrated vanadic oxide is digested in a close vessel with prussic acid, a dark brown gelatinous mass is produced which dissolves in aqueous cyanide of potassium; but the solution, when evaporated in an open vessel, gives off prussic acid and leaves vanadate of potassium. (Berzelius.)

CYANIDE OF YTTRIUM. The solution of hydrate of yttria in prussic acid yields on evaporation white efflorescent nodules easily soluble in water and alcohol. (Berlin.)

CYANIDE OF ZINC, $ZnCy$.—Zinc-salts mixed with an alkaline cyanide yield a white pulverulent precipitate of cyanide of zinc, insoluble in water and alcohol, but easily soluble in alkaline cyanides. Cyanide of zinc is likewise obtained by dissolving the oxide in hydrocyanic acid. C. Oppermann (J. Pharm. [3] xxxviii. 320) prepares it for medical purposes, by passing vapour of hydrocyanic acid into a solution of sulphate of zinc, mixed with 1 at. acetate of sodium, and slightly acidulated with acetic acid. The precipitate when washed is free from iron, even if it has been thrown down from an impure zinc-solution.

Cyanide of Zinc and Ammonium, $(NH^4)ZnCy^2$, forms colourless rhomboidal prisms which effloresce in contact with the air, and smell of hydrocyanic acid and ammonia. It is only partially soluble in water, cyanide of zinc remaining undissolved.

Cyanide of Zinc and Barium, $BaZn^2Cy^3$. White powder, sparingly soluble in water; precipitated on mixing the solutions of acetate of barium and cyanide of zinc and potassium. It generally retains a small quantity of potash.

Cyanide of Zinc and Calcium. Moderately soluble; obtained by treating cyanide of zinc with cyanide of calcium.

Cyanide of Zinc and Lead. White precipitate.

Cyanide of Zinc and Potassium, $KZnCy^2$, is obtained by dissolving cyanide of zinc in cyanide of potassium; crystallises in large regular octahedrons, colourless, fusible, having a saccharine taste and alkaline reaction, permanent in the air, very soluble in water. The aqueous solution has a faint odour of prussic acid. Small quantities of hydrochloric, sulphuric, or acetic acid precipitate the cyanide of zinc, but larger quantities of acid redissolve it. (L. Gmelin, *Handb.* vii. 424.)

Cyanide of Zinc and Sodium, $NaZn^2Cy^3 + \frac{1}{2}aq$.—Shining scales, which give off their water at $200^\circ C$.

CYANIN. *Anthokyan*. (Clamor Marquart, *Die Farben der Blüthen*. Bonn, 1835.—Frémy and Cloez, J. Pharm. [3] xxv. 249.—Filhol, Compt. rend. xxxix. 194.—Martens, Jahresb. d. Chem. 1855, 687.)—This name is applied to the blue colouring matter of flowers, which is perhaps identical with that of certain berries, roots, tubers, &c. It is contained in the blue petals of corn-flowers, violets, and several species of iris (*I. pumila* and *I. germanica*), and, according to Marquart, also in red, blue, and black flowers. To extract it, the petals are exhausted with alcohol; the liquid is evaporated to dryness; the residue treated with water, which separates a fatty or resinous substance, and dissolves the colouring matter; the aqueous solution is precipitated with acetate of lead; the green precipitate is washed, suspended in a large quantity of water, and decomposed by sulphydric acid; the filtrate is carefully evaporated over the water-bath; the residue treated with absolute alcohol; and the alcoholic solution mixed with ether, which precipitates the cyanin in blue flocks. (Frémy and Cloez.)

Cyanin thus prepared is a blue uncrystallisable mass, soluble in water and alcohol, insoluble in ether. It is decolourised by reducing agents, such as sulphurous acid, phosphorous acid, and alcohol, but recovers its blue colour when exposed to the air. It is instantly coloured red by acids, green by alkalis. With bases, such as lime, baryta, and oxide of lead, it forms green insoluble compounds.

Red flowers are said also to owe their colour to the presence of cyanin reddened by a free acid. This supposition may account for the fact that many flowers, of the borage and mallow tribes, for example, which are red in the bud, turn blue when expanded,

and green as they fade, the change being due to the disappearance of the free acid, or to the formation of ammonia resulting from the decomposition of a nitrogenous compound.

The reaction of cyanin with acids and alkalis renders it useful for the preparation of test-paper and tinctures; the alcoholic extract of the petals of *Iris germanica* or *I. pumila* is very well adapted for the purpose.

The term cyanin is also applied to a blue dye, which, according to G. Williams (Dingl. polyt. J. clix. 330 and 399), is prepared from chinoline with iodide of amyl, and used in calico-printing. The colour is fugitive.

CYANITE. See Kyanite.

CYANOCHROME. A sulphate of copper and potassium, $\text{CuKSO}_4 + 3\text{aq.}$, found, together with other salts, as a deposit on the lava of Vesuvius thrown out in the eruption of 1855. (Scaechi, Sill. Am. J. [2] xxii. 252.)

CYANOFORM? A mixture of cyanide of mercury and dehydrated acetate of calcium yields by dry distillation a yellow liquid smelling of prussic acid, and, according to Bonnet (Gm. vii. 147), containing cyanoforn, CHCy^3 , an analogue of chloroform. Bonnet, however, did not analyse the compound, and Nachbaur (Ann. Ch. Pharm. ex 303), has shown that the liquid in question contains, together with cyanide of methyl, acetone, and prussic acid, a base having the composition of dicyanhex-methyldiamine, $\text{C}^8\text{H}^{18}\text{N}^4 = \text{N}^2(\text{CH}^3)^6\text{Cy}^2$. (See METHYLAMINES.)

CYANOGEN. CN (or C^2N) = Cy .—This body, which exists, or may be supposed to exist, in a great number of compounds, the cyanides, cyanates, cyanurates, &c., was first obtained in the free state by Gay-Lussac in 1815, and afforded the first instance of the isolation of a compound radiée. Many of its compounds had been known long before, prussian blue having been discovered by Diesbach and Dippel in 1704, ferro-cyanide of potassium by Macquer about the middle of the eighteenth century, and prussic acid by Scheele in 1782. The name cyanogen is derived from *κυανος* (blue) and *γεν*.

The modes of formation of cyanogen-compounds have already been mentioned (p. 198). Cyanogen is obtained in the free state by the action of heat on the cyanides of mercury, silver, and gold, or by the dry distillation of oxamide, $\text{C}^2\text{H}^4\text{N}^2\text{O}^2$, or oxalate of ammonium, $\text{C}^2(\text{NH}^4)^2\text{O}^4$, differing, in fact, from the former of these bodies only by $2\text{H}^2\text{O}$, and from the latter by $4\text{H}^2\text{O}$:

Preparation.—Dry cyanide of mercury is heated to low redness in a glass tube or small retort, and the cyanogen, which is evolved as gas, is collected over mercury. The mercury separated from the cyanogen volatilises and condenses in the colder part of the apparatus. A small portion of the cyanogen is converted into the isomeric compound *paracyanogen* (q. v.), and remains in the form of a brown loosely coherent mass. If the cyanide of mercury is moist, a large portion of the cyanogen is decomposed, with formation of ammonia, carbonic acid, and hydrocyanic acid.

The gas may likewise be obtained by heating in a retort an intimate mixture of 2 pts. (1 at.) of perfectly dried ferrocyanide of potassium, $\text{K}^4\text{Fe}^2\text{Cy}^6$, and 3 pts. (2 at.) of mercuric chloride:

Cyanogen is then evolved, mixed with vapour of mercury, and there remains a dark-coloured mixture of chloride of potassium and cyanide of iron. (Kemp, Phil. Mag. [3] xxii.)

Properties.—Cyanogen is a colourless gas, having a pungent odour very much like that of prussic acid. Its density, as determined by experiment, is 1.8064. Hence, as the molecular weight represented by the formula CN is $26 \times 0.0693 = 1.802$, it follows that, if the molecule of cyanogen occupies 2 volumes, like that of compound gases in general, it must be represented by the formula $\text{C}^2\text{N}^2 = \text{Cy}^2$.

Cyanogen condenses to a liquid under a pressure of about four atmospheres at mean temperatures (H. Davy and Faraday, Phil. Trans. 1823, p. 196), or by exposure to a temperature of -35° or -40°C . under the ordinary atmospheric pressure (Bunsen, Pogg. Ann. xli. 101). A convenient mode of preparing liquid cyanogen is to heat cyanide of mercury in the longer arm of a strong tube, bent and sealed; the cyanogen then condenses in the shorter arm, which should be kept cold.

Liquid cyanogen is transparent, colourless, and very mobile (H. Davy and Faraday). Specific gravity at $17.2^\circ = 0.866$ (Faraday). Refracting power = 1.316 (Brewster). It does not conduct the electricity generated by a battery of 300 pairs. (Kemp.)

Liquid cyanogen freezes at a few degrees below -30°C ., forming a radiated icy

mass (Bunsen). Frozen cyanogen is transparent, crystalline, apparently of the same density as the liquid, and melts at -34.4° . (Faraday, N. Bibl. Univ. lix. 162):

Tension of Cyanogen expressed in Atmospheres.

According to Faraday.						According to Bunsen.			
At.	Atm.	At.	Atm.	At.	Atm.	At.	Atm.	At.	Atm.
-12.2° C.	1.53	+6.9° C.	3.00	+21.1° C.	4.50	-20.7° C.	1.00	0° C.	2.7
6.7	1.89	8.9	3.17	23.3	4.79	20	1.05	+5	3.2
2.8	2.20	10.0	3.28	34.2	6.50	15	1.45	10	3.8
0	2.37	11.1	3.36	35.0	6.64	10	1.85	15	4.4
3.6	2.72	17.2	4.00	39.4	7.50	5	2.30	20	5.0

According to Niemann, the tension at 12.5 is equal to 4 atmospheres.

A mixture of equal parts of solid and liquid cyanogen (therefore at -34.4° C.) does not exert a tension equal to the atmospheric pressure. When cyanogen evaporates into the air, an effect which takes place quietly on opening the containing vessel, the remaining portion does not freeze. (Faraday.)

Decompositions.—1. Cyanogen gas is not decomposed by passing through a red-hot tube.—2. When *electric sparks* are repeatedly passed through the gas, charcoal is deposited, and a volume of nitrogen set free equal to that of the gas. By the electric arc, this decomposition is effected in fifteen minutes at a temperature of 30° to 40° C. If the gas is moist, carbonic acid, carbonic oxide, and hydrogen are produced.—3. When set on fire in the *air*, it burns with a peach-blossom-coloured flame, producing carbonic anhydride and nitrogen.—4. Cyanogen mixed with excess of *oxygen* and set on fire by the electric spark, explodes violently, 1 vol. cyanogen consuming 2 vol. oxygen, and forming 2 vol. carbonic anhydride and 1 vol. nitrogen, so that the volume of the gas remains unaltered. The combustion of a mixture of cyanogen and oxygen is likewise induced by hot spongy platinum (Wöhler).—5. *Chlorine* does not act on cyanogen, even in sunshine, if both gases are perfectly dry; but if moisture is present, an oily body is formed, often mixed with a solid substance having an aromatic odour, and sparingly soluble in alcohol and ether.—6. *Hypochlorous anhydride* slowly decomposes cyanogen, forming carbonic anhydride, chlorine, nitrogen, and gaseous chloride of cyanogen. Aqueous *hypochlorous acid* in contact with cyanogen gives off the same four gases, with effervescence, the liquid afterwards containing hydrochloric and cyanic acids, and being covered with an oily mixture of chloride of cyanogen and chloride of nitrogen (Balard).—7. Cyanogen in contact with *manganic sulphate*, is resolved into carbonic anhydride and nitrogen (Berzelius).—8. When cyanogen is passed over red-hot metallic *iron*, the metal takes up carbon and becomes brittle, a coating of carbon is deposited upon it, and nitrogen is set free.

The solution of cyanogen in *water*, *alcohol*, or *ether* assumes a brown colour after a while, and deposits a dark brown powder called azulmic acid (i. 480), which, according to Pelouze and Richardson (Ann. Ch. Pharm. xxvi. 63), has the composition $C^2N^4H^2O^2$, that is to say, cyanogen together with the elements of water. The aqueous solution then contains cyanide, carbonate, and oxalate of ammonium, together with urea (Wöhler, Pogg. Ann. xv. 627). One part of the cyanogen takes up the elements of water and forms oxalate of ammonium:

while another portion is in like manner converted into cyanic and hydrocyanic acids:

The cyanic acid is immediately resolved into carbonic acid and ammonia (p. 191), which latter unites with another portion of the cyanic acid, forming urea (p. 193). This transformation of cyanogen is prevented by the presence of acids. If the water contains *aldehyde*, even in small quantity only, the cyanogen is converted into oxamide ($C^2N^2 + 2H^2O$) without formation of a brown deposit. (Liebig.)

Cyanogen is absorbed by *potash-solution*, also by red-hot *carbonate of potassium*, forming cyanide and cyanate of potassium, the latter being quickly resolved in the solution into ammonia and carbonate of potassium. Cyanogen is abundantly absorbed by *ammonia*, the solution soon turning brown and yielding the same products that are formed in the decomposition of cyanogen by water.

Combinations.—Cyanogen combines directly with *potassium* under the influence of heat. It also unites directly with *sulphydric acid gas*, in presence of water, and with certain organic bases, as *phenylamine*, *benzylamine*, *codeine*, &c. The bromide, chloride, and iodide of cyanogen, are formed by decomposing cyanides with *bromine*, *chlorine*, or *iodine*. The modes of formation of other cyanogen-compounds have already been given (p. 198).

CYANOGEN, ACETATE OF, or *Cyanate of Acetyl*, $C^2H^3NO^2 = \frac{C^2H^3O}{CN}\{O$, or

Carbacetamide $N\left\{\frac{(CO)''}{C^2H^3O}\right.$ (Schützenberger, Ann. Ch. Pharm. cxxiii. 271.)—When cyanate of silver is treated with chloride of acetyl in a cooled vessel, a dry pulverulent mass is formed containing acetate of cyanogen. On heating this mass to about 100° C., carbonic anhydride is evolved, and a colourless very pungent liquid distillate passes over, boiling at 80° to 85° , and at higher temperatures an oily liquid, which solidifies to a mass of white needles.

The volatile liquid is a mixture of liquid acetate of cyanogen with cyanide of methyl, resulting from a decomposition of the former ($C^3H^3NO^2 = CO^2 + C^2H^3N$). Water decomposes it, yielding carbonic anhydride and acetamide; a reaction which seems to indicate that the compound is really carbacetamide:

The white crystalline mass exhibits the composition of diacetamide, the formation of which is attributed by Schützenberger to the action of the acetate of cyanogen on acetic acid resulting from a secondary decomposition:

When acetate of silver is heated with iodide of cyanogen, iodide of silver is formed together with an explosive compound. (Schützenberger, Ann. Ch. Pharm. cxx. 118).

CYANOGEN, BENZOATE OF? When the product obtained by the action of chloride of benzoyl on cyanate of silver or cyanate of lead is heated, carbonic anhydride is evolved, and cyanide of phenyl passes over, produced apparently by the decomposition of benzoate of cyanogen; $C^7H^3(CN)O^2 = CO^2 + C^7H^3N$. (Schützenberger.)

CYANOGEN, BROMIDE OF. $CNBr = CyBr$. Discovered and examined by Serullas in 1827 (Ann. Ch. Phys. [2] xxxiv. 100; xxxv. 294, 315), further examined by Löwig (*Das Brom und seine chemischen Verhältnisse*, Heidelberg, 1829, p. 69). It is produced by the action of bromine on cyanide of mercury, cyanide of potassium, or aqueous hydrocyanic acid.

Preparation.—1. When 1 pt. of bromine is poured upon 2 pts. of cyanide of mercury contained in a tubulated retort or glass tube closed at the bottom and surrounded with ice, bromide of mercury and bromide of cyanogen are formed, with great evolution of heat. The bromide of cyanogen sublimes in needles, contaminated at first with bromine, but ultimately the bromine flows back and enters completely into combination. Gentle heat is then applied, and the bromide of cyanogen sublimed into a receiver connected with the retort and surrounded with ice (Serullas).—2. Aqueous hydrocyanic acid is placed in a vessel surrounded with a frigorific mixture, and bromine added—in very small portions to prevent the temperature from rising too high—till the solution begins to assume a reddish tinge; the liquid, which is in process of solidification from the acicular crystallisation of the bromide of cyanogen, is then either expressed, between blotting paper at a temperature below 0° C., or it is gently heated to drive off the bromide of cyanogen in vapour, aqueous hydrobromic acid then remaining behind (Löwig).—3. Bromine and water are placed in a tube kept very cold, and cyanide of mercury and hydrochloric acid added till the red colour disappears; the open end of the tube is then drawn out to a narrow neck, which is sealed up, and the lower part of the tube is immersed in warm water, so that the bromide of cyanogen may sublime into the upper part (Mitscherlich, *Lehrbuch der Chemie*).—4. When bromine is added to an aqueous solution of cyanide of potassium cooled to 0° C., crystals of bromide of cyanogen immediately separate. When the reaction is complete, these crystals may be separated from the solution of bromide of potassium by heating the liquid to 60 – 65° C. (Langlois, Ann. Ch. Phys. [3] lxi. 482.)

Properties.—Bromide of cyanogen sublimes, at the first moment of its formation, in long delicate needles, which afterwards change to small transparent and colourless cubes (Serullas).—It melts at $+4^\circ$ C. (Löwig), above $+16^\circ$ (Serullas), not even at 40° (Bineau). Vapour-density = 3.607 (Bineau, Ann. Ch. Phys. [2] lxxviii. 425), by calculation (2 vols.) = 3.6745. Its boiling point is lower than that of iodide of cyanogen, and it volatilises even at 15° C. (Serullas). Its vapour has a very pungent odour; it excites a copious flow of tears, and is dangerous to inhale (Serullas); its taste is extremely biting (Löwig). One grain dissolved in water and poured into the oesophagus of a rabbit, kills it instantly (Serullas). It immediately

decolorises litmus and turmeric paper, and does not redden litmus even when dissolved in water (Löwig). It is very soluble in *water* and *alcohol*, and forms a crystalline hydrate which is less fusible than the anhydrous compound.

Decompositions.—1. Aqueous *sulphurous acid* forms with bromide of cyanogen: sulphuric, hydrobromic, and hydrocyanic acids.—2. Aqueous *potash* forms cyanide, bromide, and bromate of potassium (Serullas, Löwig). On adding to a saturated solution of bromide of cyanogen, first potash and then an acid, carbonic anhydride is evolved, and the liquid is afterwards found to contain ammonia (Serullas).—3. The aqueous solution mixed, first with *ferrous sulphate*, then with potash, and then with an acid, yields a green precipitate (Serullas); but if the potash be added first, then the ferrous sulphate, and then the acid, no precipitate is obtained (Serullas).—4. The aqueous solution of bromide of cyanogen, slowly evaporated to dryness, leaves hydrobromate of ammonia (Löwig). In this case carbonic anhydride should also be produced: $\text{CNBr} + 2\text{H}_2\text{O} = \text{CO}_2 + \text{NH}_4\text{Br}$.—5. Bromide of cyanogen gently heated with *phosphorus*, evaporates for the most part undecomposed; nevertheless, a small quantity of bromide of phosphorus is formed. *Antimony*, heated in vapour of bromide of cyanogen, yields cyanogen gas and bromide of antimony. *Mercury* decomposes the saturated aqueous solution, yielding cyanogen and bromide of mercury. (Löwig.)

Bromide of cyanogen dissolves without decomposition in strong *sulphuric*, *hydrochloric*, and *nitric acids*. It absorbs *ammonia-gas*, forming a mixture of bromide of ammonium and cyanamide (p. 188), which was regarded by Bineau as an ammonio-bromide of cyanogen.

CYANOGEN, CHLORIDE OF. Three chlorides of cyanogen are known, isomeric with each other, and having molecular weights in the proportion of 1 : 2 : 3. The first is gaseous at ordinary temperatures, the second liquid, and the third a crystalline solid.

Gaseous Chloride of Cyanogen, $\text{CNCl} = \text{CyCl}$.—This compound was first observed by Berthollet (Ann. Chim. i. 35), who, however, regarded it as oxidised prussic acid. Gay-Lussac (Ann. Chim. xc. 200) ascertained its true nature and examined it more fully; and it has been further investigated by Serullas (Ann. Ch. Phys. [2] xxxv. 291, 337; Pogg. Ann. xxi. 495), Wöhler (Ann. Ch. Pharm. lxxiii. 219), Cahours and Cloez (*ibid.* xc. 97), Cloez (*ibid.* cii. 354), Klein (*ibid.* lxxiv. 85), Martius (*ibid.* cix. 79), and Langlois (Ann. Ch. Phys. [3] lxi. 481).

Gaseous chloride of cyanogen is obtained by passing chlorine into aqueous prussic acid, or by leaving moist cyanide of mercury in contact with chlorine in a dark place. The former was the method by which Gay-Lussac obtained the gas, mixed, however, with carbonic acid; the latter method is now always adopted for preparing the gas in the pure state.

Preparation.—Cyanide of mercury moistened with water, but not dissolved in it, is introduced into bottles of a capacity not exceeding 3 litres, well closed with glass stoppers, and filled with chlorine gas, the proportion of cyanide of mercury being about 5 grammes to each litre of chlorine; the bottles are left for 24 hours in the dark, till in fact the chlorine has lost its yellow colour; then cooled by immersion in a mixture of ice and salt, producing a temperature at least as low as -18°C ., till the gaseous chloride of cyanogen solidifies in crystals. 100 grammes of water are then poured into each bottle; the resulting solution is poured from all the bottles into a long-necked flask, which it must nearly fill; and this flask is connected by a bent tube with a two-mouthed bottle containing chloride of calcium, so that the gaseous chloride of cyanogen may pass from its second mouth through a second bent tube into a bottle surrounded with a freezing mixture. If now the aqueous solution in the flask be warmed, the chloride of cyanogen collects in the crystalline form in the last bottle, which must then be closed very tight with a glass stopper. At ordinary temperatures, the crystals in the bottle melt, and are converted into gas. If, however, a small quantity of water be introduced into the bottle while it is immersed in the freezing mixture, and it be then taken out, still well closed, two layers are found in it, the upper of which is an aqueous solution of chloride of cyanogen, and the lower probably a hydrate of that compound. (Serullas). If the vessels are exposed to light, or if the temperature is allowed to rise to between 30° and 40°C ., the chloride of cyanogen is decomposed.

Wöhler passes chlorine into a saturated solution of cyanide of mercury to which an excess of the salt in fine powder has been added, continuing the passage of the gas till the solution is completely saturated, and the upper part of the vessel filled with the gas. The vessel is then closed and left in the dark, till, after repeated agitation, the whole of the chlorine is absorbed, or the whole of the cyanide of mercury dissolved. To remove any remaining excess of chlorine, the solution is shaken up with mercury. It is then heated in a flask, which is connected with a chloride of calcium tube and a conducting tube, and the gaseous chloride of cyanogen is condensed as in the process last described.

Cahours and Cloez saturate 100 grm. cyanide of mercury and 4 litres of water, contained in a flask capable of holding 6 litres, with chlorine gas at 0°C . Hydrate of chlorine is then formed, which, in the course of 24 hours, is completely transformed, by the cyanide of mercury, into chloride of mercury and chloride of cyanogen, the latter remaining dissolved. The solution is slightly heated, and the gas thereby evolved, which generally contains a little free chlorine, is passed first over copper-turnings, and then over chloride of calcium.

According to Langlois, gaseous chloride of cyanogen is produced by the action of chlorine on a solution of cyanide of potassium cooled to 0°C ., and is given off as gas, partly at that temperature, partly when the action is ended, and the solution is heated to 40° or 50°C . If the solution of cyanide of potassium is not cooled, its temperature easily rises to 80° or 90°C ., and then other products are formed.

The extremely poisonous action of the gaseous chloride of cyanogen renders it necessary, in all these processes, to take the greatest care to prevent its escape into the air and consequent inhalation. For this reason, a freezing mixture made with chloride of calcium is preferable to the ordinary mixture of ice and salt.

Properties.—Chloride of cyanogen is, at ordinary temperatures, a colourless poisonous gas, having an intolerable odour, and exciting a copious flow of tears. Its specific gravity is 2.124 (by calculation for 2 vol., 2.128). At -12° to -15°C ., or at 0°C . under a pressure of four atmospheres, it condenses to a colourless liquid, which may be preserved in sealed tubes. At -18°C . it crystallises in long transparent prisms. The gas, when kept in sealed tubes, is gradually converted into solid chloride of cyanogen, Cy^2Cl^2 .

Water at 20°C . dissolves 25 times its volume of gaseous chloride of cyanogen, *ether* 50 times, *alcohol* 100 times. When a small quantity of water is introduced into a bottle containing chloride of cyanogen and standing in a freezing mixture, two layers of liquid are formed, the upper consisting of an aqueous solution of chloride of cyanogen, the lower probably of a hydrate of that compound. The solutions of chloride of cyanogen, if free from hydrochloric acid, neither redden litmus nor precipitate solution of nitrate of silver. The aqueous solution appears to undergo gradual decomposition.

Potassium heated in gaseous chloride of cyanogen forms chloride and cyanide of potassium. Antimony heated in the gas forms chloride of antimony and liberates $\frac{1}{2}$ vol. cyanogen. With *alkalis*, chloride of cyanogen forms a chloride and a cyanate:

When the aqueous solution of chloride of cyanogen is mixed, first with *ferrous sulphate*, then with potash, and then with an acid, a green precipitate is formed; but if the potash is added first, then the ferrous sulphate, and then the acid, no precipitation takes place. (Gay-Lussac, Serullas.)

Chloride of cyanogen mixed with *ammonia-gas* forms a mixture of sal-ammoniae and cyanamide (mistaken by Bineau for ammonio-chloride of cyanogen, p. 188). It acts in a similar manner on other volatile bases; with *ethylamine*, for example, it forms *cyanethylamide*. The *alcoholic* solution of chloride of cyanogen changes after some days into a mixture of hydrochloric acid or chloride of ammonium with carbonate and carbamate of ethyl. Similar products are obtained with *methyl* and *amyl* alcohols (Wurtz). With a solution of *ethylate of sodium* in absolute alcohol, chloride of cyanogen forms chloride of sodium and cyanetholine (p. 189).

Chloride of cyanogen unites in definite proportions with certain other chlorides.

Chloride of Cyanogen and Antimony, $\text{SbCl}^3.\text{CyCl}$.—When gaseous chloride of cyanogen is passed over pentachloride of antimony, the latter becomes slightly heated, turbid, and gradually filled with delicate crystals. After saturation the compound forms a white crystalline mass. When heated, only a portion of it sublimes undecomposed, the greater part giving up its chloride of cyanogen. Water decomposes it instantly. It absorbs ammonia, with rise of temperature, forming a yellow pulverulent body. (L. Klein, Ann. Ch. Pharm. lxxiv. 87.)

Chloride of Cyanogen and Boron, $\text{BCl}^3.\text{CyCl}$.—Liquid chloride of boron absorbs dry chloride of cyanogen, with great evolution of heat, and forms a white loose crystalline mass. If the saturation is not quite complete, the compound separates gradually in small colourless prisms. It smells of chloride of cyanogen, fumes in damp air, and is decomposed by water, with rise of temperature, into boric acid, hydrochloric acid, and gaseous chloride of cyanogen. It acts in like manner on absolute alcohol. It sublimes with partial decomposition when strongly heated, leaving a white substance. (Martius.)

Chloride of Cyanogen and Iron, $\text{Fe}^2\text{Cl}^3.\text{CyCl}$.—Sublimed sesquichloride of iron absorbs gaseous chloride of cyanogen, with evolution of heat, fusing with it into a black mass; the compound was not, however, obtained in a complete state of saturation. When heated it fuses, swells up, and gives off gaseous chloride of cyanogen; it is re-

markable, however, that this decomposition likewise yields solid chloride of cyanogen sublimed in crystals. (Klein.)

Chloride of Cyanogen and Titanium, $\text{TiCl}_4 \cdot \text{CyCl}$.—Gaseous chloride of cyanogen acts instantly, and with great evolution of heat, on tetrachloride of titanium, converting it into a bulky, yellow, crystalline mass, which must be shaken up and heated gently, in order that it may be completely saturated with the chloride of cyanogen.

Lemon-yellow, very volatile; begins to volatilise considerably below 100° , subliming in clear lemon-yellow crystals which appear to be rhombic octahedrons. It fumes very strongly in damp air, quickly becoming milk-white, and exhaling the odour of chloride of cyanogen. Water dissolves it, with great rise of temperature and evolution of chloride of cyanogen, forming a clear solution. It dissolves without alteration in warm tetrachloride of titanium, separating out again in crystals on cooling. It absorbs ammonia, with great rise of temperature, forming with it an orange-red compound, which also turns white in moist air, and is decomposed by water, with partial separation of titanous anhydride. (Wöhler.)

Chloride of Cyanogen with Cyanide of Ethyl, $\text{CyCl} \cdot \text{C}_2\text{H}_5\text{N}$.—Dry gaseous chloride of cyanogen is rapidly absorbed by cyanide of ethyl, producing a colourless liquid which boils between 60° and 68°C ., and exerts an intensely irritating action on the eyes and the respiratory organs. It is decomposed, with rise of temperature, by water, and decomposes spontaneously when left for several days, the whole of the chloride of cyanogen being separated as solid chloride of cyanogen, Cy^3Cl^3 . (Henke, Ann. Ch. Pharm. cvi. 289). [For the compound of chloride of cyanogen with cyanide of hydrogen, see below.]

2. *Liquid Chloride of Cyanogen*, $\text{C}^2\text{N}^2\text{Cl}^2 = \text{Cy}^2\text{Cl}^2$.—This compound, discovered by Wurtz (Ann. Ch. Pharm. lxiv. 308; lxxix. 280), is prepared by slowly passing chlorine gas into hydrocyanic acid, cooled to 0°C . in a retort connected with a cooled receiver, as long as the gas continues to be absorbed. The liquid in the retort then separates into two layers, the lighter consisting of hydrocyanate of chloride of cyanogen, $\text{Cy}^2\text{Cl}^2 \cdot \text{HCy}$, part of which is generally carried over into the receiver. From this compound the liquid chloride of cyanogen may be obtained, by mixing it, after separation from the heavier liquid, with ice-cold water, and treating it with mercuric oxide, which decomposes the hydrocyanic acid, care being taken to cool the vessel well, as otherwise the mercuric oxide may be reduced. Chloride of calcium is then added, the liquid distilled, and the vapour passed through a tube containing chloride of calcium into a flask cooled to 0°C . The chloride of cyanogen then condenses in the form of a very mobile colourless liquid, having an extremely pungent and exciting odour, and heavier than water, in which it is slightly soluble.

Liquid chloride of cyanogen solidifies in the crystalline form at 5° or 6°C ., and boils at 15.5°C . Its vapour is not inflammable. When pure, it may be kept for years in sealed tubes without passing into the state of solid chloride of cyanogen. If, on the contrary, chlorine in excess be passed into dilute prussic acid, and the liquid which separates be distilled without previous washing and treatment with mercuric oxide, an impure product is obtained which changes into solid chloride of cyanogen in the course of twenty-four hours. The same transformation takes place also in twenty-four hours, in chloride of cyanogen prepared by the action of chlorine on dry cyanide of mercury; after washing, however, it no longer exhibits this property. (Wurtz.)

Ammonia-gas converts liquid chloride of cyanogen into cyanamide and sal-ammoniac.

Hydrocyanate of Chloride of Cyanogen, $\text{Cy}^2\text{Cl}^2 \cdot \text{HCy}$.—Obtained by the action of chlorine on aqueous hydrocyanic acid in the manner above described. It is a colourless liquid, smelling strongly of chloride of cyanogen, inflammable, and burning in the air with a violet flame. It boils at about 20°C ., and solidifies perfectly in a mixture of ether and solid carbonic acid. In the pure state it may be kept for years without colouring or depositing crystals. It is perceptibly soluble in water; but a large quantity of water decomposes it, abstracting the hydrocyanic acid. In an atmosphere of chlorine it changes in about twenty-four hours into solid chloride of cyanogen. Bromine converts it into a semi-solid mass, which, when moderately warmed, gives off bromide of cyanogen, and at a higher temperature yields solid chloride of cyanogen. Mercuric oxide abstracts the hydrocyanic acid, and converts the compound into liquid chloride of cyanogen. (Wurtz, loc. cit.)

3. *Solid Chloride of Cyanogen*, $\text{C}^3\text{N}^3\text{Cl}^3 = \text{Cy}^3\text{Cl}^3$.—This compound was discovered in 1827 by Serullas (Ann. Ch. Phys. [2] xxxv. 291, 337), who regarded it as a bichloride of cyanogen; its true composition was demonstrated by Liebig (Pogg. Ann. xx. 369; xxxiv. 604). It is produced: 1. By the spontaneous transformation of gaseous chloride of cyanogen and of the impure liquid chloride.—2. By the action of excess of chlorine in sunshine on anhydrous prussic acid or on moist cyanide of mercury, by which reactions it was indeed first obtained by Serullas.—3. By heating dry sulpho-

cyanate of potassium in chlorine gas (Liebig).—4. By the action of pentachloride of phosphorus on dry cyanuric acid (Beilstein, Ann. Ch. Pharm. cxvi. 357):

Preparation.—1. Chlorine in excess is passed into dilute hydrocyanic acid, and the liquid which separates (p. 280) is distilled without previous purification. The liquid chloride of cyanogen which passes over soon changes into the solid modification (Wurtz). This is one of the easiest modes of preparation.

2. A bottle of 1 litre capacity is filled with dry chlorine gas; 0.82 grm. of prussic acid, prepared by Gay-Lussac's method, introduced into it; and the closed bottle exposed to the sun for one to three days, whereupon the hydrocyanic acid evaporates, the chlorine gas is decolorised, and a transparent colourless liquid formed, which runs down the sides of the vessel, and soon solidifies in white crystals of solid chloride of cyanogen. The hydrochloric acid gas, together with any volatile chloride of cyanogen that may be present, is then blown out of the bottle with a pair of bellows; a small quantity of water and a few pieces of glass are introduced, in order to detach the crystallised solid chloride of cyanogen from the sides of the vessel by agitation; the whole is poured into a basin; the pieces of glass are taken out; the solid chloride of cyanogen is comminuted with a glass rod, and repeatedly washed on a filter with a small quantity of cold water, till the liquid which runs away no longer forms a cloud with nitrate of silver*; the solid chloride of cyanogen is pressed between bibulous paper, till it is converted into a dry white powder; and this powder is purified by one or two distillations from a small retort, whence it passes in the form of a transparent colourless liquid into a receiver cooled with wet linen, and there solidifies. (Serullas.)

3. When dry cyanogen gas is passed over heated sulphocyanate of potassium, solid chloride of cyanogen partly sublimes in needles, partly distils over dissolved in chloride of sulphur. The needles are purified from adhering chloride of sulphur by a second sublimation in a vessel through which a continuous stream of chlorine gas is passed. The chloride of sulphur which passes over, leaves when evaporated an additional quantity of crystals of solid chloride of cyanogen, together with a yellow liquid having a high boiling point. From this residue, the chloride of cyanogen is separated by sublimation in a stream of chlorine gas, the yellow liquid then remaining behind. (Liebig.)

4. Perfectly dry cyanuric acid is well mixed with about six times its weight of pentachloride of phosphorus; the mixture is distilled; the distillate, consisting of oxychloride of phosphorus holding solid chloride of cyanogen in solution, is treated with water to decompose the oxychloride; and the solid chloride of cyanogen which then separates is washed with water and crystallised from ether. This method yields a perfectly pure product. To ensure success, however, the quantity of cyanuric acid operated upon must be somewhat considerable. The decomposition may also be effected in sealed tubes at 150° — 200° C.; but this method is less convenient. (Beilstein.)

Properties.—Shining white needles of specific gravity about 1.320, melting at 140° C. to a transparent colourless liquid, and boiling at 190° (Serullas). Vapour-density 6.35 (Bineau, Ann. Ch. Phys. [2] lxxviii. 424), by calculation (2 vol.) = 6.385. It gives out, especially when heated, a pungent odour like that of chlorine, but at the same time strongly resembling that of mice, and excites tears. Its taste is weak, but is nevertheless similar to the odour. One grain dissolved in alcohol and introduced into the alimentary canal of a rabbit, kills it instantly. (Serullas.)

Solid chloride of cyanogen dissolves in water without decomposition at first, but is afterwards resolved with it, slowly at ordinary temperatures, more quickly at the boiling heat, and instantly in presence of a fixed alkali, into hydrochloric and cyanuric acids (Serullas):

Similarly, when boiled with *ammonia*, *water*, and *alcohol*, it yields sal-ammoniac and cyanuric acid; but in the absence of alcohol, chlorocyanamide is produced. The same compound is formed, with slight evolution of heat, when dry *ammoniacal gas* is passed over pulverised chloride of cyanogen (Liebig). Solid chloride of cyanogen mixed with *potassium* is decomposed, with evolution of light and heat, yielding chloride and cyanide of potassium (Serullas). It dissolves very readily in *alcohol* and *ether*, whence it is precipitated by water. When dissolved in absolute alcohol it remains unaltered; but in hydrated alcohol, it is converted in a short time, with violent evolution of heat, into vapour of hydrochloric acid, and cyanuric acid, which settles in cubes at the bottom of the liquid. (Liebig.)

* This wash-water, which contains hydrochloric acid, cyanuric acid, and a small quantity of chlorocyanic oil, may be used for the preparation of cyanuric acid.

Chlorocyanic Oil.—This name is given to an oily liquid containing chlorine, carbon, and nitrogen, which is produced by the action of chlorine on many cyanogen-compounds, *e. g.* on cyanogen-gas in sunshine (Gay-Lussac, Ann. Chim. xcv. 200), on anhydrous hydrocyanic acid in sunshine (Gay-Lussac, Serullas, Ann. Ch. Phys. [2] xxxv. 300), on the strong aqueous acid (Gay-Lussac), on dry cyanide of mercury in sunshine. (Gay-Lussac.)

Preparation.—A concentrated aqueous solution of 5 grms. cyanide of mercury is poured into a bottle of 1 litre capacity, filled with chlorine gas and exposed to the sun: in an hour or two, drops of oil are seen running down the sides, and in four hours, if the sunshine is strong, the action is complete. In diffused daylight, the decomposition goes on more slowly and yields less oil. The oil is mechanically separated from the water above it—a large quantity of volatile chloride of cyanogen then escaping—and drawn up into tubes under water (Serullas). Bouis (Ann. Ch. Phys. [3] xx. 446) proceeds in the same manner, except that he prepares a solution of cyanide of mercury saturated at the boiling heat, and pours it while still hot into bottles filled with chlorine. The crystals of chloride of mercury which form at first, soon dissolve, and are replaced by elongated crystals, the formation of which appears, however, to be merely accidental; afterwards the oily drops appear. The chlorine must be repeatedly renewed, till it no longer loses its colour. In the bright sunshine of summer, the saturation of the liquid with chlorine is completed in two hours; in winter it takes two or three weeks. Four parts of cyanide of mercury yield 1 pt. of the oil.

Chlorocyanic oil is a yellow liquid, heavier than water; it has a very caustic taste (Bouis), and a very pungent odour, like that of cyanogen, but with a peculiar aromatic character, causing a copious flow of tears and coughing. It is not nearly so poisonous as chloride of cyanogen, a tolerably strong dose killing rabbits only after several hours. When recently prepared, it does not redden litmus or precipitate nitrate of silver (Serullas). Its boiling point is at least as high as that of oil of vitriol (Liebig). It makes grease-spots on paper, which are dissipated by heat. It is insoluble in water, but soluble in alcohol and ether. It decomposes gradually, whether moist or dry, depositing crystals of trichloride of carbon, C^2Cl^6 . It explodes when heated. Bouis found it to contain 10.6 per cent. carbon, 8.4 nitrogen, and 75.6 chlorine, whence he deduces the formula $C^6N^4Cl^{14}$. Serullas regards it as a mixture of chloride of cyanogen with chloride of carbon and chloride of nitrogen.

The oil, when moderately heated, boils, gives off nitrogen (mixed with carbonic anhydride), and yields a liquid distillate which deposits crystals of trichloride of carbon. The distillate is colourless, limpid, heavier than water; has a strong irritating odour; is insoluble in water, soluble in alcohol, more soluble in ether; boils at about $85^\circ C.$, the boiling point, however, gradually rising. Bouis found in it 11.6—12.4 per cent. carbon, 4.9 to 5.1 nitrogen, and 80.4—81.8 chlorine, and represents it by the formula $C^{10}N^4Cl^{22}$.

When the chlorocyanic oil is slightly heated with nitric acid, the mixture gives off torrents of gas, which often blow the apparatus to pieces. The gases consist of nitrogen, carbonic anhydride, and nitrous vapours, mixed with a yellowish vapour having a very powerful odour. By distillation, crystals of trichloride of carbon are obtained, together with a colourless, very volatile liquid, having an odour still more irritating than the preceding products. Bouis found it to contain 10.3 to 10.9 per cent. carbon, 8.2 to 7.85 nitrogen, and 75.9 to 75.7 chlorine, numbers which he represents by the formula $C^{12}N^4Cl^{102}$.

In connection with these compounds, we may describe a crystalline substance, which Stenhouse (Ann. Ch. Pharm. xxxiii. 92) obtained by the action of dry chlorine on an alcoholic solution of cyanide of mercury, or of hydrocyanic acid.

When an alcoholic solution of cyanide of mercury, cooled by cold water, is saturated with dry chlorine gas, large quantities of sal-ammoniac are produced; the mass becomes heated, giving off carbonic anhydride with effervescence, and the liquid retains a peculiar compound, together with mercuric chloride. The solution is heated with water, which dissolves the sal-ammoniac and the chloride of mercury, and deposits the new body in white shining needles. If boiling water is used, the crystals form slowly and are of larger size. Care must be taken not to let the liquid get heated during the passage of the chlorine, and to stop the current of gas as soon as sal-ammoniac ceases to be deposited, otherwise secondary products will be formed. A more economical mode of preparation is to pass chlorine slowly into a strong alcoholic solution of hydrocyanic acid till crystals of sal-ammoniac make their appearance, and the liquid gives off carbonic anhydride with effervescence.

The compound crystallises in long, colourless, shining needles, much like sulphate of quinine. It is neutral, tasteless, inodorous, and melts at $120^\circ C.$ with partial sublimation. It dissolves sparingly in cold water, easily in alcohol and ether. Potashley decomposes it, ammonia being given off, and the liquid assuming a dark brown

colour. It dissolves in hot aqueous ammonia, and separates out on cooling. Sulphuric acid and nitric acid likewise dissolve it.

This substance gives by analysis (mean) 35.4 per cent. carbon, 5.0 hydrogen, 10.35 nitrogen, and 26.0 chlorine, whence Stenhouse deduces the formula $C^1H^7Cl.N.O^2$. Laurent supposes it to contain 1 at. hydrogen less, and represents it by the formula $C^1H^6N.Cl.O^2$, supposing it to be formed as shown by the equation:

The evolution of carbonic anhydride is ascribed to a secondary reaction. According to Laurent's formula, the body might be resolved into oxalic acid, alcohol, and sal-ammoniac:

CYANOGEN, DETECTION and ESTIMATION OF. The detection of cyanogen in *metallic cyanides* which give off prussic acid when treated with dilute acids, is very simple, especially when only the alkali-metals or alkaline-earth-metals are present. The liquid is first rendered strongly alkaline (if not so already); a small quantity of a ferroso-ferric solution is added; and the mixture is warmed for a short time (to favour the formation of yellow prussiate), then supersaturated with hydrochloric acid. Prussian blue is then formed if a cyanide is present, or if in very small quantity, the liquid assumes a green colour, and slowly deposits prussian blue on standing, the green colour of the liquid changing at the same time to yellow. (See also TESTS FOR HYDROCYANIC ACID, p. 218.)

To detect cyanogen in *double cyanides* which do not give off prussic acid with dilute acids, they must first be fused with dry carbonate of sodium, the mass then lixiviated with water, and the solution tested with a ferroso-ferric salt as above.

The detection of cyanogen in its other compounds is more difficult. The *cyanates*, *sulphocyanates*, and *cyanamides* are not easily converted into cyanides; most of them, however, exhibit reactions of their own, by which they may be easily recognised, *e.g.* cyanic acid by splitting up with water into ammonia and carbonic acid; sulphocyanic acid by the blood-red colour which it produces with ferric salts. Chloride, bromide, and iodide of cyanogen, mixed first with solution of ferrous sulphate and then with potash-ley, yield a green precipitate after acidulation with hydrochloric acid.

From the *cyanides of the alcohol-radicles* and *organic bases*, such as cyanophenylamine, the cyanogen cannot be separated as such, so that it is doubtful whether these compounds actually contain cyanogen. On treating them with acids or alkalis, ammonia is separated, and the carbon of the cyanogen is left in combination with the remaining carbon of the organic body, *e.g.*

To test a *gas* for cyanogen, the gas is shaken up with potash-ley, which absorbs the cyanogen, forming cyanide and cyanate of potassium; the solution may then be tested with a ferroso-ferric salt as above. The same reaction will however be obtained if the gas contains hydrocyanic acid instead of cyanogen; but in that case no cyanate of potassium will be formed. The potash-solution must therefore be further tested for cyanate by acidulating it with hydrochloric acid, and heating gently; the cyanic acid will then be resolved into carbonic acid and ammonia, which latter will be given off on supersaturating with potash. Another method of detecting free cyanogen in presence of hydrocyanic acid, is to remove the latter by means of red mercuric oxide, which does not absorb the cyanogen at all if dry, and only very slowly if it is moist. The remaining gas may then be tested with potash as above.

The *quantitative estimation* of cyanogen may often be effected by loss, that is to say, by determining the amount of the body (generally a metal) united with the cyanogen. To determine the cyanogen directly, the cyanogen-compound is generally burnt in a combustion-tube with oxide of copper, and the carbon determined as in organic analysis. 100 pts. by weight of carbonic anhydride, CO^2 , are equivalent to 59.1 pts. cyanogen, CN.

If other compounds are present containing carbon, but free from nitrogen, the cyanogen may be converted into ammonia by ignition with soda-lime, and the

ammonia quantitatively determined. 100 pts. ammonia correspond to 152.94 pts. cyanogen.

In cyanides which are soluble in water or in dilute acids, the amount of cyanogen may generally be determined by precipitation with nitrate of silver as described in the article CYANIDE OF HYDROGEN (p. 219). In some cases, however, as with cyanide of mercury and many double cyanides, *e. g.* the ferro- ferri- and cobaltcyanides, this method is not directly applicable; such compounds must be treated by some of the methods previously mentioned.

The amount of cyanogen in *cyanide of mercury* may be accurately determined by mixing the aqueous solution of the salt with caustic potash and sulphide of potassium, the latter in slight excess only, and adding a solution of zinc-oxide in potash. The cyanogen may then be precipitated from the neutralised filtrate by nitrate of silver. When cyanide of mercury is decomposed by sulphydric acid, part of the cyanogen is sure to escape as hydrocyanic acid. Another very exact method is to decompose the mercuric cyanide, dissolved in more than 25 to 30 pts. water in a stoppered bottle with cadmium filings. The decomposition is complete in about 36 hours, and the cyanogen may then be precipitated from the solution of cyanide of cadmium by nitrate of silver. (H. Rose, Zeitsch. Anal. Chem. i. 288.)

CYANOGEN, IODIDE OF. CNI = CyI. (H. Davy, Gilb. Ann. liv. 384. Wöhler, *ibid.* lxix. 281. Serullas, Ann. Ch. Phys. [2] xxvii. 184; xxix. 184; xxxiv. 100; xxxv. 293, 344. Van Dyk, Repert. Pharm. xxi. 223.) This compound, discovered by Sir H. Davy in 1816, is not formed by the direct union of its elements, but is easily obtained by the action of iodine on cyanide of mercury, cyanide of silver, or other metallic cyanides; it is likewise found as an impurity in commercial iodine (Scanlan, Chem. Soc. Mem. iii. 321. F. Meyer, Arch. Pharm. [2] li. 29. Klobach, *ibid.* lx. 34).—1. Two pts. of cyanide of mercury are mixed with 1 pt. of iodine, very intimately, but quickly, to prevent loss by volatilisation, and the mixture gradually and gently heated, either in a retort provided with a receiver, or in a wide-necked flask, the mouth of which passes under a bell-jar partly closed with a glass plate; or the mixture is heated in a small porcelain dish till the iodide of cyanogen begins to volatilise, the dish then placed upon a large glass plate, and covered with a bell-jar; the iodide of cyanogen then sublimes on the sides of the jar in large white flocks (Serullas). The product is usually contaminated with iodide of mercury, which sublimes with the iodide of cyanogen, chiefly towards the end of the operation; it may be purified by a second sublimation over the water-bath or in sunshine, but the operation takes a long time. If the iodide of cyanogen, when supersaturated, first with strong aqueous potash and then with nitric acid, yields no precipitate of mercuric iodide, it may be considered free from that impurity. (Serullas.)

2. By heating a mixture of iodine and cyanide of silver. This process yields a purer product (Wöhler)—134 pts. (1 at.) cyanide of silver require rather less than 252 pts. (2 at.) of iodine.

3. Iodine is dissolved in a concentrated solution of cyanide of potassium, in such quantity that the solution may solidify in a crystalline mass on cooling, and the solid mass is gently heated till the iodide of cyanogen sublimes. (Liebig, Chim. org. i. 180.)

Properties.—Iodide of cyanogen forms long, white, very delicate needles, loosely united in feathers and stars (Serullas). From its solution in ether or absolute alcohol, it crystallises in small four-sided tables; from a solution in spirit of 80 per cent., in long feathery needles (Herzog, Arch. Pharm. [2] lxi. 129). It is very heavy, sinking rapidly in oil of vitriol. It boils at a temperature considerably above 100° C., and volatilises undecomposed even at ordinary temperatures. It has a highly penetrating and pungent odour of iodine and cyanogen together; excites a copious flow of tears; and has an extremely acid taste (metallic if it is contaminated with iodide of mercury) (Serullas). It is very poisonous, acting like iodine and cyanogen together. It dissolves in *water*, and more readily in *alcohol*, forming colourless solutions which do not change the colour of litmus or turmeric, or turn starch blue, or precipitate nitrate of silver. It dissolves with still greater facility in *ether* and in *volatile oils*, and is likewise soluble in *fixed oils*.

Decompositions.—1. Iodide of cyanogen thrown upon red-hot coals (Serullas), or passed through a red-hot tube (Wöhler), gives off violet vapours of iodine. Even its aqueous solution, when kept for some time, imparts a pale violet colour to the superincumbent air (Serullas). Strong *sulphuric acid* decomposes iodide of cyanogen very slowly, acquiring thereby a red colour, and precipitating iodine (Serullas); according to Herzog, the decomposition does not take place without the aid of heat. It dissolves also without decomposition in *nitric* and in *cold hydrochloric acid*.—

3. *Sulphurous anhydride* exerts no action on iodide of cyanogen; but the aqueous solution of sulphurous acid forms with it (water being decomposed) sulphuric acid,

hydrocyanic acid and iodine, which last substance, by the further action of the sulphurous acid, yields hydriodic and sulphuric acids. (Serullas):

and:

Sulphydric acid gas, in the absence of water, converts iodide of cyanogen into hydriodic acid and black iodide of sulphur; in presence of water, the products are hydrocyanic acid, hydriodic acid, and a precipitate of sulphur:

and:

5. Iodide of cyanogen dissolves in *caustic potash*, forming cyanide, iodide, and perhaps also iodate of potassium (Serullas). Probably thus:

6. An aqueous solution of iodide of cyanogen mixed, first with potash, then with *ferrous sulphate*, then with hydrochloric acid,—or first with ferrous sulphate, then with potash, and then with hydrochloric acid,—yields a green precipitate (Serullas). This reaction distinguishes iodide of cyanogen from the bromide and chloride, which yield the green precipitate in the latter case only.—7. *Phosphorus* melts in contact with iodide of cyanogen, and yields iodide of phosphorus, often with emission of light and heat; the cyanogen is probably set free in this reaction (Wöhler, Dyk). Similarly, powdered *antimony* heated with iodide of cyanogen decomposes it with noise, and forms iodide of antimony; and *mercury* agitated with aqueous iodide of cyanogen liberates the cyanogen, and is converted into iodide of mercury, exhibiting first a yellow and then a red colour. (Wöhler.)

Dry chlorine gas and nitric acid do not decompose iodide of cyanogen. (Serullas.)

With *ammonia-gas*, iodide of cyanogen forms a mixture of iodide of ammonium and cyanamide, formerly regarded as ammonio-iodide of cyanogen. (See CYANAMIDE, p. 188.)

CYANOGEN, SULPHYDRATES OF. Dry sulphydric acid gas does not act upon cyanogen, but in the moist state, the two gases unite, forming two crystalline compounds, according to the proportions in which they are mixed.

Monosulphhydrate. *Flavcanwasserstoffsäure* (Berzelius). *Sulphoxalcnide* (Laurent). $\text{C}^2\text{N}^2\text{H}^2\text{S} = \text{Cy}^2.\text{H}^2\text{S}$.—This compound is formed when cyanogen and sulphydric acid gas, both moist and the former in excess, are passed into a glass receiver standing over mercury, or into alcohol. Laurent (Compt. chim. 1850, p. 373) passes the two gases (the cyanogen in large excess) into a large bottle moistened with water, and purifies the crystals which form, by recrystallisation from ether.

The compound crystallises in yellow needles having a pungent and afterwards bitter taste. It dissolves in water, alcohol, and ether. The solutions are not acid; they become darker-coloured on standing, and deposit brown flocks, emitting at the same time an odour of prussic acid. Heated with dilute acids or alkalis, it yields oxalic acid, ammonia, and sulphydric acid:

With a strong solution of potash, it forms sulphocyanate and cyanide of potassium:

With silver-salts, it forms sulphide of silver, cyanogen being at the same time set free; from acetate of lead, after a while, it precipitates sulphide of lead.

Disulphhydrate. *Rubcanwasserstoffsäure* (Berzelius). *Sulphoxamide* (Laurent), $\text{C}^2\text{N}^2\text{H}^2\text{S}^2 = \text{Cy}^2.2\text{H}^2\text{S}$.—This compound, which has the composition of oxamide in which the oxygen is replaced by sulphur, is prepared by passing cyanogen gas and excess of sulphydric acid simultaneously into water, or better, into alcohol. The liquid gradually acquires a yellow-red colour, and deposits small crystals of the compound, which may be recrystallised from alcohol. It forms yellow-red shining opaque crystals very slightly soluble in cold water, somewhat more in boiling water, also in alcohol and ether. Strong sulphuric acid dissolves it with yellow colour, and deposits it again unaltered on addition of water. When it is gently heated, a small portion sublimes unaltered, the rest being resolved into sulphide of ammonium

and free carbon. It dissolves without alteration in cold potash; but when boiled with dilute potash, it yields oxalate and sulphide of potassium, together with ammonia:

A similar decomposition takes place when the compound is boiled with hydrochloric acid. Boiled with strong potash-solution it yields cyanide, sulphocyanate, and sulphide of potassium:

The compound is not decomposed by dry hydrochloric acid, or by sulphurous acid or ammonia either dry or aqueous. Chlorine decomposes it with aid of heat, forming chloride of sulphur; with boiling nitric acid, it forms sulphuric acid. The aqueous solution, mixed with nitrate of silver, gives off cyanogen and throws down sulphide of silver. With neutral acetate of lead, it yields an orange-yellow precipitate $\text{C}^2\text{N}^2\text{H}^2\text{Pb}^2\text{S}^2$, which retains its colour when carefully dried, but yields sulphide of lead when boiled with water (Wöhler, Völcckel). With cupric salts it yields a black-green precipitate which resembles the lead-salt in its reactions. With mercuric chloride it forms a thick white precipitate, and gives off hydrochloric acid. (Wöhler.) (For further details respecting these compounds, see *Gmelin's Handbook*, viii. 116.)

CYANOGEN, SULPHIDE OF. See SULPHOCYANIC ANHYDRIDE.

CYANOÏL. $\text{C}^2\text{H}^4\text{N}^2\text{O}$? (Rossignon, *Compt. rend.* xiii. 551.)—A volatile oil produced by the fermentation of pressed almond-cake and of many stone-fruits containing prussic acid. To prepare it, the bruised and moistened almond-cake is spread out on paper till the mass begins to ferment; the fermented mass is carefully distilled; and the distillate, which at first contains a small quantity of acetic acid, is collected in a receiver containing potash-ley. The cyanoil, which floats on the liquid in oily drops, is first treated with chlorine, and then rectified over potash. Cyanoil may also be obtained by fermenting almond-cake with cheese.

Cyanoil is a colourless, oily liquid which smells like bitter almonds, tastes somewhat sharp and astringent, is insoluble in water, and has a specific gravity of 1.009; it burns with a purple-red flame. When exposed to the air, it slowly volatilises without alteration. It is said not to be decomposed by potash, chlorine, bromine, or iodine. It mixes in all proportions with nitric acid, and dissolves camphor, naphthalin, and wax. It is said to contain 69.42 per cent. carbon, 10.54 hydrogen, 13.02 nitrogen, and 7.02 oxygen, numbers which may be represented by the empirical formula above given; but the investigation of this substance is altogether very imperfect.

CYANOLITE. A hydrated silicate of calcium occurring, intergrown with cerinite and centrallassite, in a kidney-shaped mass in the trap of Fundy Bay, a mile to the east of Black Rock, and forming the innermost portion of the mass. It is amorphous, with a fracture varying from flat conchoidal to even. Colour bluish grey; iridescent; opaque in the mass, translucent at the edges. Specific gravity = 2.495. Hardness = 4.5. Soluble in hydrochloric acid, with separation of gelatinous silica. Before the blowpipe it melts on the thin edges, forms clear beads with soda and borax, and a translucent glass with phosphorus-salt.

The analysis gave:

SiO^2	Al^4O^3	Ca^2O	Mg^2O	K^2O	H^2O
72.52	1.24	18.19	trace	0.61	6.91 = 99.47;

agreeing nearly with the formula $14\text{CaO} \cdot 10\text{SiO}^3 + 5\text{H}^2\text{O}$ or $14\text{Ca}^2\text{O} \cdot 5\text{SiO}^2 + 5\text{H}^2\text{O}$. (How, *Edinb. N. Phil. J.* x. 847.)

CYANOSITE, or *Cyanose*. Native sulphate of copper. (See SULPHATES.)

CYANOTOLUIDINE. Syn. with CYANOBENZYLAMINE. (See BENZYLAMINE.)

CYANOTRICHITE. *Lettsonite*, *Samnterz*, *Kupfersamnterz*.—A mineral from Moldawa, in the Bannat, occurring in velvety deposits, consisting of delicate smalt-blue fibres. Two specimens analysed by Percy (*Phil. Mag.* [3] xxxv. 100) gave:

SO^3	Al^4O^3	Fe^4O^3	Cu^2O	H^2O	
15.38		11.70	48.16	23.06	= 98.30
14.12	11.06	1.18	46.59	23.06 insol.	2.35 = 98.36

whence the formula, $6\text{Cu}^2\text{O} \cdot \text{Al}^4\text{O}^3 \cdot 2\text{SO}^3 + 12\text{H}^2\text{O} = \left. \begin{matrix} 12\text{Cu}' \\ 2\text{Al}''' \\ 2(\text{SO}^2)'' \end{matrix} \right\} \text{O}^{11} + 12\text{aq}.$

CYANOUS ACID. The name originally given by Serullas to cyanic acid, on the supposition that it contained only half as much oxygen as the acid then called *cyanic*, but now *cyanuric acid*.

CYANURAMIC ACIDS. *Ameline*, $C^3N^5H^5O$, and *Melanurenic acid*, $C^3N^4H^4O^2$, may be regarded as amic acids of cyanuric acid, both being intermediate in composition between cyanuric acid and cyanuramide or melamine, thus :

Ameline, $C^3N^5H^5O$. (Liebig, Ann. Ch. Pharm. x. 30; lviii. 249. Knapp, *ibid.* xxi. 244. Laurent and Gerhardt, Ann. Ch. Phys. [3] xix. 92.)—This compound, which may also be regarded as composed of 2 at. cyanamide and 1 at. cyanic acid, $2CyH^2N.CyHO$, is produced by boiling melam with dilute sulphuric acid or potash-ley, or by boiling melamine (cyanuramide) with dilute nitric acid. It is precipitated from its solutions by ammonia or carbonate of potassium, as a chalky white powder. It is insoluble in water, alcohol, and ether, but dissolves in caustic alkalis and in most acids. Strong acids and alkalis convert it, first into ammelide, then into cyanuric acid. When heated it gives off ammonia and leaves mellone. Fused with potash, it yields cyanate of potassium (p. 193).

Ameline is a weak base, forming crystalline salts, which are partially decomposed by water. The *nitrate*, $C^3N^5H^5O.HNO^3$, crystallises from solutions containing a slight excess of nitric acid, in long colourless four-sided prisms. When heated in the dry state, it gives off nitric acid and nitrate of ammonia—or the products of its decomposition, nitrous oxide and water—and leaves melanurenic acid :

The *argento-nitrate*, $C^3N^5H^5O.AgNO^3$, obtained by mixing a solution of nitrate of ameline with nitrate of silver, is a white crystalline precipitate.

Melanurenic acid, $C^3N^4H^4O^2 = CyH^2N.2CyHO$. (Liebig and Wöhler, Ann. Ch. Pharm. liv. 371.—G m. ix. 470.)—This body remains, together with cyanuric acid, when urea is subjected to a continuous but moderate heat. On dissolving out the cyanuric acid with water, the melanurenic acid remains as a white chalky powder, insoluble in water, soluble in acids and alkalis, and precipitable therefrom by neutralisation. When heated, it yields ammonia and mellone; and when boiled with acids or alkalis, it gives up ammonia and is converted into cyanuric acid.

Ammelide, $C^6N^6H^6O^3 = 3(CyH^2N.CyHO) = \left. \begin{matrix} Cy^6 \\ H^6 \end{matrix} \right\} N^3$ (Liebig, Ann. Pharm. x. 30; lviii. 249. Knapp, *ibid.* lxix. 244. Laurent and Gerhardt, Ann. Ch. Phys. [3] xix. 94.)—This body, discovered by Liebig in 1834, stands, according to the above formula, intermediate between ammeline and melanurenic acid, just as ammeline does between melamine (cyanuramide) and melanurenic acid, and as melanurenic acid does between ammeline and cyanuric acid (see table above). Gerhardt, however (*Traité*, iv. 888), regards it identical with melanurenic acid. It is obtained by dissolving melam, melamine, or ammeline in nitric, or better, in strong sulphuric acid, and precipitating with alcohol or carbonate of potassium. It is a white powder, insoluble in water, soluble in acids, but does not form definite salts. It dissolves easily in dilute potash, and in boiling aqueous ammonia; and when the latter solution, freed from excess of ammonia by heat, is mixed with nitrate of silver, a precipitate of *ammelidate of silver* is formed, consisting of $C^3N^4H^4AgO^3$.

A solution of this salt in strong nitric acid deposits colourless laminae or tables of *argentonitrate of ammelide*, $C^3N^4H^4O^3.AgNO^3$. The same compound is obtained on mixing a cold saturated solution of ammelide in nitric acid with a solution of nitrate of silver not containing ammonia. The crystals treated with water dissolve, for the most part, leaving white flakes of ammelide. Heated in a tube, it first gives off nitrous vapours, then cyanic acid, and leaves metallic silver.

Ammelide boiled for some time with acids or alkalis is converted into cyanuric acid, and when fused with potash, yields cyanate of potassium.

CYANURAMIDE. *Tricyano-triamide*, *Melamine*. $C^3H^6N^6 = \left. \begin{matrix} Cy^3 \\ H^6 \end{matrix} \right\} N^3$. (Liebig, Ann. Ch. Pharm. x. 18; xxvi. 187.)—This compound, polymeric with cyanamide,

swells up strongly, gives off white fumes of sal-ammoniac, together with nitrogen and hydrochloric acid, and is converted into cyanuric acid. (Wurtz.)

2. Urea is heated till it ceases to give off ammonia, the residue is dissolved in boiling water, and the filtrate is left to crystallise by cooling (Wöhler). As the urea-residue may still contain ammonia and still exhibit colour, it must be dissolved in hot sulphuric acid, nitric acid dropped into the solution till all effervescence ceases and the solution is decolorised, and after cooling, the cyanuric acid precipitated from it by water; it is then obtained as a snow-white crystalline powder; or it may be dissolved in boiling hydrochloric acid, which will deposit the cyanuric acid as it cools; or the pulverised residue may be suspended in water, and chlorine passed through the liquid, whereupon the residue dissolves, forming a solution which deposits cyanuric acid in proportion as the chlorine escapes. (Wöhler and Liebig.)

3. Pulverised urea is saturated with dry hydrochloric acid gas; the compound is heated in the oil-bath to 145°C ., at which temperature it begins to decompose, then taken out, whereupon violent decomposition takes place, and the temperature of the mass rises to 200° ; and the residue is dissolved in hot water, which on cooling deposits white cyanuric acid, whilst sal-ammoniac remains in the solution. If the mass were left in the oil-bath, the compound $\text{C}^{\text{N}}\text{N}^{\text{H}}\text{O}^{\text{S}}$ would be obtained instead of cyanuric acid. (De Vry.)

4. Solid chloride of cyanogen is boiled with a large quantity of water in a flask provided with a long neck, that which sublimes in the neck being continually returned to the liquid by agitation, till the odour of chloride of cyanogen is no longer perceptible. The liquid is then placed in a basin and evaporated nearly to dryness at a gentle heat, the greater part of the hydrochloric acid escaping; the crystallised cyanuric acid is washed on a filter with small quantities of cold water till the water gives, with nitrate of silver, only a slight precipitate which dissolves in nitric acid; the acid is then dissolved in boiling water, and the filtrate evaporated to a certain point, and left to crystallise. (Serullas.)

Properties.—Cyanuric acid crystallises from water in colourless oblique rhombic prisms containing 2 at. water of crystallisation: $\text{C}^{\text{N}}\text{N}^{\text{H}}\text{O}^{\text{S}} + 2\text{H}^{\text{O}}$. The finest crystals are obtained by saturating a solution at the boiling heat, evaporating it at 60° — 80°C ., and leaving it to cool slowly. According to Keferstein (Pogg. Ann. xcix. 275) and Schabus (*Bestimmung*, p. 142), the crystals are monoclinic, exhibiting the faces ∞P . $\infty\text{P}\infty$. oP . $-\text{P}\infty$. $-\frac{1}{2}\text{P}\infty$. Ratio of axes $a : b : c = 0.5728 : 0.7526 : 1$. Inclination of $\infty\text{P} : \infty\text{P}$ in the clinodiagonal principal section = $76^{\circ} 48'$ ($77^{\circ} 13'$ Keferstein); $\text{oP} : \infty\text{P} = 99^{\circ} 59'$; $\text{oP} : -\text{P}\infty = 137^{\circ} 3'$; $\text{oP} : -\frac{1}{2}\text{P}\infty = 151^{\circ} 42'$. Cleavage very distinct parallel to $-\text{P}\infty$; less distinct parallel to oP .

The crystals, exposed to dry air or gently heated, give off their water of crystallisation, amounting to 21.69 per cent., and leave anhydrous cyanuric acid in the form of a white efflorescent mass. The anhydrous acid likewise separates from a hot saturated solution of the acid in nitric or hydrochloric acid. By sublimation it is obtained in delicate needles.

Cyanuric acid is inodorous, has a slightly acid taste, and reddens litmus faintly. It is not poisonous. It is but slightly soluble in cold water (in 40 pts. according to Chevallier and Lassaigue), dissolves in 24 pts. of boiling water, and is insoluble in alcohol.

Decompositions.—1. Cyanuric acid when heated alone is converted into cyanic acid ($\text{C}^{\text{N}}\text{N}^{\text{H}}\text{O}^{\text{S}} = 3\text{CNHO}$), part of the latter being at the same time converted into cyanamide (p. 186) which sublimes (Liebig and Wöhler). When mixed with nitrate of ammonia, it undergoes this change at a lower temperature than when heated alone (Pelouze, Ann. Ch. Phys. [3] vi. 69).—2. By prolonged boiling with nitric or hydrochloric acid, it is resolved into ammonia and carbonic acid (Liebig).—3. Heated with six times its weight of pentachloride of phosphorus, it yields solid chloride of cyanogen and oxychloride of phosphorus (Beilstein, p. 181).—4. Heated with potassium, it yields cyanide and hydrate of potassium, $\text{C}^{\text{N}}\text{N}^{\text{H}}\text{O}^{\text{S}} + \text{K}^{\text{S}} = 3\text{CNK} + 3\text{KHO}$. (Serullas.)

Cyanurates. Cyanuric acid is tribasic, being the analogue of solid chloride of cyanogen. It forms neutral salts, $\text{Cy}^{\text{S}}\text{M}^{\text{O}}\text{O}^{\text{S}}$, of which, however, only the lead and silver salts have been obtained, and acid salts containing 2 at. and 1 at. metal in place of hydrogen, viz. $\text{Cy}^{\text{S}}\text{HM}^{\text{O}}\text{O}^{\text{S}}$ and $\text{Cy}^{\text{S}}\text{H}^{\text{M}}\text{O}^{\text{O}}\text{O}^{\text{S}}$. All the cyanates appear to be crystallisable, even those which are obtained by precipitation appearing crystalline under the microscope. They are decomposed by hydrochloric and nitric acid, with separation of cyanuric acid. The cyanurates of the alkali-metals when heated give off cyanic acid, cyanate of ammonium, carbonic anhydride, and nitrogen, and leave a

residue of cyanate. They are easily soluble in water; the other cyanurates are insoluble, or sparingly soluble.

Cyanurate of Ammonium, $\text{Cy}^3\text{H}^2(\text{NH}^1)\text{O}^3 + \text{aq.}$ (dried in vacuo).—White shining prisms which effloresce in contact with the air, and give off ammonia when heated. They are but slightly soluble in water, the solution smelling of ammonia.

Cyanurate of Barium.—The *monobarytic salt*, $\text{Cy}^3\text{H}^2\text{BaO}^3 + \text{aq.}$, is produced by dropping baryta-water into a boiling solution of the acid as long as the resulting precipitate redissolves. The salt, which is nearly insoluble, gradually separates in small shining prisms. It begins to give off water at 200°C. , and becomes anhydrous and milk-white at 280° .

The *dibarytic salt*, $\text{Cy}^3\text{HBa}^2\text{O}^3 + \text{aq.}$, is obtained, on pouring a hot solution of the acid into an excess of baryta-water, as a pulverulent precipitate composed of microscopic crystals. It is likewise produced on mixing a boiling solution of the acid with chloride of barium and adding ammonia. The free acid does not precipitate either chloride or acetate of barium. At 200°C. it begins to give off water of crystallisation (amounting to 6.3 per cent.), and at a higher temperature, gives off ammonia, then cyanic acid, and leaves fused cyanate of barium.

Cyanurate of Calcium crystallises in nodules. It is easily soluble in water; has a sharp, bitter taste; melts at a gentle heat, and solidifies on cooling in a yellowish waxy mass. It contains 8.6 per cent. lime. (Chevallier and Lassaigue, Ann. Ch. Phys. xiii. 155.)

Cyanurate of Copper.—A definite salt appears difficult to obtain.—*a.* Recently precipitated cupric hydrate added by small portions to hot aqueous cyanuric acid till the liquid is saturated, forms a clear solution, and, on cooling, soon yields a bluish-green crystalline precipitate, which assumes a fine blue colour at 100°C. , and at 250° gives off 9 per cent. water, and changes to pure green just like chromic oxide; it appears to be a basic salt with more than 3 at. copper.—*b.* Crystallised cyanurate of ammonium dissolved in water, forms with cupric sulphate a greenish-blue amorphous precipitate, which when heated becomes crystalline and assumes, first, a blue, then a green colour; it is free from ammonia, but contains sulphuric acid as an essential constituent. The liquid filtered from this precipitate deposits crystallised cyanuric acid.—*c.* When aqueous solutions of cyanuric acid and cupric acetate saturated while hot, are boiled together for some time, a green precipitate is formed containing acetic acid in combination. (Wöhler.)

Cyanurate of Cuprammonium, $\text{Cy}^3\text{H}(\text{NH}^3\text{Cu})^2\text{O}^3 + \text{aq.}$ —A solution of cyanuric acid in very dilute ammonia, mixed while hot with a solution of cupric sulphate in very dilute ammonia, deposits, on cooling, crystals which may be washed with water, inasmuch as they dissolve in it but sparingly. The salt forms small amethyst-coloured crystals, which, when examined by the microscope, appear to be four-sided prisms, with two of the lateral faces broader than the others, and bevelled with two faces. It is permanent in the air, begins to give off ammonia at 100°C. , and at 230° assumes a dark-olive green colour, with loss of 14.85 per cent. At a still higher temperature it suddenly becomes yellow, then takes fire, and glimmers away till it is converted into cupric oxide.

If in the preparation of this salt, the ammonia is not used in too great excess, and the liquids are mixed at the boiling heat, a beautiful peachblossom-coloured crystalline precipitate is formed, which is likewise an ammonio-cupric salt. It dissolves in ammonia, forming an azure-blue solution which soon begins to deposit small crystals having a smalt-blue colour, but changing into the peach-blossom-coloured salt on exposure to the air, from loss of ammonia.

Cyanurates of Copper and Ammonium.—The dark-green salt obtained, as above mentioned, by heating cyanurate of cuprammonium to 230°C. , contains, according to Wöhler, $\text{Cy}^3\text{Cu}^2(\text{NH}^1)\text{O}^3 + \frac{1}{2}\text{aq.}$; according to Gerhardt and Gmelin, $\text{Cy}^3\text{Cu}^2(\text{NH}^1)\text{O}^3$. Wiedemann (Pogg. Ann. lxxiv. 73), by adding a solution of cyanuric acid in excess of ammonia to an ammoniacal solution of cupric sulphate, obtained a violet precipitate of the salt, $\text{Cy}^3\text{HCu}(\text{NH}^1)\text{O}^3$, insoluble in cold water, and sparingly soluble in ammonia.

Cyanurate of Ethyl. See CYANURIC ETHERS.

Cyanurate of Lead, $\text{Cy}^3\text{PbO}^3 + \text{aq.}$, is produced when a boiling solution of cyanuric acid is mixed with a hot solution of neutral, or better, of basic acetate of lead, the salt then separating after a few seconds in the form of a pulverulent precipitate. It is also produced when recently precipitated carbonate of lead is boiled with a large excess of cyanuric acid. In the mass, it exhibits a pale yellowish colour. Under a strong magnifier, it is seen to consist of transparent prisms with obliquely set terminal faces, often united in twins or in fern-like groups. It begins to give off water

at $240^{\circ}\text{C}.$; but the last portions do not go off till the salt is raised to a higher temperature, at which also ammonia begins to escape. When still more strongly heated, it leaves pure protoxide of lead; when heated in a stream of hydrogen, it leaves metallic lead, a large quantity of cyanide of ammonium being formed at the same time together with urea. (Wöhler.)

Cyanurate of Methyl. } See CYANURIC ETHERS.
Cyanurate of Phenyl. }

Cyanurates of Potassium.—The *monopotassic salt*, $\text{Cy}^3\text{H}^2\text{KO}^3$, is obtained by mixing a boiling saturated solution of cyanuric acid with a quantity of potash not sufficient for complete neutralisation: it is then deposited in shining cubes. It is also precipitated on adding acetic or nitric acid by small portions to a strong aqueous solution of cyanate of potassium. Campbell (Ann. Ch. Parm. xxviii. 52) prepares it by roasting ferrocyanide of potassium in an open vessel, digesting the product with a small quantity of water, precipitating the cold solution with hydrochloric acid, and crystallising the precipitated cyanurate from boiling water. It is sparingly soluble in water, and the solution has an acid reaction. 1 at. of this salt ignited with 2 at. hydrate of potassium, yields 3 at. cyanate: $\text{Cy}^3\text{H}^2\text{K}^2\text{O}^3 + 2\text{KHO} = 3\text{CyKO} + 2\text{H}^2\text{O}$ (Liebig). The crystals, when fused, are resolved, without blackening, into cyanate of potassium and cyanic acid vapour, which condenses as cyamelide: $\text{Cy}^3\text{H}^2\text{K}^2\text{O}^3 = \text{CyKO} + 2\text{CyHO}$. (Liebig and Wöhler.)

The *dipotassic salt*, $\text{Cy}^3\text{HK}^2\text{O}^3$, is precipitated on adding alcohol to a solution of the preceding salt in caustic potash. It crystallises in white needles: its solution has an acid reaction, and decomposes after some time into potash and monopotassic cyanurate. Acetic acid added to the solution also throws down the monopotassic salt, so likewise does a small quantity of nitric acid, but a larger quantity precipitates cyanuric acid. The dipotassic salt is decomposed by heat, like the monopotassic salt, into cyamelide and cyanate of potassium: $\text{Cy}^3\text{HK}^2\text{O}^3 = 2\text{CyKO} + \text{CyHO}$. (Liebig and Wöhler.)

Cyanurates of Silver.—The *diargentie salt*, $\text{Cy}^3\text{HAg}^2\text{O}^3$, is obtained:—1. By adding recently precipitated carbonate of silver to a boiling solution of cyanuric acid, in such proportion as not to saturate it completely.—2. By mixing a boiling solution of cyanuric acid with acetate of sodium, and adding this mixture drop by drop to a dilute boiling solution of nitrate of silver, in such proportion as to leave the latter in excess—otherwise the precipitate will be mixed with an insoluble double cyanurate of silver and sodium.—3. By adding a solution of cyanurate of ammonium drop by drop to a boiling solution of nitrate of silver, the latter being kept in excess.—4. By mixing a hot solution of acetate of silver with a boiling solution of cyanuric acid. This last process yields the purest product. The presence of free acetic acid in the solution of the silver-salt does not interfere with the result, as cyanurate of silver is not decomposed by acetic acid, even when concentrated; but it is completely decomposed by dilute nitric acid, and is consequently not precipitated on adding cyanuric acid to nitrate of silver.

Diargentie cyanurate is colourless, crystalline, insoluble in water, and blackens when exposed to light. When examined by the microscope, it appears to be composed of transparent rhombohedrons. At $200^{\circ}\text{C}.$ it neither loses weight nor changes colour; at a higher temperature, it acquires a cinnamon colour, but does not diminish in weight by more than a few thousandths. At a still stronger heat, it emits a strong odour of cyanic acid, acquires a deep violet colour, and finally leaves a residue of metallic silver. In an atmosphere of hydrogen, it is reduced to an argentous salt, even at $100^{\circ}\text{C}.$ It dissolves in nitric acid, but is decomposed at the same time, yielding free cyanuric acid. (Wöhler.)

The *triargentie salt*, $\text{Cy}^3\text{Ag}^3\text{O}^3$, is obtained by adding nitrate of silver to a boiling solution of cyanuric acid in excess of ammonia, boiling the precipitate with the liquid for a quarter of an hour, then filtering, and washing with hot water. (Liebig.)

It is snow-white, and does not blacken when exposed to light; the microscope shows it to consist of small prisms. It is insoluble in water, very slightly soluble in dilute nitric acid. When dried at $100^{\circ}\text{C}.$ it retains $1\frac{1}{2}$ at. water ($2\text{Cy}^3\text{Ag}^3\text{O}^3 + \text{aq.}$), which it appears to retain till heated to $300^{\circ}\text{C}.$ The anhydrous salt absorbs water greedily from the air.

According to Wöhler, the salt gives off ammonia when heated, partly below $100^{\circ}\text{C}.$, but the greater part between 100° and $300^{\circ}\text{C}.$; also when digested with potash; hence Wöhler supposes that the precipitated salt consists of $\text{Cy}^3\text{Ag}^3\text{O}^3.\text{NH}^3 + \frac{1}{2}\text{aq.}$ According to Debus, however, potash does not eliminate ammonia from it, except at a very high temperature.

Cyanurate of Argentammonium, $\text{Cy}^3\text{H}(\text{NH}^3\text{Ag})^2\text{O}^3$, is obtained by digesting diargentie cyanurate with caustic ammonia, whereby it is altered in appearance, but does

not dissolve. The product begins to give off ammonia at 60° C., and between 200° and 300°, is completely reduced to diargentate cyanurate.

Cyanurates of Silver and Ammonium.—The liquid filtered from the precipitate of triargentate cyanurate obtained as above, deposits, on cooling, a white powder consisting of $\text{Cy}^6(\text{NH}^4)_3\text{Ag}^3\text{O}^6 + \text{H}_2\text{O}$, which may be washed and dried at the temperature of the air.* The same salt is obtained by boiling together the solutions of nitrate of silver and cyanurate of ammonium. It crystallises in very slender microscopic prisms. It gives off ammonia when treated with potash, also when heated to a temperature below 100° C. Heated for two hours to 250° C., it gives off ammonia and water, and leaves the salt $\text{Cy}^6[\text{H}^2(\text{NH}^4)\text{Ag}^3]\text{O}^6$, which, at a stronger heat, assumes a violet colour and fumes strongly. Wöhler likewise obtained another salt, which, after drying over sulphuric acid, contained 41.4 p. c. silver. It was soluble in hot dilute ammonia, and separated therefrom on cooling.

Cyanurate of Silver and Lead, $\text{Cy}^3\text{Ag}^2\text{PbO}^3 + \text{aq.}$ —When cyanurate of lead is boiled with a large excess of nitrate of silver, till its appearance is quite altered, a filtrate is obtained, containing a large proportion of lead, the double salt remaining on the filter. The latter, after drying at 100° C., yields, when reduced by hydrogen, 69.64 p. c. of an alloy consisting of 45.94 p. c. silver, and 23.70 lead. (Wöhler.)

Cyanurate of Silver and Potassium.—Diargentate cyanurate boiled with caustic potash is not decomposed, but takes up potassium, forming a double salt which melts and decomposes when heated, leaving a residue of cyanate and carbonate of potassium, together with 60 p. c. silver. The salt $\text{Cy}^3\text{Ag}^2\text{KO}^3$ should leave 55 p. c. silver; the product probably contained unaltered diargentate cyanurate. (Wöhler.)

Cyanurate of Sodium.—Uncrystallisable, very soluble in water.

Cyanurate of Urea?—By dissolving cyanuric acid in a boiling saturated solution of urea, and cooling the liquid, delicate needles are obtained. (Kodweiss, Pogg. Ann. xix. 11.)

CYANURIC ETHERS. (Wurtz, Compt. rend. xxvi. 368; xxvii. 341; Ann. Ch. Phys. [3] xlii. 43; l. 120. Limpricht, Ann. Ch. Pharm. lxxiv. 208. Limpricht and Habich, *ibid.* cv. 395. Gerhardt, Compt. chim. 1850, p. 391.)—Three of these compounds are known, analogous in composition to the trimetallic cyanurates, and one analogous to the dimetallic cyanurates. They are crystalline solids which distil without decomposition, and react with alkalis in the same manner as the cyanic ethers, yielding an alkaline carbonate and an amine.

CYANURATES OF ETHYL.—*a. Triethyllic Cyanurate. Neutral Cyanuric ether,*

$\text{C}^9\text{N}^3\text{H}^{15}\text{O}^3 = \left\{ \text{C}^2\text{H}^5 \right\}_3 \left\{ \text{CO} \right\}_3 \text{O}^3$, or *Triethyl-tricarbonyl-triamide*, $\text{N}^3 \left\{ \left\{ \text{CO} \right\}_3 \right\}_3 \left\{ \text{C}^2\text{H}^5 \right\}_3$.—This compound, discovered by Wurtz, is obtained by distilling a mixture of ethylsulphate and cyanate or cyanurate of potassium; or by heating cyanate of silver, either neutral or acid, with iodide of ethyl to 120° C., and lastly, by molecular transformation of the cyanate in contact with triethylphosphine. (Hofmann, Chem. Soc. Qu. J. xiii. 322.)

When a mixture of equal parts of ethylsulphate of potassium and dipotassic cyanurate (p. 291) is heated in a retort, cyanurate of ethyl distils over, together with carbonate of ammonium, ethylamine, cyanide of ethyl, and other secondary products, and condenses in the neck of the retort and in the receiver, as a crystalline mass, which may be purified by repeated crystallisation from dilute alcohol.—On distilling the ethylsulphate with cyanate of potassium, an acid liquid distillate is obtained, consisting of cyanurate and cyanate of ethyl (p. 195). The latter, which is very volatile, may be distilled off at 60° C., and the crystalline cyanurate which remains may be purified by recrystallisation from alcohol. This process, according to Wurtz, is easier than the former.

Triethyllic cyanurate crystallises in trimetric combinations, $\infty \text{P} . \infty \tilde{\text{P}} \infty . \tilde{\text{P}} \infty$. Inclination of $\infty \text{P} : \infty \text{P} = 128^\circ$; $\tilde{\text{P}} \infty : \tilde{\text{P}} \infty$ over the principal axis = 93.5° . Ratio of axes, $a : b : c = 0.4877 : 1 : 0.9407$. It melts at 95° C. to a colourless liquid heavier than water, volatilises easily with vapour of water, and boils without decomposition at 235° C. Vapour-density, obs. = 7.4; calc. (2 vol.) = 7.37. It is slightly soluble in water, easily in alcohol and ether. The solutions are perfectly neutral. From the cold alcoholic solution, it is precipitated in the crystalline form by water.

Triethyllic cyanurate dissolves easily and without decomposition in acids, even in hot concentrated nitric acid. It is not altered by heating with pentachloride of phos-

* Wöhler, regarding cyanuric acid as dibasic, gave for this salt the formula: $3\text{AgO} . \text{C}^6\text{N}^3\text{HO}^4 + 3\text{NH}^4 . \text{O} . \text{C}^6\text{N}^3\text{HO}^4$, or $\text{AgO} . \text{Cy}^3\text{Ag}^2\text{HO}^6 + \text{NH}^4 . \text{O} . \text{Cy}^3(\text{NH}^4)^2\text{HO}^6$.

phorus. It is decomposed by boiling with *alkalis*, the ultimate products of the reaction being ethylamine and a carbonate of the alkali-metal :

Intermediate products are, however, formed, which are obtained in the greatest degree of purity by heating the cyanuric ether with baryta-water. Carbonate of barium then separates, and on removing the excess of baryta from the solution by means of carbonic acid, there remains a liquid sparingly soluble in water, easily in alcohol and ether, and composed of $\text{C}^8\text{H}^{17}\text{N}^3\text{O}^2$. (Limpricht and Habich.)

This body heated to 170° — 200° C. is resolved into cyanate of ethyl and diethyl-carbamide, the latter distilling over at 250° .

Cyanurate (and sometimes also cyanate, p. 196) of ethyl, heated with dry *ethylate of sodium*, yields, together with ethylene, a distillate containing alcohol, ethylamine, and hydrate of triethyl-carbotriamine, $\text{C}^8\text{H}^{19}\text{N}^3\text{O} = \text{N}^3[\text{C}^1\text{H}_4(\text{C}^2\text{H}^3)^3\text{H}^2]\text{H}^2\text{O}$ (Hoffmann, *Compt. rend.* lii. 1290). The formation of this compound may be represented by the equation,

The formation of Limpricht's compound, $\text{C}^8\text{H}^{17}\text{N}^3\text{O}^2$, of hydrate of triethylcarbotriamine, and of ethylamine (3 at.) from triethylic cyanurate, may be supposed to take place by the successive subtraction of CO^2 and addition of H^2O .

Tetrachloro-triethylic Cyanurate, $\text{C}^8\text{H}^{11}\text{Cl}^4\text{N}^3\text{O}^3$, is produced, with elimination of hydrochloric acid, when triethylic cyanurate is heated to 150° C. in dry chlorine gas. It is a hard solid body, perfectly transparent, but rarely crystalline; melts to a mobile liquid when heated; and may be distilled without decomposition. Its alcoholic solution mixed with alcoholic potash, even in the cold, yields chloride and carbonate of potassium, together with the compound $\text{C}^8\text{H}^{11}\text{Cl}^2\text{N}^3\text{O}^2$, which, when the excess of alcohol has been removed by evaporation, remains as a viscid mass. (Limpricht and Habich.)

Diethylic Cyanurate, *Diethylicyanuric acid*, *Cyanuric ether*, $\text{C}^8\text{H}^{11}\text{N}^3\text{O}^3 =$

$\frac{\text{Cy}^3}{\text{H}(\text{C}^2\text{H}^3)^2} \text{O}^3$; or *Diethyl-tricarboxyl-triamide* $= \frac{(\text{CO})^3}{\text{H}(\text{C}^2\text{H}^3)^2} \text{N}^3$.—This compound is obtained, together with the preceding, by distilling a mixture of cyanurate and ethylsulphate of potassium. It passes over when the heat is raised, towards the end of the distillation, and remains in the mother-liquor after the triethylic cyanurate has crystallised out; but on evaporating this mother-liquor to dryness, boiling the residue with baryta-water as long as volatile bases are given off, removing the baryta with sulphuric acid, and leaving the filtrate to evaporate, the diethylic cyanurate separates in crystals (Limpricht).—Wurtz obtained this compound in the preparation of diethyl-carbamide.

Diethylic cyanurate crystallises from alcohol in rhombohedrons, or in six-sided prisms with rhombohedral summits. It melts at 173° C., and volatilises without decomposition at higher temperatures. It is easily soluble in *alcohol*, *ether*, and *hot water*, the aqueous solution having an acid reaction. It dissolves readily also in *alkalis*, but does not form definite salts with them. It does not alter in weight when immersed either in *ammonia* or in *hydrochloric acid gas*. When heated with *potash*, it gives off ethylamine and ammonia. *Baryta-water* decomposes it in like manner at a temperature above 100° C.

Diethylicyanurate of Silver, $\text{C}^8\text{H}^{10}\text{AgN}^3\text{O}^3$, is precipitated in white needles on mixing an ammoniacal solution of the acid with nitrate of silver. *Diethyl-cyanurates of mercurousum, cupricum, and lead*, are obtained in like manner. The lead-salt distilled with ethylsulphate of potassium, yields triethylic cyanurate. (Limpricht and Habich.)

CYANURATE OF METHYL, $\text{C}^6\text{N}^3\text{H}^9\text{O}^3 = \frac{\text{Cy}^3}{(\text{CH}^3)^3} \text{O}^3$, or *Trimethyl-tricarboxyltriamide*,

$\frac{(\text{C}^{\text{O}})}{(\text{CH}^3)^3} \text{N}^3$. Prepared, like triethylic cyanurate, by distilling methyl-sulphate of

potassium with cyanurate or cyanate of potassium, and purified by crystallisation from alcohol. It is likewise formed by molecular transformation of methylic cyanate when kept in sealed tubes. It forms small, colourless, opaque prisms, which melt at 175° — 176° C., and boil at 274° (higher than the ethyl-compound). It is insoluble in cold water, slightly soluble in hot water, easily in alcohol. Vapour-density (obs.) = 5.98 (cal. 2 vol. = 5.94).—Boiled with *potash*, it yields methylamine. (Wurtz.)

CYANURATE OF PHENYL, $C^6H^5N^3O^3 = Cy^3(C^6H^5)^3O^3$. Produced by molecular transformation of the cyanate (p. 197), in contact with triethylphosphine. The mixture on cooling solidifies to a mass of shining crystals, which are insoluble in water, nearly insoluble in ether, and dissolve with difficulty in alcohol, even at the boiling heat. (Hofmann, Chem. Soc. Qu. J. xiii. 322.)

CYANURIN. This name is applied to a pathological blue deposit, sometimes found in urine (*q. v.*)

CYANYL. This name is applied by Boutin (Compt. rend. x. 452; xi. 820) to a product which he obtained, together with aloetic, chrysammic, and picric acids, by oxidising aloes with nitric acid. He describes it as a colourless liquid, smelling like prussic acid, insoluble in water, heavier than water, distilling without decomposition at a high temperature, and very poisonous.

CYANYLIC ACID. $CN^3H^3O^3$. (Liebig, Ann. Ch. Pharm. x. 32.) An acid isomeric with cyanuric acid. It is obtained by dissolving mellone in boiling nitric acid, either dilute or concentrated, leaving the solution to cool till it crystallises, freeing the crystals from nitric acid by cold water, and then recrystallising from hot water. Cyanuric acid is often mixed with the product, but always crystallises out first.

The acid crystallises in combination with water, in long, transparent, colourless, rhombic prisms, or in broad laminae having a pearly lustre.

The crystals effloresce when exposed to the air. The acid, like cyanuric acid, volatilises in the form of cyanic acid when heated.—By solution in strong sulphuric acid, and precipitation by water, it is converted into cyanuric acid, and no longer exhibits the pearly lustre above mentioned, after crystallisation from water. It dissolves in water somewhat more readily than cyanuric acid; and the hot saturated aqueous solution solidifies almost wholly in a laminated mass on cooling.

All the *Cyanylates*, *e. g.* those of the fixed alkali-metals and alkaline-earth-metals, are completely decomposed by the stronger acids, so that as the liquid cools, the cyanylic acid crystallises out in the free state.

Cyanylic acid neutralised with ammonia, forms with nitrate of silver a white, tumefied precipitate, which after drying is pulverulent, amorphous, and contains 45.36 per cent. of silver; but the precipitate obtained with cyanylate of potassium has the composition of cyanurate of silver, probably because the potash converts the cyanylic acid into cyanuric.

CYCLAMEN EUROPEUM. *Sow-bread*.—A small plant of the primulaceous order, forming flat round tubers, which, in addition to the ordinary constituents of plants, contain, according to Saladin, arthanitin (i. 412), according to De Luca, cyclamin and mannite. The juice of the tubers is harmless to most animals, though small fishes die when immersed in water containing only $\frac{1}{3000}$ of it; but when introduced into the blood it acts as a powerful poison, like curara, only not so strongly (Bernard); bromine is found to be an antidote to it, as well as to curara.

CYCLAMIN. A non-azotised glucoside, extracted from the tubers of *Cyclamen europeum*, and constituting the poisonous principle of that plant. Saladin (J. Chim. med. vi. 417) obtained from *Radices arthanite*, the official roots of *Cyclamen europeum*, an impure substance called arthanitin or cyclamin (i. 412), but the substance to which the latter name is now applied was first prepared by De Luca (*Cimento nuovo*, v. 225; viii. 182) and Martius (Buchner's N. Repert. [1859] viii. 388).

Preparation.—The tubers, cleansed and cut in pieces, are macerated for about six weeks with rather less than their own weight of rectified spirit, in the dark and in a cool place, then pressed; the residue again treated for about a month with a somewhat smaller quantity of alcohol; and the second residue again submitted to the same treatment. On filtering off the alcoholic liquid, a gelatinous substance remains, which is to be evaporated over the water-bath in the dark, and then exhausted with alcohol. The filtered solution left to evaporate in the dark, leaves cyclamin in small amorphous lumps, which may be washed with cold alcohol and dissolved in boiling alcohol; the solution on cooling deposits cyclamin.

Properties.—Cyclamin is a white, amorphous, neutral, inodorous substance, producing, after a short time, a very irritating sensation in the throat. It turns brown when exposed to light, absorbs water from moist air to the amount of about half its weight, and swells up. In contact with cold water, it is converted into a translucent glutinous

substance, which dissolves slowly, forming a liquid which has a slight optical lævoro-rotatory power, froths when agitated, and coagulates like white of egg at 60°—75° C.; the coagulum redissolves when left for some days in the cold, and is reproduced on heating.

The formula of cyclamin is not yet fixed. De Luca deduces from his own analysis the empirical formula $\text{nC}^2\text{H}^4\text{O}$; Martius, from Klinger's analysis, calculates the formula $\text{C}^{30}\text{H}^{34}\text{O}^{10}$.*

	Calculation.		Analyses.	
	$\text{C}^2\text{H}^4\text{O}$	$\text{C}^{30}\text{H}^{34}\text{O}^{10}$	De Luca.	Klinger.
Carbon	54.5	55.2	54.5	55.2
Hydrogen	9.1	7.8	9.1	7.8
Oxygen	36.4	37.0	36.4	37.0
	100.0	100.0	100.0	100.0

Cyclamin dissolves readily in alcohol at a gentle heat, and separates again in the amorphous state on cooling or evaporation; it is insoluble in wood-spirit, glycerin, ether, chloroform, sulphide of carbon, volatile oils, and alkalis.

A solution of cyclamin exposed to light in a sealed tube, deposits a white amorphous substance, which redissolves at a moderate heat. Moist cyclamin produces a large crop of cryptogamous plants, among which is a new alga, *Hygrocrocis Cyclaminae*.

The aqueous solution of cyclamin absorbs chlorine and bromine, and is coagulated thereby without colour; neither is it coloured by iodine. Hydrochloric acid dissolves it in the cold, and coagulates it at about 80° C. with formation of sugar. Strong sulphuric acid forms with it a yellow liquid, which turns violet after a while, and yields a white precipitate with water. Acetic acid dissolves it in the cold, and does not coagulate it when heated. Nitric acid decomposes it in the cold, and more quickly when heated, forming acid products which have not been examined. Fused with hydrate of potassium, it gives off hydrogen and forms a peculiar sparingly soluble acid. Cyclamin does not reduce an alkaline solution of cupric tartrate. It does not ferment with yeast. Synaptase at 30°—35° C. decomposes it, forming a solution which contains a non-fermentable sugar (De Luca). According to Martius, cyclamin boiled with dilute acids takes up water and is converted into glucose and cyclamiretin, a body not examined:

CYCLAMIRETIN. See above.

CYCLOPITE. A felspathic mineral, discovered by Waltershausen in the dolerite of a cyclopien rock, near Catania. It forms very small, white, translucent, lozenge-shaped prisms belonging to the trimetric system, the form of which closely resembles that of Anorthite and Labrador. The mean of two analyses gave:—

SiO_2	Al_2O_3	Fe_2O_3	Ca_2O	Mg_2O	Na_2O	K_2O	H_2O
41.45	29.83	2.20	20.83	0.65	2.32	1.71	1.91 = 100.90;

leading to the formula $3(2\text{M}^2\text{O}.\text{SiO}_2) + 2(2\text{Al}^3\text{O}_3.3\text{SiO}_2)$ or $3\text{MO}.\text{SiO}_3 + 2(\text{Al}^2\text{O}_3.\text{SiO}_3)$ (Jahresber. d. Chem. 1853, p. 811). If in the first formula ($\text{M}^{12}\text{Al}^6\text{Si}^9\text{O}^{36}$) we substitute $\text{al} = \frac{2}{3}\text{Al}$, it becomes $3\text{M}^4\text{al}^2\text{Si}^3\text{O}^{12}$ which is reducible to that of an orthosilicate, R^4SiO_4 .

CYMENE or **CYMOL**. $\text{C}^{10}\text{H}^{14} = \text{C}^{10}\text{H}^{13}.\text{H}$. *Cymin*, *Camphogen*, *Hydride of Cymyl* or *Thymyl*.—A hydrocarbon discovered in 1840 by Gerhardt and Cahours (Ann. Ch. Phys. [3] i. 102, 372; Ann. Ch. Pharm. xxxviii. 101, 345). It occurs, together with hydride of cumyl, in the volatile oil of Roman cumin, obtained from *Cuminum Cuminum* (Gerhardt and Cahours); in the seed of the water-hemlock, *Cicuta virosa* (Trapp, Ann. Ch. Pharm. cviii. 386); in oil of thyme (Lallemand, Ann. Ch. Phys. [3] xlix. 156); and, according to Haines (Chem. Soc. Qu. J. viii. 289), in the volatile oil of *Ptychotis Ajowan*; according to Stenhouse, however, this oil contains, not cymene, but a camphene, $\text{C}^{10}\text{H}^{16}$.

Formation.—By the dehydration of common camphor with phosphoric anhydride (Delalande, Ann. Ch. Phys. [3] i. 368) or with chloride of zinc (Gerhardt):

2. By the action of hydrate of potassium on *cymylic alcohol* (Kraut, *Dissertation über Cuminol und Cymen*. Göttingen, 1854).—3. By the action of iodine or nitric acid on *wormseed-oil* (Hirzel, Zeitschr. Pharm. 1854, pp. 23, 67; 1855, pp. 84, 181; see

* In Martius' paper the formula is $\text{C}^{20}\text{H}^{24}\text{O}^{10}$, probably a misprint.

also WORMSEED-OIL).—4. By the dry distillation of *coal*, passing over, partly in the lighter, but more abundantly in the heavy oil of coal-tar. The latter yields it by rectification between 170° and 180° C. (Mansfield, Chem. Soc. Qu. J. i. 244).—5. By treating *caoutchou* or oil of turpentine with bromine and sodium alternately (Gr. Williams, Phil. Mag. [4] xxxii. 15).—6. By the action of moist carbonic acid gas at a red heat on oil of turpentine, an oil is produced having the composition of cymene (Deville, Ann. Ch. Phys. [2] lxxv. 66):

7. Oil of wormwood distilled with phosphoric anhydride and then with potassium yields an oil isomeric, if not identical, with cymene.

Preparation.—1. From oil of Roman cumin.—When this oil, which is a mixture of cymene and hydride of cumyl (p. 182), is distilled, the cymene passes over first. It cannot, however, be obtained quite pure by simple distillation, as a portion of the hydride of cumyl always passes over with it; the separation may, however, be effected by rectifying the first portions of the distillate with melting potash, which takes up the hydride of cumyl, converting it into cuminate of potassium, and allows the cymene to pass over free (Noad, Phil. Mag. [3] xxxii. 15). A better mode of separation is to shake up the oil with a strong solution of acid sulphite of potassium or sodium, which unites with the hydride of cumyl, forming a crystalline compound and leaves the cymene free (Kraut, Bertagnini). Noad obtained 7 oz. of cymene from 1 lb. of oil of cumin.—2. In like manner cymene may be obtained from the oil of *water-hemlock seed*, by separating the hydride of cumyl by means of acid sulphite of sodium, pressing the oily residue, and distilling.—3. From *camphor*, it is obtained by distillation with phosphoric anhydride, or better, with fused chloride of zinc. A few pieces of this substance are placed in a capacious retort, and heated till they melt into a pasty mass. The camphor is then added by small portions, whereupon the mixture swells up and blackens, and a liquid passes over containing a considerable quantity of camphor, from which it may be freed by a fresh distillation over chloride of zinc. This process yields a considerable quantity of cymene with the use of a comparatively small quantity of chloride of zinc.

Properties.—Colourless strongly refracting liquid, having a very agreeable odour of lemons; that which is prepared from camphor has a somewhat camphorous odour. Specific gravity = 0.857 at 16° C. (Noad); 0.861 at 14° C. (Gerhardt); 0.8678 at 12° C., and 0.8778 at 0° C. (Kopp). It boils at 171.5° C. (Noad); 175° C. (Gerhardt and Cahours); 177.5° C. (Kopp). Vapour-density 4.59 to 4.70 (Gerhardt and Cahours), by calculation (2 vol.) = 4.64. It is permanent in the air, insoluble in water, but dissolves readily in alcohol, ether, and oils, both fixed and volatile.

Decompositions.—1. Cymene is not attacked by strong sulphuric acid in the cold, but fuming sulphuric acid dissolves it, producing cumyl-sulphurous acid, $\text{SO}_2\text{C}^{10}\text{H}^{13}\text{H}$.—2. Nitric acid of ordinary strength does not attack it in the cold; but on heating the mixture, red vapours are evolved, and the cymene is ultimately converted into toluyllic, and ultimately into nitrotoluyllic acid. With fuming nitric acid the action is very violent, and a yellow resin is formed at the same time (Gerhardt and Cahours). If the nitric acid and the cymene are carefully cooled by immersion in a mixture of ice and salt, and the cold cymene is then added by drops to the nitric acid, nitrocymene, $\text{C}^{10}\text{H}^{13}(\text{NO}_2)$ is produced (Barlow)*. A mixture of sulphuric and nitric acid converts it, with aid of heat, into dinitrocymene, $\text{C}^{10}\text{H}^{12}(\text{NO}_2)_2$ (Kraut, Ann. Ch. Pharm. xcii. 70).—3. Caustic potash has no action on cymene.—4. Chlorine and bromine attack it in the cold, forming chlorinated and brominated compounds which are decomposed by distillation (Gerhardt and Cahours).—5. Chromic acid converts it into insolinic acid, $\text{C}^9\text{H}^8\text{O}^4$ (Hofmann, Ann. Ch. Pharm. xevii. 197):

Derivatives of Cymene.

NITROCYMENE. $\text{C}^{10}\text{H}^{13}\text{NO}_2$. When cymene cooled by a freezing mixture is cautiously dropped into nitric acid likewise cooled, the mixture first turns brown, then green, and at length acquires the consistence of cream; and by washing it with water, and afterwards with dilute carbonate of sodium, nitrocymene is obtained as a reddish-brown, oily liquid, heavier than water. It is not altered by contact with the air, but when

* In the preparation of cymylamine by the action of ferrous acetate on nitrocymene (p. 297), Barlow likewise obtained an oil insoluble in hydrochloric acid, and exhibiting, after repeated distillation, the composition and boiling point (175°) of cymene. It differed however from ordinary cymene in this respect, that the nitro-cymene obtained from it by the action of nitric acid floated on water, whereas ordinary nitrocymene is heavier than water. For this reason Barlow distinguishes the cymene and nitrocymene thus obtained as α -cymene and α -nitrocymene. Further investigation is however required to establish the distinction.

distilled it yields an oil which floats on water. By the action of ferrous acetate it is converted into cymylamine. (Barlow, Ann. Ch. Pharm. xcviii. 245.)

DINITROCYMENE. $C^{10}H^{12}(NO_2)^2$. When cymene is added drop by drop to a mixture of 2 pts. strong sulphuric acid and 1 pt. fuming nitric acid heated to about $50^\circ C.$, and water added after the mixture has been left to itself for an hour or two, a liquid is deposited which solidifies after a while; and on dissolving this product in boiling alcohol, the uncrystallisable portion is deposited on cooling, and dinitrocymene crystallises out on evaporation. It forms rhombic, iridescent tablets, melting at $54^\circ C.$, soluble in alcohol and ether, insoluble in water. From saturated solutions, it is deposited as an oil. When heated in the air, it decomposes with deflagration, leaving a residue of charcoal. (Kraut, Ann. Ch. Pharm. xcii. 70.)

CYMENE, BROMIDE OF. $C^{10}H^{14}Br^2$ or perhaps $C^{10}H^{13}Br.HBr$. When cymene is mixed with water and bromine till the colour of the latter disappears, and the product is washed with soda-solution and with water, bromide of cymene is obtained, as a transparent, colourless, oily liquid, insoluble in water, and but slightly soluble in alcohol. It turns yellow by keeping, giving off hydrobromic acid. It cannot be distilled without decomposition. When boiled with alcoholic potash, it yields a colourless oil, very much like cymene; perhaps $C^{10}H^{12}$. (Sieveking, Ann. Ch. Pharm. xcviii. 245.)

CYMENE, CHLORIDE OF. $C^{10}H^{14}Cl^2$ or perhaps $C^{10}H^{13}Cl.HCl$. Obtained by passing chlorine gas into water on which cymene floats. It resembles the bromide. Fuming sulphuric acid decomposes it, with evolution of hydrochloric acid, forming a red-brown mass, which when diluted with water forms a solution of cymyl-sulphurous acid. (Sieveking, *loc. cit.*)

When cymene is repeatedly distilled in dry chlorine gas, hydrochloric acid is evolved, and an oil containing 10.7 p. c. chlorine passes over between 170° and $230^\circ C.$ (Sieveking.)

CYMENE-SULPHURIC ACID. Syn. with CYMYL-SULPHUROUS ACID (p. 298).

CYMIID. Löwig's name for cymyl, $C^{10}H^{13}$.

CYIMIDINE. Syn. with CYMYLAMINE.

CYMIN. Syn. with CYMENE.

CYMINIC ACID. Syn. with CUMINIC ACID.

CYMO-GLYCOL. Syn. with CUMO-GLYCOL.

CYMOL. Syn. with CYMENE.

CYMOPHANE. Syn. with CHRYSOBERYL (i. 958).

CYMYL. $C^{10}H^{13}$. The radicle of cymene, cymylic alcohol, &c. The *chloride* $C^{10}H^{13}Cl$ is produced by passing hydrochloric acid gas into cymylic alcohol (Rossi), perhaps also by the action of chlorine on cymene; the *bromide* also by the action of bromine on cymene. (Sieveking.)

CYMYLAMINES. Ammonia-bases containing 1, 2, or 3 at. cymyl in place of hydrogen. Monocymylamine was discovered by Barlow in 1855 (Phil. Mag. [4] x. 454; Ann. Ch. Pharm. xcviii. 245); the other two by Rossi (Compt. rend. li. 570). They are all produced by the action of ammonia on chloride of cymyl; monocymylamine also by the action of reducing agents on nitrocymene.

When a mixture of chloride of cymyl and strong alcoholic ammonia is heated for some hours in a sealed tube placed in the water-bath and then left to cool, sal-ammoniac separates, together with a few drops of oily tricymylamine. The liquid filtered and evaporated leaves a crystalline residue consisting of the hydrochlorates of cymylamine and dicymylamine, mixed with oily tricymylamine, which may be dissolved out by ether, and remains, after evaporation of the ether, as an oil which may be made to crystallise by agitation.—The hydrochlorates of the other two bases are separated by fractional crystallisation from water, the hydrochlorate of dicymylamine being much less soluble in water than the cymylamine-salt. The bases are separated from the hydrochlorates by distillation with potash.

Cymylamine. $C^{10}H^{15}N = N.H^2.C^{10}H^{13}$.—*Monocymylamine, Cymidine* (Barlow), *Cuminamine primaire* (Rossi). Barlow prepares this base by distilling nitrocymene with iron-filings and acetic acid, the mixture being made up to a stiff paste. A distillate of complex character is then obtained, a considerable portion of which is insoluble in hydrochloric acid. From the portion which dissolves in that acid, soda throws down cymylamine, which, after agitation with ether and evaporation of the ethereal solution, separates as a brown oil, which cannot be distilled without alteration, except in an atmosphere of hydrogen.

Cymylamine is a colourless oily liquid which does not solidify in a mixture of ice

298 CYMYLIC ALCOHOL—CYMYL-SULPHUROUS ACID.

and salt (Rossi). It is lighter than water, inodorous, and without action on litmus paper (Barlow). It is volatile at ordinary temperatures, and produces white fumes on the approach of a rod moistened with hydrochloric acid. It begins to boil at about 280°C ., with partial decomposition. Boils at about 250°C . (Barlow). It is slightly soluble in water, easily in alcohol and ether.

Cymylamine is violently attacked by *nitric acid*, and on adding soda to the liquid, a semi-solid substance is separated. *Bromine* acts but slightly on cymylamine, iodine not at all. *Chloride of cyanogen* appears to form with cymylamine, a base corresponding to melaniline. *Chloride of benzoyl* forms, with cymylamine, small crystals probably consisting of benzoyl-cymylamine. Cymylamine absorbs *carbonic acid* from the air, forming a solid compound. (Rossi.)

Hydrochlorate of Cymylamine, $\text{C}^{10}\text{H}^{15}\text{N.HCl}$, is formed by mixing the base with strong hydrochloric acid, as an oily layer, which crystallises on agitation or evaporation (Barlow), in nacreous rhomboidal laminae (Rossi). It colours deal-shavings yellow, but does not exhibit any particular reaction with hypochlorite of calcium. Its solution colours the skin red. (Barlow.)

Chloroplatinate of Cymylamine, $\text{C}^{10}\text{H}^{15}\text{N.HCl.PtCl}_2$, is yellow, sparingly soluble in water, more soluble in alcohol, and still more in ether. The *chloro-aurate* is yellow, crystalline, sparingly soluble in water.

The *Sulphate and Oxalate of Cymylamine* are white, crystalline, soluble in water. (Barlow.)

Dicymylamine, $\text{C}^{20}\text{H}^{27}\text{N} = \text{N.H.}(\text{C}^{10}\text{H}^{13})_2$.—*Cuminamine secondaire*. Dense, colourless, oily liquid, beginning to boil with decomposition above 300°C . Insoluble in water, soluble in alcohol and ether. The *hydrochlorate* crystallises in needles slightly soluble in cold water.—The *chloroplatinate* is sparingly soluble in cold water, and crystallises from alcoholic solution in small roseate needles. (Rossi.)

Tricymylamine, $\text{C}^{30}\text{H}^{39}\text{N} = \text{N.}(\text{C}^{10}\text{H}^{13})_3$.—*Cuminamine tertiaire*. Crystallises in small rhomboidal laminae, which melt at 81° — 82°C . Insoluble in water, very soluble in ether and in boiling alcohol, slightly in cold alcohol. It does not affect the colour of litmus. The *hydrochlorate*, which crystallises in needles grouped in crosses, is nearly insoluble in water, very soluble in alcohol.—The *chloroplatinate* crystallises with difficulty; the alcoholic solution deposits it as a viscous mass which solidifies on drying. (Rossi.)

CYMYL-DITHIONIC ACID. Syn. with CYMYL-SULPHUROUS ACID.

CYMYLIC ALCOHOL. $\text{C}^{10}\text{H}^{14}\text{O} = \text{C}^{10}\text{H}^{13}.\text{H.O}$. *Hydrate of Cymyl. Cuminic Alcohol.* (Kraut, *Dissertation über die Derivate des Cuminols und des Cymens*. Göttingen, 1854. Ann. Ch. Pharm. xcii. 66.)—This compound, which is isomeric with hydrate of thymyl (oil of thyme), is produced by the action of alcoholic potash on hydride of cumyl:

When hydride of cumyl is boiled for about an hour with several times its volume of alcoholic potash, in an apparatus which allows the condensed vapours to flow back again, the potash is converted into cuminate, and on adding water to the liquid, an oil separates, consisting of cymylic alcohol and cymene, the latter being produced by a secondary reaction (*vid. inf.*). The oil is agitated with acid sulphite of sodium, to separate any remaining hydride of cumyl, then dried and subjected to fractional distillation.

Properties.—Colourless liquid, having a very faint but agreeably aromatic odour, and a sharp spicy taste. It boils at 243°C . without decomposition, and is not acidified by prolonged contact with the air. It is insoluble in water, but soluble in all proportions in alcohol and ether.

Decompositions.—1. Heated with *potassium*, it evolves hydrogen and forms a granular mass, decomposed by water into potash and cymylic alcohol.—2. Heated with *nitric acid*, it is converted into cuminic acid.—3. Strong *sulphuric acid* transforms it into a resinous brittle substance which becomes semifluid in boiling water.—4. By boiling with *alcoholic potash*, it is converted into cuminate of potassium and cymene:

It does not combine with the acid sulphites of the alkali-metals.

CYMYL-SULPHUROUS ACID. $\text{C}^{10}\text{H}^{11}\text{SO}^3 = \text{C}^{10}\text{H}^{13}\text{H}\left\{ \begin{array}{c} (\text{SO})'' \\ \text{O}^2 \end{array} \right\}$. *Cymene-sulphuric, Cymol-sulphuric, Sulphocymenic, Sulphocymylic, Camphogene-sulphuric, Sulphocamphic, Thymyl-sulphurous acid. Cymyl-dithionic acid* $= \text{HO.C}^{20}\text{H}^{13}\text{S}^2\text{O}^5$ (Kolbe).—

This acid, first obtained by Gerhardt and Cahours (Ann. Ch. Phys. [3] i. 106) from cymene, and almost at the same time by Delalande (*ibid.* i. 368), has been further examined by Sieveking (Ann. Ch. Pharm. cvi. 257). It is produced by the action of fuming sulphuric acid on cymene, and perhaps also on chloride of cymene (p. 297). To prepare it, cymene is dissolved in a slight excess of fuming sulphuric acid, no sulphurous acid being then evolved if the mixture is kept cool; the liquid is diluted with water, saturated with carbonate of lead, and filtered; and the solution of cymylsulphite of lead is evaporated to the crystallising point. The aqueous solution of the crystals decomposed by sulphydric acid and evaporated in vacuo after filtration, yields the acid. As the solution of the lead-salt is apt to decompose during evaporation, and leave a dark brown mass, the solution of which is not decolorised by sulphydric acid, it is better, according to Sieveking, to decompose the barium-salt with sulphuric acid, remove the excess of that acid by carbonate of lead, and the dissolved lead by sulphydric acid.

The acid is obtained, by evaporating its aqueous solution, in small deliquescent crystals. Fuming nitric acid converts it into nitrocymyl-sulphurous acid, the salts of which detonate when heated. (Church, Phil. Mag. [4] ix. 256.)

The cymylsulphites are all soluble in water.

Cymylsulphite of Barium, $C^{10}H^{13}BaSO_3$, crystallises with 1, $1\frac{1}{2}$, and 2 at. water. The hydrated salts have a fine nacreous lustre, and a bitter taste, with nauseously sweet aftertaste. They dissolve easily in water, alcohol, and ether. The aqueous solution may be boiled without decomposition. The water of crystallisation is given off at $100^\circ C$. (Gerhardt and Cahours), at $130^\circ C$. (Trapp), not completely below 170° (Sieveking).

Cymylsulphite of Calcium, $C^{10}H^{13}CaSO_3 + \frac{3}{2}aq.$, crystallises in thin colourless laminae, easily soluble in water and alcohol, becoming anhydrous at $170^\circ C$. (Sieveking.)

Cymyl-sulphite of Copper, obtained by decomposing the barium-salt with sulphate of copper. Crystallises in fine silky needles, or laminae, soluble in water and alcohol. (Sieveking.)

Cymyl-sulphite of Lead, $C^{10}H^{13}PbSO_3 + 2aq.$ —Crystallises in nacreous laminae, which give off all their water at $120^\circ C$. (Delalande.)

Cymyl-sulphite of Silver.—On dissolving carbonate of silver in the aqueous acid, and evaporating in vacuo, the liquid turns brown and leaves a brown residue containing a few white needle-shaped crystals. (Sieveking.)

Cymyl-sulphite of Sodium, $C^{10}H^{13}NaSO_3 + \frac{5}{2}aq.$ —Obtained by decomposing the barium-salt with sulphate of sodium. Crystallises in fine silky needles or laminae, soluble in water and alcohol, and giving off all their water at $170^\circ C$. (Sieveking.)

CYNAPINE. A poisonous alkali contained, according to Ficinus (Mag. Pharm. xx. 357), in fool's parsley (*Aethusa Cynapium*). It is said to crystallise in rhombic prisms, to have an alkaline reaction, to be soluble in water and alcohol, and to form a crystallisable sulphate.

CYNENE. $C^{12}H^{18}(?)$.—A hydrocarbon obtained by distilling wormseed-oil (the volatile oil of *Semen-contra*) several times with phosphoric anhydride, and treating the distillate with strong sulphuric acid to separate a heavy, less volatile oil. Cynene is a mobile colourless oil, permanent in the air, and having a peculiar odour like that of wormseed. It is insoluble in water, very soluble in ether, and boils between 173° and $175^\circ C$. Specific gravity 0.825 at $16^\circ C$. Gives by analysis 88.8 per cent. carbon and 11.1 hydrogen. It is not attacked by ordinary sulphuric acid, but the fuming acid dissolves it, forming a conjugated acid. Strong nitric acid acts violently upon it when heated, forming a yellow oil heavier than water. (Völckel, Ann. Ch. Pharm. lxxxix. 358.)

CYNODINE. An uncrystallisable substance obtained from the root of creeping dog's-tooth grass (*Cynodon dactylon*). (Semmla, Berzelius Jahresber. xxiv. 535.)

CYNOSURUS CRISTATUS. *Dog's-tail grass*.—This grass, gathered in the flowering season, yields in the fresh state 2.38 per cent., and in the dry state 6.38 per cent. ash, containing in 100 pts. 25.0 per cent. K_2O , 10.1 CaO , 2.4 MgO , 0.1 FeO_3 , 3.2 SO_3 , 40.1 SiO_2 , 7.2 P_2O_5 , and 11.6 KCl . (Way and Ogston.)

CYNURENIC ACID. Syn. with KYNURENIC ACID.

CYPERUS ESCULENTUS. *Earth-almond* (*Erdmandel*).—The tubers of this sedge, which is indigenous in Sicily, Egypt, &c., cultivated in Arabia, and used as food, contain in 100 pts., according to Semmla (J. Chim. méd. xi. 256), 22 pts. starch, 4 inulin, and 1 crystallisable sugar; according to Muñoz y Luna (Ann. Ch. Pharm. lxxviii. 370), 29 starch, 14 cane-sugar, 7 gum and salts, and 28 of a fixed oil resembling oil of sweet almonds. According to Landerer (Buchn. N. Repert. iv. 20), the oil has a specific gravity of 0.94, resembles oil of sesame, and is easily saponifiable.

CYPRIN. See VESUVIAN.

CYPRIPEDIN. The name applied in North America to a brown powder prepared from *Cypripedium pubescens*, and used as a medicine.

CYSTINE. *Cystic oxide*, $C^3NH^7SO^2$.—An organic base constituting the chief constituent of a rare kind of urinary calculus, occurring in men and dogs. It was discovered by Wollaston (Phil. Trans. 1810, p. 223), and has been found in renal concretions and urinary gravel (Golding Bird, *Treatise on Urinary Concretions*; Toel, Ann. Ch. Pharm. xvi. 247), in the kidneys of the ox (Cloetta, *ibid.* xcix. 289), and in the liver of a drunkard who died of typhus fever (Scherer, N. Jahrb. Pharm. vii. 306). Researches on cystine and cystic calculi have also been published by Lassaigne (Ann. Ch. Phys. [2] xxiii. 328); Baudrimont and Malaguti (J. Pharm. xxiv. 633); Thaulow (Ann. Ch. Pharm. xxvii. 197); Marchand (J. pr. Chem. xvi. 254); Robert (J. Pharm. vii. 165); Buchner (Repert. xxi. 113); Walchner (Schw. J. xlvii. 106); Wurzer (Schw. J. lvi. 472); Schindler (Mag. Pharm. xxix. 264); VENABLES (N. Quart. J. of Sc. vii. 30); O. Henry (J. Pharm. xxiii. 11); Dranty (J. Chim. méd. xiii. 230); Taylor (Phil. Mag. [3] xii. 337); Lecanu and Ségalas (J. Pharm. xxiv. 460); Schweig (Heidelb. Medic. Annal. xiii. 364); Bley (Arch. Pharm. [2] ii. 165); Civile (J. Chim. méd. 1838, p. 355); Schlossberger (N. Jahrb. Pharm. viii. 4).

Urinary calculi are occasionally found consisting of pure cystin, but if the calculus likewise contains phosphate of calcium, the cystine is either dissolved out by ammonia and the filtrate left to evaporate to the crystallising point; or it is dissolved in potash and precipitated from the filtrate by acetic acid. (Lassaigne.)

Properties.—In urinary calculi, cystine presents the appearance of a yellowish, shining, confusedly crystallised mass (Wollaston); wax-yellow, translucent, elongated, square octahedrons (Schindler); yellowish, translucent, with a faint lustre; confusedly crystalline; crackles between the teeth; is easily rubbed to a yellowish powder; tasteless, neutral (Robert). Specific gravity of a calculus containing 97.5 pts. cystine to 2.5 pts. phosphate of calcium = 1.577 (Wollaston); of a calculus containing 91 per cent. of cystine = 1.13 (Taylor); of a pure cystine calculus = 1.7143 (Venables). From a solution in hot aqueous potash, cystine slowly crystallises on addition of acetic acid, in neutral six-sided laminæ (Wollaston); from an ammoniacal solution by evaporation, in transparent colourless laminæ (Lassaigne) in rhombic crystals (Thaulow). (See *Funke's Atlas d. physiolog. Chem.* Taf. v. fig. 6). Cystine is insoluble in water and in alcohol.

Decompositions.—1. Cystine yields by dry distillation, carbonate of ammonia, a volatile, viscid, stinking oil, and spongy charcoal (Wollaston and Walchner). It likewise gives off hydrocyanic acid (Schindler).—2. When heated in the air, it gives off a quite peculiar and extremely disagreeable odour (Wollaston), sulphurous and resembling that of oil of mustard (O. Henry). It takes fire at the same time, without melting (Wollaston), assumes a black-brown colour, and splits into fragments, which disappear without fusion or intumescence, emitting a strong smell of hydrocyanic acid and a faint empyreumatic odour (Buchner).—3. Fused with hydrate of potassium, it gives off an inflammable gas, which burns with a flame of sulphide of carbon, producing sulphurous anhydride (Thaulow).—4. Its solution in excess of nitric acid leaves, when concentrated by boiling, first a white opaque substance (Lecanu and Ségalas), then a substance which becomes continually browner, and at last black, is free from oxalic acid (Wollaston), but contains sulphuric acid (Thaulow).

Combinations.—Cystine dissolves in the aqueous solutions of the stronger acids; and, on evaporation at a gentle heat, yields crystals which are soluble in water. The solution is precipitated by carbonate of ammonia. The *hydrochlorate*, *nitrate*, *phosphate*, and *sulphate* of cystine crystallise in needles grouped in tufts (Wollaston).

Cystine dissolves readily in aqueous *ammonia*, *potash*, *soda*, and *lime*, also in the *acid carbonates of potassium and sodium*, but not in acid carbonate of ammonia. All these solutions yield granular crystals by evaporation (Wollaston).—From alkaline solutions, cystine is not precipitated by sulphuric, hydrochloric, or nitric acid; but acetic, tartaric, and citric acids precipitate it in a few seconds as a fine white powder. (Wollaston, Lassaigne, Walchner, Robert.)

The solution in ammonia, when left to evaporate, yields pure cystine in crystals.—The solution in potash deposits, on evaporation, white crystalline grains, which are tasteless, leave a small quantity of potash when burned, are insoluble in water, but dissolve readily in water containing potash. (Lassaigne.)

CYSTINOÏD TUBERCLES. *Xanthocystin*. A substance resembling cystine and xanthine, and found in small whitish grains on the mucous membrane of the digestive organs, liver, &c. of the body, two months after interment, of a person

who died of inflammation of those organs. (A. Chevallier and Lassaigue, J. Chim. méd. [3] vii. 208; Pharm. Centr. 1851, p. 717.)

CYTISINE. A bitter substance obtained from *Cytisus Laburnum* by Chevallier and Lassaigue (J. Pharm. iv. 340; vii. 235). The alcoholic extract of the seeds is treated with water; the solution precipitated with neutral acetate of lead, and the lead removed from the filtrate by sulphydric acid. The liquid filtered from the sulphide of lead leaves, when evaporated, a yellowish green mass of the consistence of an extract, soluble in water and in alcohol, precipitated by basic acetate of lead and nitrate of silver. When taken internally, it produces giddiness, spasms, and vomiting. — According to Peschier (J. Chim. méd. vi. 65), cytisine is identical with the cathartine of senna-leaves; but these substances have not been sufficiently studied to decide the question with certainty.

D.

DACTYLIS. The cleansed root-fibres of *Dactylis glomerata*, yield, according to Schulze's analysis (Ann. Ch. Pharm. cix. 180), 24 p. c. dry substance containing 9.4 p. c. ash, of which 3.9 pts. (= 41.9 p. c. of the ash) consists of silica.

For Way and Ogston's analysis of the ash of the flower of this plant, see GRASSES.

DADYL. The name given by Blanchet and Sell to the camphre obtained from crystallised hydrochlorate of turpentine-oil. (See TURPENTINE, OIL OF.)

DAEDALEA QUERCINA. This sponge, dried at 100° C., contains 3.2 p. c. nitrogen and leaves 3.1 p. c. ash. (Schlossberger and Döpping.)

DAGGED. See BIRCH-TAR (i. 589).

DAGUERREOTYPE. See LIGHT (CHEMICAL ACTION OF).

DAHLIA. The tubers of *Dahlia pinnata* contain 10 p. c. inulin (thence called *Dahlin*), also citric and malic acids, chiefly as calcium-salts, a fixed oil, and a volatile oil which is lighter than water and quickly resinises when exposed to the air. In water this volatile oil solidifies after some time, and yields crystals apparently consisting of benzoic acid. (Payen, J. Pharm. ix. 384; x. 239.)

DALANOUITE. See DELANOVITE.

DALARNITE, Breithaupt's name for the arsenical pyrites from Dalarne or Dalecarlia in Sweden.

DALLEIOCHIN or **THALLEIOCHIN.** An imperfectly investigated product of the action of ammonia and chlorine on quinine (*q. v.*).

DAMALURIC and **DAMOLIC ACIDS.** Two volatile acids said to exist in cows' and horses' urine. Damaluric acid $C^7H^{12}O^2(?)$ is oily, heavier than water, and smells somewhat like valerian. (Städeler, Ann. Ch. Pharm. lxxvii. 27.)

DAMASCUS STEEL. See IRON.

DAMMARA RESIN, AUSTRALIAN. *Cowdie gum, Cowdie-pine resin.*

The produce of a large coniferous tree, *Dammara Australis*, which grows in New Zealand. It forms white or yellow masses very difficult to break, having a shining fracture, and a very decided odour of turpentine. According to R. D. Thomson (Ann. Ch. Phys. [3] ix. 499) it consists of an acid resin, dammaric acid, and a neutral resin, dammaran, the former of which may be extracted by alcohol.

The acid resin is deposited, by spontaneous evaporation of its alkaline solution, in crystalline grains containing 72.64 p. c. carbon, 9.31 hydrogen, and 18.00 oxygen. On precipitating the boiling alcoholic solution with alcoholic nitrate of silver containing ammonia, a precipitate is formed containing 14.60 to 14.75 p. c. oxide of silver. Thomson represents the acid resin by the formula $C^{40}H^{31}O^7$ (75.4 C and 9.4 H), and the silver-precipitate by $AgO.C^{10}H^{30}O^6$.

The neutral resin, insoluble in weak alcohol, yields a colourless varnish with absolute alcohol and with oil of turpentine. Its analysis gives 75.02 C and 9.6 H, which Thomson represents by the formula $C^{40}H^{31}O^6$. When exposed to continued heat it absorbs oxygen.

The resin, when distilled alone at a gentle heat, yields an amber-coloured volatile oil called dammarol, containing 82.2 p. c. carbon, and 11.1 hydrogen; and by distilling it with lime, another yellow oil is obtained, called dammarone. All these products require further examination.

DAMMARA RESIN, EAST INDIAN. *Dammar-Puti* (i. e. *Cat's-eye resin*, so called on account of its lustre). This is the more ordinary kind of dammara resin; it

302 DAMMARIC ACID—DAMMARYL, HEMI-HYDRATE OF.

comes chiefly from Singapore, and is said to be obtained from *Pinus Dammara*, Lamb., or *Dammara alba* (*D. orientalis*, Rumph., or *Agathis loranthifolia*, Salisb.), a coniferous tree, indigenous in the East Indies and in the Moluccas. The resin, which exudes from excrescences on the stem near the root, forms colourless or yellowish, more or less transparent lumps, varying in size between that of a pea and that of a hen's egg; of specific gravity 1.04 to 1.09; having a resinous odour and conchoidal fracture. According to Brandes, it melts at 150° C.; according to Dulk, it begins to melt at 73° C. It dissolves partially in *absolute alcohol* (to about $\frac{2}{3}$) and in *ether* (to about $\frac{3}{10}$); in *aqueous alcohol* it is less soluble in proportion as the alcohol is weaker; *oils*, both *fixed* and *volatile*, dissolve it more completely. It is insoluble in dilute acids, but *strong sulphuric acid* dissolves it completely even in the cold; and on dropping the yellow or red solution into water, a white precipitate is formed, consisting, apparently, of the unaltered resin. The resin heated with sulphuric acid is decomposed, with evolution of sulphurous acid. *Nitric acid* likewise decomposes it with aid of heat. When suspended in water and treated with *chlorine gas*, it takes up 26 p.c. chlorine. It is scarcely attacked by *potash* or *soda*, even when heated therewith; heated with *soda-lime*, it gives off hydrogen and carburetted hydrogen, and if the heat has not been raised above 320° C., a resinous body is found in the residue.

East Indian Dammara resin contains about 0.2 p.c. ash, a small quantity of gum, a hydrocarbon, dammaryl, and three resinous bodies. According to analyses by Schrötter (Pogg. Ann. lix. 37), and Dulk (J. pr. Chem. xlv. 16), the entire resin yields numbers answering to the empirical formula $C^{80}H^{64}O^5$.

Weak alcohol extracts from Dammara resin an acid resin called hydrated dammarylic acid (or *a-resin*) amounting to about $\frac{1}{3}$ of the whole, and consisting of $C^{80}H^{64}O^7$ (or $C^{15}H^{37}O^4$, according to Dulk): it is white, becomes electric by friction, melts at 50° C.; does not oxidise by exposure to the air. It unites with bases, but the salts are very unstable.

If the dammara resin, after exhaustion with weak spirit, be treated with *absolute alcohol*, a resin *b*, consisting of anhydrous dammarylic acid $C^{10}H^{23}O^3$ (or $C^{15}H^{36}O^3$, according to Dulk), is dissolved, and remains, on evaporating the alcohol, as a white powder, melting at 60° C., perfectly soluble in absolute alcohol, in ether, in oils, both fixed and volatile, and in strong sulphuric acid; the alcoholic solution has a stronger acid reaction than that of the resin *a*. With *bases*, it behaves like the resin *a*, forming salts which, according to Dulk, are identical with those of the resin *a*.

When the dammara resin, after exhaustion with alcohol, is treated with *ether*, a portion of the residue (= about $\frac{1}{2}$ of the original resin) dissolves, and the solution yields by evaporation a hydrocarbon, called dammaryl, = $C^{10}H^{32}$ (or $C^{15}H^{36}$ according to Dulk). It is a tasteless, inodorous powder, which becomes electric by friction, dissolves easily in cold ether, softens at 145°, and melts at 190° C. It oxidises quickly when exposed to the air, taking up from 3 to 5 p.c. oxygen (= 1 or 2 at *O*, according to the formula $C^{10}H^{32}$). By exposure for some time to moist air at 110° C., it acquires the composition of the crude resin $C^{80}H^{64}O^5$. Dammaryl suspended in water and treated with chlorine, yields a substitution-product containing 34 p.c. chlorine.

After the resin has been exhausted with alcohol and ether, there remains an insoluble resin *c*, a hemi-hydrate of dammaryl $C^{80}H^{64}O$ (or $C^{90}H^{72}O$, according to Dulk). It is a green, shining, brittle mass, which melts at 215° C., is insoluble in acids and alkalis, but dissolves in oil of turpentine and in the strongest sulphuric acid.

Brandes separated dammara resin into an *a-resin* easily soluble in alcohol and ether, and amounting to about $\frac{2}{3}$ of the whole, and a *β-resin* or dammarin soluble only in 1000 pts. absolute alcohol and 40 or 50 pts. ether, and insoluble in alkalis.

Dammara resin is much used for the preparation of varnishes (Dingl. polyt. J. cxxviii. 58; cxxxi. 141), for which purpose it is dissolved, after drying, in 2 or 3 pts. of oil of turpentine; to obtain a thicker varnish, it is usual to add a certain quantity of thick turpentine or boiled linseed oil. (Handw. d. Chem. 2^{te}. Aufl. ii. [3] 340.)

DAMMARIC ACID. The constituent of Australian dammara resin which is insoluble in weak spirit (p. 301).

DAMMARIN. See DAMMARA-RESIN, EAST INDIAN.

DAMMAROL. }
DAMMARONE. } See DAMMARA-RESIN, AUSTRALIAN.

DAMMAR-PUTI. See DAMMARA-RESIN, EAST INDIAN.

DAMMARYL. The constituent of East Indian dammara-resin, insoluble in alcohol, soluble in ether.

DAMMARYL, HEMI-HYDRATE OF. The constituent of East Indian dammara-resin which is insoluble in alcohol and ether.

DAMMARYLIC ACID. The constituent of East Indian dammara-resin, which is insoluble in weak, but soluble in absolute alcohol (p. 302).

DAMMARYLIC ACID, ANHYDROUS. The constituent of East Indian dammara-resin, which is soluble in weak alcohol (p. 302).

DAMOURITE. A hydrated mica, forming crystalline laminae in the interstices of crystals of kyanite, found at Pontivy in Bretagne. It is colourless, yellowish-white or yellow, transparent in thin laminae, and of scaly texture. Specific gravity 2.792. Hardness = 2.0 to 3.0. Heated in a tube, it gives off water and swells up. Before the blowpipe, it intumesces, becomes white and opaque, and melts to a white enamel. It is decomposed by strong sulphuric acid.

According to Delesse (Ann. Ch. Phys. [3] xv. 248), it consists of $KO \cdot \text{SiO}_3 + 3(\text{Al}^{2\text{O}_3} \cdot \text{SiO}_3) + 2\text{H}_2\text{O}$ or $\text{K}^{2\text{O}} \cdot 3\text{Al}^{2\text{O}_3} \cdot 6\text{SiO}_2 + 2\text{H}_2\text{O}$, which (by substituting $\text{al} = \frac{2}{3}\text{Al}$) may be reduced to $(\text{K}^{2/3}\text{H}^2)\text{Si}^{10/12}$, the formula of an orthosilicate. It likewise contains a small quantity of fluorine, and appears to be a variety of margarodite.

DANAITE. A mineral consisting of sulphur, arsenic, and iron with a little cobalt, and agreeing in form with arsenical pyrites, of which it is probably only a cobaltiferous variety. Hayes, however (Sill. Am. J. xxiv. 386), assigns to it the formula $\text{Fe}^4\text{As}^3 \cdot \text{Fe}^1\text{S}^3$. It is found in the gneiss near Franconia in New Hampshire, United States. (See *Kenngott's Uebers.*, 1852, p. 99; *Jahresber. d. Chem.* 1853, p. 778.)

DANBURITE. A borosilicate of calcium found at Danbury in Connecticut, in shining, translucent, pale yellow crystals belonging to the trimetric system. Hardness 7 to 7.5. Specific gravity 2.95. Melts before the blowpipe and colours the flame green. Two analyses made by Smith and Brush give the following results:

SiO_2	Al^{2O_3}	$\text{Mn}^{2\text{O}}$	$\text{Ca}^{2\text{O}}$	$\text{Mg}^{2\text{O}}$	B^{2O_3}	Loss by ignition.	Total.
48.10	0.30	0.56	22.41	0.40	27.73	0.50	100.00
48.20		1.02	22.33		27.95	0.50	100.00

whence Smith and Brush deduce the formula $3\text{CaO} \cdot 2\text{SiO}_3 + 3\text{B}^{2\text{O}_3} \cdot 2\text{SiO}_3$, which is equivalent to $\text{Ca}^{2\text{O}} \cdot \text{SiO}_2 + \text{B}^{2\text{O}_3} \cdot \text{SiO}_2$ (Brush, Sill. Am. J. [2] ix. 286. Smith and Brush, *ibid.* xvi. 365. See also *Rammelsberg's Mineralchemie*, p. 770).

DANNEMORITE. A variety of hornblende found in the iron mines of Dannemora in Sweden. Its structure is fibrous or radiating, the individual crystals being closely aggregated. Colour yellowish-brown to greenish-brown. Specific gravity 3.516. Blackens before the blowpipe, and in thin pieces melts to a dark slag. Contains:

SiO_2	Al^{2O_3}	$\text{Ca}^{2\text{O}}$	$\text{Mg}^{2\text{O}}$	$\text{Mn}^{2\text{O}}$	$\text{Fe}^{2\text{O}}$
48.9	1.5	0.7	2.9	8.5	38.2

corresponding nearly to the formula $8\text{M}^{2\text{O}} \cdot 9\text{SiO}_2$, where M is almost entirely represented by iron. (Erdmann, *Jahresber. d. Chem.* 1856, p. 846.)

DAPHNETIN. $\text{C}^{18}\text{H}^{14}\text{O}^9$ (Zwenger [1860], Ann. Ch. Pharm. cxv. 8).—A product of the decomposition of daphnin, which when subjected to dry distillation, or heated with aqueous acids, or fermented with emulsin, splits up into daphnetin and glucose:

The same decomposition also takes place under the influence of yeast; but it is necessary first to add glucose to the liquid, in order to set up the fermentation, and even then the decomposition is very imperfect.

Preparation.—1. A solution of daphnin in dilute hydrochloric or sulphuric acid is boiled till it turns yellow, then diluted with water and left to cool; the impure daphnetin which separates is dissolved in hot water, and precipitated by neutral acetate of lead; and the yellow precipitate is washed, suspended in hot water, and decomposed by sulphydric acid. The liquid filtered at the boiling heat, deposits daphnetin on cooling.—2. The alcoholic extract of mezereon bark is treated with strong hydrochloric acid, and evaporated on the sand-bath till the acid is completely expelled; the carbonaceous residue is then boiled with water; and the impure daphnetin which separates on cooling is purified as above.—3. The alcoholic extract of mezereon bark yields by dry distillation a distillate containing small needle-shaped crystals of impure daphnetin, which may be purified as above.

Properties.—Daphnetin forms small needle-shaped monoclinic prisms having a strong refracting power. It has a slightly astringent taste, and dissolves easily in boiling water, still more in boiling alcohol, sparingly in ether. When heated it emits an agreeable odour, and melts at a temperature above 250°C . to a yellowish mass,

which solidifies in the crystalline form on cooling. In a stream of gas it sublimes easily, even below its melting point; but when heated in a close vessel, it suffers partial decomposition.

Hot *hydrochloric acid* easily dissolves daphnetin without decomposing it; strong *sulphuric acid* dissolves it with decomposition. *Nitric acid* colours it deep red.

Alkalis and *alkaline carbonates* dissolve daphnetin, with yellow colour, the solution becoming darker on exposure to the air. *Lime-water* and *baryta-water* form with it yellow precipitates, which also become darker by exposure. *Ferric salts* colour daphnetin green, the colour disappearing, however, on addition of free acid or of excess of ferric salt. *Ferrous salts* produce only a faint greenish colouring in solutions containing excess of daphnetin. Daphnetin reduces an *alkaline cupric* solution, even in the cold; also *nitrate of silver*.

Lead-compound, $C^{19}H^{10}Pb^{4}O^{19}$.—A warm aqueous solution of daphnetin mixed with acetate of lead, yields a light yellow gelatinous precipitate, which when dry forms a brittle mass, dark-coloured in thick layers, translucent with yellow-red colour in thin layers. It dissolves sparingly in water, easily in acetic acid. Nitric acid turns it red. On boiling it with water, part of the daphnetin is removed, and a compound richer in lead remains.

DAPHNIN. $C^{31}H^{31}O^{19} + 4H^2O$.—A crystallisable non-azotised glucoside, occurring in the bark of certain species of *Daphne*. Vauquelin in 1808 (Ann. Chim. lxxxiv. 173), first obtained from *Daphne alpina*, an acrid volatile substance soluble in water, to which Berzelius gave the name of daphnin.—C. G. Gmelin and Baer (Schw. J. xxxv. 1) afterwards prepared the body now called daphnin, which has since been more particularly examined by Zwenger (Ann. Ch. Pharm. cxv. 1). It occurs in the bark of the common mezereon plant (*Daphne mezereum*), and somewhat more abundantly in that of *D. alpina*.

Preparation.—1. The alcoholic extract of the bark of *D. mezereum* or *D. alpina* is exhausted with water; the solution is precipitated with acetate of lead; the precipitate washed with water, and decomposed by sulphydric acid; and the filtrate evaporated to dryness and treated with absolute alcohol. Daphnin then crystallises from the alcoholic solution (Gmelin and Baer).—2. The alcoholic extract of fresh mezereon bark stripped off in the early flowering time, is dissolved in water; the solution is first precipitated with neutral acetate of lead; the filtrate is subsequently mixed with excess of basic acetate of lead and boiled for a long time; and the resulting precipitate is washed and decomposed by sulphydric acid. The filtrate yields crystallised daphnin on evaporation or on addition of alcohol. (Zwenger.)

As daphnin is soluble in ether, it may be advantageously prepared from the residual bark left after the preparation of *Extr. mezerei æthereum*.

Properties.—Daphnin crystallises in colourless, transparent, rectangular prisms, sparingly soluble in cold, more freely in warm water, more soluble still in alcohol, especially at the boiling heat, insoluble in ether. The aqueous solution concentrated by heat, tastes bitter at first, afterwards astringent. According to Gmelin, it is neutral when pure, but according to Zwenger, the saturated aqueous solution is decidedly acid.

The crystals of daphnin give off their water at $100^{\circ} C$. At a stronger heat daphnin emits an agreeable odour, like that of coumarin. When cautiously heated in small quantities, it melts at about $200^{\circ} C$. to a colourless mass, which solidifies again in the crystalline form on cooling; but the melting point and decomposing point are so close together, that unless the heat is very carefully applied, vapours are given off, the residue continues amorphous after cooling, and then forms a yellow precipitate with neutral acetate of lead, and a green mixture with sesquichloride of iron, showing that it contains daphnetin (p. 303). Daphnin heated in a close vessel is decomposed, yielding a sublimate of daphnetin and a residue of charcoal; when heated in the air, it burns with a bright flame. *Nitric acid* decomposes it in the cold and colours it red, and when boiled converts it partly into acetic acid.

Alkalis and *alkaline carbonates* dissolve daphnin in the cold, forming a yellow solution which quickly turns brown-red on exposure to the air, especially if warmed. The yellow solution of daphnin in *baryta-* or *lime-water* yields a gelatinous precipitate when heated. Neutral *ferric chloride* imparts a bluish colour to the aqueous solution of daphnin; the liquid turns yellowish when boiled, and deposits a deep yellow precipitate on cooling. *Basic acetate of lead* colours the solution of daphnin yellowish in the cold, and on boiling the liquid an insoluble compound is deposited. *Hydrated oxide of lead* also precipitates daphnin on continued boiling. *Nitrate of silver* forms no precipitate in the cold, but a slight reduction takes place on boiling, and a considerable reduction on addition of ammonia. It reduces an *alkaline cupric solution* only after prolonged boiling.—By heating with aqueous acids, or by the action of *emulsin* or of *yeast*, daphnin is resolved into daphnetin and glucose (p. 303).

DAPICHO or *Zaspis*. The South American name of the dirty-white spongy caoutchouc which exudes from the roots of *Siphonia elastica*. It is blackened over an open fire, and used for making stoppers.

DARWINITE. The name applied by Forbes (Phil. Mag. [4] xx. 423) to a mineral from Chili, identical with the Whitneyite (*q. v.*) of Genth.

DASSIPIS. See HYRACEUM.

DATES. *Dactyli*. The fruit of the date-palm (*Phoenix dactylifera*). They are generally gathered in the ripe state and exposed to the sun, whereby they lose their original bitterness and acquire a pure sweet taste. The fleshy portion of the fruit contains, according to Bonastre (J. Pharm. xviii. 784), crystallisable sugar; according to Reinsch (Buchn. Repert. lxxi. 36) only fruit-sugar (58 p. c.), together with pectin (9 p. c.), gum, and other substances. Kletzinsky (Jahresber. d. Chem. 1858, p. 434) found that dates contain 85 p. c. fleshy substance, 10 kernel, and 5 husk; and the dates freed from the kernel contain in 100 pts.: 36 sugar, 9 pectin and pectinous matter, 23 pts. of other substances soluble in water, 30 water, 0.1 coumarin, citric acid, and other substances. The kernels contain, according to Reinsch, 36 pts. gummy substance and 40 cellulose, together with tannin, fat, &c.

The juice of the flower-buds of the date-palm, which is very rich in sugar, is used for the preparation of arrack, and on the small scale for the preparation of crystallisable sugar. According to Fourcroy and Vauquelin, the pollen of the flowers contains a large quantity of free malic acid.

DATHOLITE. *Datolite*. *Dystomite*. *Humboldite*. *Botryolite*. *Esmarkite* (in part). *Natrocalcite* (in part). *Borate of Lime*. *Borosilicate of Lime*. *Chaux boratée siliceuse*. A borosilicate of calcium, crystallising, according to Kopp, in monoclinic combinations, with numerous faces, the primary form of which is the monoclinic prism ∞P of $77^\circ 30'$ with a nearly rectangular base, deviating only $10'$ from perpendicularity. The combinations exhibit also the prism $\infty P2 = 116^\circ 9'$; the transverse hemidome $2P\infty = 43^\circ 56'$, the hemipyramid $P = 122^\circ 0'$, and many others. Cleavage indistinct parallel to ∞P and the transverse faces. On the other hand, Brooke and Miller, and Dana (Mineralogy, ii. 335) regard the crystals as trimetric and hemihedral, with cleavage parallel to $\infty P\infty$ and $\infty P\infty$. The crystals are small and glossy, having the form of short prisms or thick tablets, often implanted. The mineral also occurs massive, with coarse or fine-grained structure.

Hardness = 5.0 to 5.5. Specific gravity = 2.9 to 3.1. Colour white, or with a shade of green, yellow, grey, or red. Streak white. Lustre glassy on the crystalline, waxy on the fractured surfaces. Translucent. Fracture uneven, subconchoidal. Brittle.

Ignited in a tube, it gives off water. Before the blowpipe, it swells up and melts easily to a clear glass, occasionally with a greenish or a reddish tint. Colours the flame green. Dissolves in borax; in phosphorus-salt it leaves a skeleton of silica, and if added in considerable quantity forms an enamel-white glass. With a small quantity of soda it forms a clear glass; with a larger quantity, the bead becomes opaque on cooling, and with a still larger quantity, the mass sinks into the charcoal. With gypsum, it fuses to a clear bead.

Analyses: *a*. Andreasberg in the Harz (Stromeyer, Pogg. Ann. xii. 157).—*b*. Andreasberg (Du Menil, Schw. J. lii. 364).—*c*. Andreasberg (Rammelsberg, Pogg. Ann. xlvii. 175).—*d*. Arendal in Norway (Rammelsberg, *loc. cit.*).—*e*. Isle Royal, Lake Superior (Whitney, Sill. Am. J. [2] xv. 435).—*f*. Nieder-Kirchen, Rhenish Bavaria (Dellmann, Rammelsberg's Mineralchemie, p. 507).—*g*. From the gabbro of Tuscany (Beehi, Sill. Am. J. [2] xiv. 65).

	SiO ²	B ² O ³	CaO	H ² O	
<i>a</i> .	37.36	21.26	35.67	5.71	= 100
<i>b</i> .	38.51	21.34	35.59	4.67	= 100.04
<i>c</i> .	38.48	20.31	35.64	5.57	= 100
<i>d</i> .	37.65	21.24	35.41	5.70	= 100
<i>e</i> .	37.64	21.88	34.68	5.80 Mn ² O ³ trace	= 100
<i>f</i> .	37.44	24.63	32.23	5.70	= 100
<i>g</i> .	37.50	22.63	35.34	1.56 Mg ² O 2.12 Al ³ O ³ 0.85	= 100

These analyses of the purer specimens lead to the formula $\text{Ca}^2\text{O} \cdot 2\text{SiO}^2 + \text{Ca}^2\text{O} \cdot \text{B}^2\text{O}^3 + \text{aq.} = \text{Ca}^2\text{Si}^2\text{O}^2 \cdot 2\text{CaBO}^2 + \text{aq.}$, or $2\text{Ca}^2\text{O} \cdot \text{SiO}^2 + \text{B}^2\text{O}^3 \cdot \text{SiO}^2 + \text{aq.} = 2\text{Ca}^4\text{Si}^4\text{O}^8 \cdot \text{B}^2\text{SiO}^5 + \text{aq.}$ (calc. 38.15 SiO², 21.15 B²O³, 34.67 CaO, 5.58 H²O). According to Fownes and Sullivan (Pogg. Ann. Ergänzb. ii. 368), datholite contains a small quantity of phosphoric acid.

Datholite occurs in numerous localities, among which, in addition to the above, may

be mentioned Toggiana in Modena, the island of Utoë near Sweden, the Scisser Alp in the Tyrol, and Bergen Hill in New Jersey. It is found in amygdaloid and gneiss; sometimes also in beds of iron ore in primitive rocks.

Botryolite, a variety of datholite occurring in botryoidal concretions, is usually regarded as containing twice the quantity of water shown by the above formula (i. 651). An analysis by Rammelsberg gave 36.085 per cent SiO_2 , 12.340 B_2O_3 , 35.215 CaO and 8.685 water; but Dana is of opinion that additional analyses are required to show that this amount of water is constant.

DATISCA CANNABINA. *Bastard Hemp.* This plant, indigenous in the Levant and in India, is much used in India, Italy, the south of France, and other places for communicating a permanent yellow dye to silk. According to Braconnot, the leaves contain a peculiar colouring matter, *datisca*-yellow, which is prepared by precipitating the aqueous decoction of the leaves with a small quantity of neutral acetate of lead, filtering to separate the gummy precipitate thereby formed, mixing the filtrate with potash, then precipitating completely with acetate of lead, decomposing the yellow precipitate with sulphuric acid, and evaporating the filtrate. *Datisca*-yellow then remains in the form of a pale yellow-brown, translucent mass, insoluble in cold alcohol, but easily soluble in water. The solution is coloured lighter by acids, darker by alkalis and by ferrous sulphate, bright yellow by alum. Stuffs mordanted with alum are dyed permanently yellow by it. Walzl recommends a concentrated decoction of the plant mixed with a little potash as a yellow ink (Handw. d. Chem. 2^{te} Aufl. ii. [3] 377).

DATISCETIN, $\text{C}^{15}\text{H}^{10}\text{O}^6$ (Stenhouse [1856], Ann. Ch. Pharm. xcvi. 166). A product of the decomposition of *datiscin*, obtained by treating the latter body with aqueous acids, or with strong potash, not by the action of yeast or emulsin:

When *datiscin* is boiled with dilute sulphuric acid, the liquid becomes turbid in a few minutes, and deposits *datiscetin* in colourless needles.

As *datiscetin* crystallises very easily, it may also be prepared from the mother-liquor obtained in the preparation of *datiscin*, by precipitating this liquor with basic acetate of lead, decomposing the washed precipitate with sulphydric acid, evaporating the filtrate, and boiling it with dilute sulphuric acid. The *datiscetin* thus obtained is easily purified by recrystallisation.

Datiscetin is tasteless, nearly insoluble in *water*, easily soluble in *alcohol*, and is precipitated therefrom by *water*. It dissolves in all proportions in *ether*, and crystallises in needles on evaporation.

Datiscetin melts at a somewhat high temperature, and, if carefully heated, may be partially sublimed. When strongly heated, it takes fire and burns away.

Nitric acid acts violently on *datiscetin*, even in the cold, nitrous acid being evolved and a resinous substance formed, which ultimately dissolves with red colour; on evaporating the liquid, picric acid is obtained, but no oxalic acid. Boiled with weak nitric acid (1 pt. ordinary nitric acid to 10 pts. water), it yields nitrosalicylic acid. Distilled with *sulphuric acid* and *acid chromate of potassium*, it yields oily drops, which smell like salicylic acid, and colour ferric salts purple. When *datiscetin* is gradually added to melting *hydrate of potassium*, it dissolves with deep orange colour and evolution of hydrogen; and on supersaturating the cooled mass with hydrochloric acid, a resinous substance separates, which, when heated, yields a colourless sublimate of needle-shaped crystals, having the aspect of benzoic acid, but giving with ferric chloride the reaction of salicylic acid.

Datiscetin dissolves in aqueous *alkalis*, and is reprecipitated by acids. An alcoholic solution of *datiscetin* forms with *neutral acetate of lead* a deep yellow precipitate, consisting of $\text{C}^{15}\text{H}^9\text{Pb}^2\text{O}^6$.

DATISCIN. $\text{C}^{21}\text{H}^{22}\text{O}^{12}$. A glucoside closely allied to *salicin*. It was first obtained by Braconnot in 1816 (Ann. Ch. Phys. [2] iii. 277), from the leaves of *Datisca cannabina*, and to a great extent correctly examined; but his statements were so far forgotten, that the body was universally regarded as identical with inulin, till Stenhouse in 1855 (Ann. Ch. Pharm. xcvi. 166; Chem. Gaz. 1856, No. 318) re-examined the roots of *Datisca cannabina*, and showed that the body obtained by Braconnot was really a distinct compound.

Preparation.—The alcoholic extract of the root is evaporated to a syrup and mixed with half its bulk of water; the liquid is decanted from a resin which separates; and the impure *datiscin* which crystallises by spontaneous evaporation is pressed between paper, and then dissolved in alcohol; on subsequent addition of water, a further portion of resin separates, and the dilute solution after a while yields purer *datiscin*. By repeat-

ing the treatment with alcohol and water it is obtained quite pure. It may also be freed from tannin by mixing the alcoholic solution with a small quantity of gelatin, the purification being completed as above.

Properties.—Pure datiscin forms colourless silky needles. It is sparingly soluble in cold, somewhat more easily in hot water, easily in cold alcohol, and in all proportions in boiling alcohol, very slightly in ether. From a strong alcoholic solution it is immediately precipitated by water, from a weaker solution after some time only; from the ethereal solution it separates by spontaneous evaporation in large crystalline laminae. The solutions of datiscin have a very bitter taste, and a neutral reaction.

Datiscin melts at 180°C .; on carefully heating it in a current of air, it yields a small quantity of a crystalline sublimate. When more strongly heated alone, it is carbonised, and gives off the odour of burnt sugar. When boiled with dilute sulphuric or hydrochloric acid, it is easily resolved into crystallisable sugar and datiseetin (p. 306.) Yeast and emulsin do not appear to act upon it. Dilute nitric acid dissolves it even in the cold, converting it into picric and oxalic acids. Stronger nitric acid forms the same products.

Datiscin, although neutral to test-paper, nevertheless exhibits with bases the properties of a weak acid, dissolving with deep yellow colour in aqueous alkalis, and in lime- and baryta-water, and being separated therefrom by acids. The aqueous solution of datiscin forms a light yellow precipitate with acetate of lead, either neutral or basic, also with stannic chloride, greenish with cupric salts, brownish with ferric salts. By boiling with strong potash-ley, it is decomposed, with formation of datiseetin. Melting potash acts in like manner, but the resulting datiseetin suffers further decomposition (p. 306).

DATOLITE. Syn. with DATHOLITE.

DATURA. A genus of plants belonging to the solanaceous order. The herb and seed, especially the latter, of the common thorn-apple, *Datura Stramonium*, contain a poisonous alkaloid, daturine, which, according to Planta, is identical with atropine. The herb and seeds contain also an organic acid, which Peschier (N. Trommsd. xxv. 2, 83) regarded as peculiar, and distinguished by the name daturic acid; but according to Brandes (Buchn. Repert. viii. 1), it is nothing but malic acid. The ash of the seed contains 17.8 per cent. potash, 12.6 soda, 3.6 lime, 15.5 magnesia, 3.4 ferric oxide, 30.6 phosphoric anhydride, 4.6 silica, and 10.2 charcoal. (Souhay, J. pr. Chem. xxxviii. 32.)

The flowers of thorn-apple are said also to exert a poisonous action. The leaves and seeds are used medicinally as a narcotic.

The seeds of *Datura arborea* contain daturine, malic acid, fixed oil, &c. The ash contains in 100 pts. 8.5 potash, 4.5 soda, 7.0 lime, 11.4 magnesia, 9.5 alumina, 21.2 silica, 5.7 sulphuric anhydride, 2.5 chlorine, and 13.4 carbonic anhydride. (Walz, J. pr. Pharm. xxiv. 355.)

DAUCUS CAROTA. The carrot. The roots of this well known esculent contain a red colouring matter, carotin, $\text{C}^{18}\text{H}^{24}\text{O}$, together with a colourless substance hydrocarotin, $\text{C}^{18}\text{H}^{30}\text{O}$, from which the red compound is probably formed by oxidation as the root ripens. (See CAROTIN, i. 806.)

Carrots contain, according to Wackenroder, a colourless volatile oil, sugar, and starch, and the residue left on evaporating the recently expressed juice, contains 9.3 per cent. uncrystallisable sugar, 0.3 carotin, 1.0 fixed oil, together with starch, malic acid, albuminous substances, ash, &c.

Bibra found in fresh carrots 87.4 per cent. water, and in the air-dried root 15.1 per cent. water, 0.05 fat and carotin, 0.6 resin and oil, 29.0 sugar, 3.0 inulin, 2.8 albumin, 11.8 organic acid, and 37.8 cellulose. Schmidt found in carrots grown on various soils, from 86.5 to 87.0 water, and in the dry substance 7.2 to 8.0 cane-sugar. Völkcl found in 100 pts. of fresh carrots, 87.3 per cent. water, 6.5 sugar, 0.2 oil, 0.8 gum and pectin, 0.6 nitrogen-compounds, and 3.4 cellular tissue.

Ritthausen found in large field-carrots weighing from 168 to 1255 grms., from 84.5 to 87.8 per cent. water, and in the dry substance 1.0 to 1.3 per cent. nitrogen, and 6.0 to 8.7 per cent. ash-constituents. The proportion of nitrogen in the entire carrot is 0.3 per cent. (Boussingault), 0.2 (Millon), 0.2 to 0.3 (Schmidt). (Handw. d. Chem. 2^{te} Aufl. ii. [3] 381.)

For Way and Ogston's analysis of the ash of the carrot, see vol. i. p. 807.

DAUPHINITE. Syn. with ANATASE.

DAVIDSONITE. An impure variety of beryl, found in the coarse-grained granite vein near Tory in Aberdeenshire, and in the Rubieslaw mine. Contains 12.5 per cent. glucina.

DAVY LAMP. The miner's safety-lamp. (See vol. i. p. 1101.)

DAVYNE. A variety of nepheline from Vesuvius. See NEPHELINE.

DAVYTE. Syn. with STYPTERITE.

DECANTATION. The separation of a clear liquid from a precipitate or deposit by inclining the vessel and suffering the liquid to run out. The best form of vessel for the purpose is the ordinary beaker glass having its edge inclined outwards, but not turned over, and rendered smooth by fusion, not cut or ground. The sides should be perpendicular or slightly inclining outwards from top to bottom, and the bottom flat, or with only a slight indentation inwards in the middle. It is important that the sides and bottom be of uniform thickness, so that the beaker may be heated in the sand-bath without fear of cracking, as the application of heat is often necessary to make a precipitate subside completely.

The glass should not be filled above $\frac{2}{3}$ or $\frac{3}{4}$ of its depth, as otherwise the stream of liquid which runs out on inclining the vessel, makes too sharp an angle with the side, and a portion of it is very apt to run down the edge. In many cases this inconvenience may be obviated by smearing the edge with a little tallow or lard; but with hot liquids, or such as dissolve fats, like caustic alkalis or ether, this method is of course inapplicable. The decantation may often be greatly facilitated by holding a wet glass rod in a nearly vertical position against the edge of the beaker, so as to cause the stream of liquid to run down it: this method prevents the liquid from running down the sides of the beaker, and also enables it to run into the lower vessel without splashing.

It is only, however, from very heavy precipitates that a liquid can be thus decanted without carrying some of the solid particles with it. For preparations, in which the loss of a few particles is unimportant, simple decantation is often advantageously resorted to; but for quantitative analysis, excepting when the precipitates are very heavy, like metallic gold, or clotted, like chloride of silver, complete separation cannot be effected without filtration. This operation and the subsequent washing may, however, be greatly facilitated by first leaving the precipitate to subside as completely as possible, then pouring the clear liquid as above into the filter, and after it has run through, rinsing the precipitate in the beaker with pure water, pouring this through the filter, again washing the precipitate with water, and so on, till the greater part of the soluble matter is removed. The precipitate is then to be poured on to the filter, and the washing completed. This mode of proceeding saves time, and enables the washing to be performed with a much smaller quantity of water than if the liquid and precipitate were at once thrown in the filter. (For further details, see Handw. d. Chem. 2^{te} Aufl. i. 11. art. ABGIESSEN.)

DECHENITE. A native vanadate of lead from the Lauter valley near Niederschlettenbach in Rhenish Bavaria, where it occurs in botryoidal crystalline masses and scaly deposits, of dark red to yellowish colour, translucent, with waxy lustre on the recently fractured surfaces. Specific gravity = 5.81. Hardness = 4.0. Melts easily before the blowpipe to a yellowish bead; on charcoal it yields globules and a deposit of lead, sometimes emitting an odour of arsenic. With borax and phosphorus-salt, it gives the reactions of vanadium; with soda it melts to a white enamel. Soluble in dilute nitric acid and in hydrochloric acid.

According to C. Bergmann's analysis, the dark red variety contains 47.2 per cent. V_2O_5 and 52.9 Pb_2O ; the yellowish variety, 49.27 V_2O_5 and 50.57 Pb_2O ; whence the formula $Pb_2O.V_2O_5$ or $PbVO_2$. According to Brush (Sill. Am. J. [2] xxiv. 116), it contains a considerable quantity of zinc, and is identical with aræoxene (i. 354).

DECOCTION. The operation of boiling. This term is likewise used to denote the liquid itself, which has been made to take up certain soluble principles by boiling.

DECREPITATION. The crackling noise which several salts make when suddenly heated, accompanied by a violent exfoliation of their particles. The effect is generally due to the sudden conversion of the water enclosed within their substance into steam; not, however, the combined water, for the salts which decrepitate most powerfully are anhydrous salts, chlorate of potassium and nitrate of lead, for example; and those which contain water of crystallisation generally fuse quietly when heated. The water, which is the cause of decrepitation, is merely mechanically enclosed between the solid particles of the body. Decrepitation, especially in natural minerals, is also frequently due to the unequal expansion of the laminæ which compose them, in consequence of their being imperfect conductors of heat, like glass and cast iron. The true cleavage of minerals may often be detected in this way, for they fly asunder at their natural fissures.

DECOLORIMETER. An instrument invented by Payen for estimating the decolorising power of charcoal. It depends upon the fact that a longer column of a comparatively lighter coloured liquid exhibits by transmitted light the same depth of colour as a proportionally shorter column of a more strongly-coloured solution.

(Dict. Techn. viii. 532. Dingl. Polyt. J. xxvii. 372; Handw. d. Chem. 2^{te} Aufl. ii. [3] 383.)

DECOMPOSITION. See CHEMICAL AFFINITY (i. 853).

DEGERÖITE or **DEGERÖEITE.** An amorphous brown mineral, found near Stansvik, on Degerö, not far from Helsingfors in Finland. It contains, according to Thoreld's analysis, 36.6 p. c. silica, 13.7 water, 41.4 ferric oxide, 1.16 ferrous oxide, 2.9 lime, 2.5 magnesia, 0.8 alumina, and a small quantity of phosphoric acid: it appears to be a product of decomposition. (Arppe, *Analyser af finska mineralier*, p. 18.)

DEÏAMBA, or *Congo Tobacco*, is a plant growing wild in the marshy districts of Congo, the flowers of which produce a narcotic effect when smoked, and are much used in the locality.

DELANOVITE. A manganiferous bole from Michac, Dep. de Dordogne, in France. It is amorphous, reddish-white or red, slightly translucent on the edges. Hardness = 1 to 1.5. Fracture splintery. Lustre slightly waxy. Adheres strongly to the tongue, and becomes somewhat plastic by immersion in water. Decomposed by sulphuric acid. An analysis by C. v. Hauer gave 50.55 SiO₂, 19.15 Al₂O₃, 0.63 CaO, 4.40 Mn₂O, 24.05 H₂O (total 98.78). Of the water, 14.05 pts. go off at 100° C., and the remainder at a red heat. (Jahresber. d. Chem. 1853, p. 829.)

DELESSITE. Ferruginous chlorite. (See CHLORITE, i. 914.)

DELIQUESCENCE. The property which certain very soluble salts and other bodies possessed of absorbing moisture from the atmosphere, and dissolving therein.

DELPHIN. *Delphinin*, *Phocenin*, *Dolphin-fat*, *Huile de Dauphin*. (Chevreul [1818] Ann. Ch. Phys. [2] xxii. 374.—*Recherches sur les corps gras*. pp. 190, 287, and 467.—Berthelot, Ann. Ch. Phys. [3] xli. 251).

A neutral fat found in the oil of *Delphinus globiceps*, *D. Phocæa*, and *D. marginatus*; it has not yet been obtained in the pure state, the olein not having been completely separated.

To prepare it, 100 pts. of dolphin-oil are dissolved in 90 pts. of warm alcohol of specific gravity 0.797; the solution is decanted from the oil which precipitates on cooling, and distilled with water; the oil which remains in the retort, and consists of a mixture of delphinin and olein, is separated from the watery liquid and treated with cold dilute alcohol; and the alcohol is evaporated, after the solution has been separated from the undissolved olein.

Delphin is an oil very mobile at 17° C.; specific gravity 0.954 (Chevreul), 0.948 (Berthelot). It has a faint, peculiar, somewhat ethereal odour, like that of valeric acid. Does not redden litmus. Boiling point 258° C. (Berthelot.)

It dissolves abundantly in hot alcohol. The alcoholic solution, diluted with a large quantity of water, and distilled, leaves delphin, which reddens litmus from containing free valeric acid. The fat, when exposed to warm air, likewise acquires the power of reddening litmus, and a powerful odour proceeding from the liberated valeric acid. Delphin heated to 100° C. with an equal quantity of oil of vitriol, and then left to itself, gives off, after a week, the odour of valeric and sulphurous acids; water added to it takes up sulphuric, sulphoglyceric, and valeric acid, and glycerin, and leaves an oily mixture of valeric acid, oleic acid, and a small quantity of unsaponified fat. 100 pts. delphin saponified with potash, yield 36 pts. valeric acid, 59 pts. oleic acid, and 15 pts. of glycerin.

100 pts. of the oil of the common porpoise (*Delphinus Phocæa*) saponified with baryta yielded 82.2 pts. of fixed fatty acids, 16.0 pts. phocenate (valerate) of barium, and 14.0 glycerin, or 6.7 pts. glycerin to 10.0 pts. valeric acid (C¹⁰H¹⁸O⁴). The same oil treated with alcohol yielded successively three oils, containing respectively 4.4 pts., 4.4 pts. and 5.1 pts. glycerin to 10. pts. valeric acid. The first of these three oils when again treated with alcohol, yielded a new liquid (phocenin) containing 2.7 pts. glycerin to 10 pts. of valeric acid (Chevreul). The oil of *Delphinus globiceps* was found to contain, besides fixed fatty acids and ethal, 5.9 pts. glycerin to 10.0 valeric acid. Now for 10 pts. of valeric acid, monovalerin contains 9.0 pts.; divalerin 4.5 pts., and trivalerin 3.0 pts. of glycerin. Hence it appears that phocenin is intermediate in composition between the artificial valerins, and may therefore be regarded as a mixture of them—a conclusion further warranted by its separation into valeric acid and glycerin by saponification. (Berthelot.)

DELPHINIC ACID. *Phocenic acid*. The acid thus denominated by Chevreul, and discovered by him, first in dolphin-oil and afterwards in the ripe berries of the guelder rose, is now known to be identical with valeric acid.

DELPHININE. (Lassaigne and Feneuille (1820), Ann. Ch. Phys. xii. 358. Brandes, Schw. J. xxv. 369. O. Henry, J. Pharm. xviii. 661. Couerbe, Ann. Ch. Phys. lii. 352.) An alkaloïd discovered by Lassaigne and Feneuille, in the *Delphinium Staphisagria*, or *Stavesacre*. It is thus obtained:—

The seeds, deprived of their husks, and ground, are boiled in a small quantity of distilled water, and then pressed in a cloth. The decoction is filtered, and boiled for a few minutes with pure magnesia. It must then be refiltered, and the residue left on the filter well washed, and then boiled with highly rectified alcohol, which dissolves out the alkali. By evaporation, a white pulverulent substance, presenting a few crystalline points, is obtained.

It may also be procured by the action of dilute sulphuric acid on the bruised but unshelled seeds. The solution of sulphate thus formed is precipitated by carbonate of potassium. Alcohol separates the base from this precipitate in an impure state. It may be purified by treating it with boiling water to separate a small quantity of nitre, then digesting the residue with ether, which dissolves out the pure delphinine, and evaporating the ethereal solution (Couerbe). The matter insoluble in ether Couerbe designates as *Staphisaine*.

Delphinine is slightly yellow, but yields a nearly white powder. It does not crystallise. Its taste is bitter and acrid. When heated it melts, and on cooling becomes hard and brittle like resin. If more highly heated, it blackens and is decomposed. Water dissolves a very small portion of it. Alcohol and ether dissolve it very readily. The alcoholic solution renders syrup of violets green, and restores the blue tint of litmus reddened by an acid. It forms soluble neutral salts with acids. Alkalis precipitate the delphinine in a white gelatinous state, like alumina.

Sulphate of Delphinine does not crystallise, but becomes a transparent mass like gum. It dissolves in alcohol and water, and its solution has a bitter acrid taste.

Nitrate of Delphinine, when evaporated to dryness, is a yellow crystalline mass. If treated with excess of nitric acid, it becomes converted into a yellow matter, little soluble in water, but soluble in boiling alcohol. This solution is bitter, is not precipitated by potash, ammonia, or lime-water, and does not appear to contain nitric acid, though it is not alkaline. It is not destroyed by further quantities of nitric acid, nor does it form oxalic acid. Delphinine is distinguished from strychnine and morphine by not assuming a red colour when treated with nitric acid. The *hydrochlorate* is very soluble in water.

The *Acetate of Delphinine* does not crystallise, but forms a hard transparent mass, bitter and acrid, and readily decomposed by cold sulphuric acid. The *oxalate* forms small white plates, resembling in taste the preceding salts. (Lassaigne and Feneuille.)

Delphinine produces nausea when taken internally, and excites a prickly burning sensation when rubbed on the skin. It is said to act on the nervous system, and is used as a remedy in chronic swellings of the glands.

DELPHINITE. Syn. with **EPIDOTE**.

DELPHINIUM. The seeds of *Delphinium Staphisagria* contain, in 100 pts., 19·1 pt. of an oil for the most part soluble in alcohol, 1·4 stearin, 8·1 delphinine, together with gum, starch, &c. According to Couerbe, they contain also staphisagrine, and according to Hofschläger, a peculiar acid.

DELPHINONE. Syn. with **VALERONE**.

DELVAUXITE. *Delvauxene*. A hydrated ferric phosphate occurring at Berneau near Visé in Belgium, in black or brown-black kidney-shaped masses, having a perfectly conchoidal fracture. Before the blowpipe, it melts to a green magnetic globule. Its composition may be expressed, according to Rammelsberg, by the formula $2\text{Fe}^4\text{O}^3 \cdot \text{P}^2\text{O}^5 + 24\text{H}^2\text{O}$, but it is generally mixed with carbonate of calcium and silica. C. v. Hauer (J. pr. Chem. lxiii. 15) analysed two specimens of this mineral: *a*. from the locality above mentioned, *b*. from Leoben in Styria. The former gave off 12·2 p. c. water at 100° C., and 13·84 p. c., more at a red heat; the latter 12·8 p. c. at 100°, and 13·91 at a red heat. After drying over chloride of calcium, the former contained 17·02 p. c. water, the latter 16·79. These last amounts of water are adopted in the calculation of the following analyses, after deducting 2·08 silica in *a* and 1·24 silica in *b*:

	P^2O^5	Fe^4O^3	Ca^2O	H^2O	Total.
<i>a</i> .	20·93	52·03	7·94	19·08	99·98
<i>b</i> .	20·04	52·54	8·37	19·04	99·99

From these analyses, Hauer deduces the formula $2\text{Ca}^2\text{O} \cdot \text{P}^2\text{O}^5 + 5\text{Fe}^4\text{O}^3 \cdot \text{P}^2\text{O}^5 + 16\text{H}^2\text{O}$.

DEMIDOFFITE. A mineral from Nischne Tagilsk in the Ural, where it occurs as a thin coating on malachite; it was formerly called blue malachite. Its surface

is tolerably specular, and covered with fine cracks. Colour sky-blue, sometimes with a tinge of green. It is amorphous, translucent on the edges; brittle. Hardness = 2. Specific gravity 2.25. It consists essentially of cupric silicate. Analysis gave 31.55 SiO_2 , 9.53 Al_2O_3 , 33.14 Cu_2O , 3.15 Mg_2O , and 23.03 H_2O . (Nordenskiöld, Sill. Am. J. xxiv. 116.)

DENDRACHATES. Moss agate (i. 62).

DENDRITES. Dendritic or arborescent forms indicate imperfect crystallisation, the crystals laying themselves end to end in long aggregations, somewhat like the branches of a tree. This mode of grouping is particularly frequent in bodies which crystallise in the regular system; striking examples are afforded by the native metals, copper, silver, and gold. The ores of manganese also frequently form dendrites in cracks of rocks, and even in the interior of minerals, as in compact magnesite, and in the variety of carbonate of calcium used as lithographic stone. Good examples of artificial dendrites are afforded by the so-called lead and silver trees, formed by precipitating those metals from their solutions by another metal. Remarkable dendritic crystallisations of iodide and chloride of potassium are described by Warington (Chem. Soc. Qu. J. v. 136; viii. 31; see also CRYSTALLOGRAPHY, p. 159).

DEOXIDATION. The abstraction of oxygen. This term is to a certain extent synonymous with reduction, but it is sometimes restricted to partial abstraction of oxygen, the term reduction being applied to the total abstraction of that element: thus peroxide of manganese is said to be deoxidised by heat; oxide of silver to be reduced; this distinction is, however, not very frequently made. The abstraction of oxygen (or other electro-negative radicle) from a compound is evidently equivalent to the addition of a metal (or other positive radicle); thus the conversion of ferric oxide Fe_2O_3 into ferrous oxide FeO , is the same as the addition of Fe^2 to the former, whereby it is converted into Fe^3O_3 . A deoxidising agent may therefore be called a *metal-adding agent*.

DEPHLEGMATION. An old term, applied to the process of freeing spirituous or acid liquids from water (*phlegma*). The apparatus used for this purpose in distilleries are called dephlegmators.

DEPHLOGISTICATION, or the abstraction of phlogiston, was, according to Stahl's theory, the process of combustion (i. 1089). The "dephlogisticated" bodies of this system were in part the same as those now called "oxidised;" thus oxygen was dephlogisticated air, litharge was dephlogisticated lead, chlorine was dephlogisticated muriatic acid, &c.

DEPILATORIES. Substances used for removing the hair. Such are rhusma (*Rhusma turcorum*), sulphurate of calcium, &c.

DERMATIN. *Dermatite*.—A silicate of iron and magnesium, $\text{M}^2\text{SiO}_3 + 2\text{aq}$; occurring at Waldheim in Saxony, in kidney-shaped and stalactitic masses, unctuous to the touch, of dark green or brownish colour. Hardness = 2.5. Specific gravity 2.1. Decrepitates and blackens before the blowpipe.

According to two analyses by Ficinus (Min. Ges. zu Dresden, ii. 215) it contains:

SiO_2	Mg_2O	Fe_2O	Mn_2O	H_2O	CO_2	Al_2O_3	CaO	Na_2O
35.80	23.70	11.33	2.25	25.20	0.42	0.83	0.83	0.50 = 100.03
40.17	19.33	14.00	1.17	22.00	0.83	0.83	1.33	$\text{SO}_3 = 0.43 = 100.10$

DENSITY. See SPECIFIC GRAVITY.

DESCLOÏZITE, PbVO_2 or 2PbO.VO^3 . An ore of vanadium from La Plata. It is found in rhombic crystals 1 or 2 millimetres thick, of a dark olive colour and strong lustre, reddish-brown by transmitted light, and yielding a brown streak. Hardness 3.5. Specific gravity 5.839. The crystals are united in botryoidal groups and are implanted on quartz-rock, together with pyromorphite. On charcoal before the blowpipe, the mineral yields a metallic bead of lead, together with a black slag. Dissolves in cold dilute nitric acid, leaving a residue of manganic oxide and quartz. The mean of two analyses gave 22.46 per cent. V_2O_3 , 54.70 Pb_2O , 2.04 Zn_2O ; 0.90 Cu_2O , 5.32 Mn_2O , 1.50 Fe_2O_3 , 2.20 H_2O , 0.32 Cl and 9.44 insoluble residue, consisting of manganic oxide and silica. (A. Damour, Ann. Ch. Phys. [3] xli. 72.)

DESMIN. See STILBITE.

DESOKALIC ACID. Syn. with RACEMO-CARBONIC ACID.

DETONATION. The noise accompanying the sudden decomposition of a compound or mixture of chemical compounds, or the sudden combination of two or more substances, as the union of oxygen and hydrogen under the influence of heat or

electricity, of chlorine and hydrogen under that of light, the decomposition of fulminating silver, of chloride or iodide of nitrogen, &c., the combustion of sulphur or phosphorus when mixed with chlorate of potassium, and struck or triturated, the explosion of gunpowder, &c. In all these cases, the noise is due to the concussion of the air resulting from the sudden production of a large quantity of gas; a mixture of oxygen and hydrogen exploded by the electric spark in a tightly closed vessel, produces no report.

DEUTO-COMPOUNDS. The proper use of the prefix *deuto* (from *δευτερος*) is to denote the second in order of the terms of any series: thus, in the several series of oxides Fe^2O , Fe^3O^3 ; Mn^2O , Mn^4O^3 , Mn^2O^2 ; Pb^4O , Pb^2O , Pb^4O^3 , Pb^2O^2 ; SnO , SnO^2 the compounds Fe^4O^3 , Mn^4O^3 , Pb^2O , SnO^2 are, properly speaking, the deutoxides of the respective metals, the *deuto* denoting simply the place of the compound in the series, not its atomic composition. Such, indeed, was the original use of this prefix; but it has often been confounded with *bi* or *di*, which properly refers to the constitution of the compound, as compared with that of the *proto*- or *mono*-compound of the same series. It is not at present so much used as formerly.

DEVONITE. Syn. with **WAVELLITE**.

DEWEYLITE. An amorphous hydrated silicate of magnesium, occurring with serpentine at Middlefield, Massachusetts, in Texas county, Pennsylvania, at Bare Hills, Maryland, and in the Tyrol. Hardness = 2 to 3·5. Specific gravity = 2·246, Middlefield (Shepard); 2·19 to 2·31, Bare Hills (Tyson); 2·216 *ibid.* (Thompson); 1·936 to 2·155 Tyrol (Vellacher). Colour, whitish, yellowish, wine-yellow, greenish, reddish. Translucent. Brittle and often much cracked. Before the blow-pipe it decrepitates, becomes opaque, and fuses with great difficulty on the edges. In powder it forms with borax a transparent glass.

Analyses.—*a.* Middlefield (Shepard, Sill. Am. J. xviii. 31, 1830; analysis imperfect).—*b.* Texas, Pennsylvania (Brush, *Dana's Mineralogy*, ii. 286).—*c.* Bare Hills (Thompson, Phil. Mag. 1843, 191).—*d.* Tyrol (Vellacher, Zeitsch. Geol. Gesellsch. iii. 222).—*e.* *Ibid.* (Kobell, Münch. gel. Ang. xxxiii. 1).—*f.* *Ibid.* (Widtermann, Jahrb. geol. Reichsanst. iv. 525.)

	SiO^2	Mg^2O	Ca^2O	H^2O	Al^3O^3	Fe^4O^3	
<i>a.</i>	40	40	. .	20	= 100
<i>b.</i>	43·15	35·95	. .	20·25	trace	= 99·35
<i>c.</i>	40·16	36·00	0·80	21·60	trace	1·16 . .	= 99·72
<i>d.</i>	40·40	35·85	. .	22·60	. .	0·38 Apatite	0·78 = 100
<i>e.</i>	41·50	38·30	. .	20·50	= 100·30
<i>f.</i>	40·82	36·06	. .	21·72	. .	0·42, CO^2	0·59 = 99·61

Hence the formula $4\text{Mg}^2\text{O} \cdot 3\text{SiO}^2 + 6 \text{ aq.}$ or $2\text{Mg}^2\text{SiO}^3 \cdot \text{Mg}^4\text{SiO}^4 + 6 \text{ aq.}$

The mineral from Bare Hills, and that from the Tyrol, analysed by Widtermann, have been called *gymnite*; but they belong to the same species as the rest.

An earthy variety from the Tyrol yielded 49·06 SiO^2 , 28·50 Mg^2O , 16·25 H^2O , 0·69 Fe^4O^3 , 4·76 CO^2 (= 99·28). (Widtermann.)

DEXTRIN. $\text{C}^6\text{H}^{10}\text{O}^5$, or $\text{C}^{12}\text{H}^{20}\text{O}^{10}$. *British gum*. *Leiocome*. (Biot and Persoz, Ann. Ch. Phys. [2] lii. 72. Payen, *ibid.* lv. 225; lxi. 372; lxx. 225, 334. Guérin-Varry, *ibid.* lx. 68. Jacquelin, *ibid.* [3] viii. 225. Béchamp, Compt. rend. li. 256. Gm. xv. 185.)—When starch is subjected to a high temperature, or to the action of dilute acids or alkalis, or of diastase, it is converted into a new substance, identical in composition, but possessing totally different properties, being completely soluble in boiling water, and forming a solution which turns the plane of polarisation of a luminous ray to the right; hence the name *dextrin*. This compound is also formed from starch by the action of saliva, bile, blood-serum, pancreatic juice and other animal matters, and by the action of light upon starch-paste.

Preparation.—1. By submitting starch to gentle *torrefaction*. The starch in the state of powder is placed in a thin layer in a shallow iron vessel with double bottom containing oil, which is heated to a temperature not exceeding 160°C ; it may also be heated in revolving cylinders, like those used for roasting coffee. The operation is finished when the substance exhibits a light brown colour, and exhales the odour of strongly baked bread.

2. One part of starch is acted upon by $\frac{1}{2}$ pt. oil of vitriol and 2·8 pts. water. The acid is mixed with part of the water, and the starch stirred up with the rest; the diluted acid is gradually poured upon the starch, and the mixture is kept for some time at 90°C . The dextrin is precipitated by alcohol from the clarified solution (Biot and Persoz). Dextrin so prepared cannot be purified from sugar which is formed at the same time and adheres to it, except by dissolving it at least ten times in water, and precipitating the solution with alcohol, which should not be employed in excess.

3. By the action of *dilute acids* aided by heat. To convert 1000 pts. of dry starch into dextrin by this process, it is mixed with 2 pts. of nitric acid of 36° Bm. diluted with 300 pts. of water, and spread in layers about an inch thick on brass drawers placed in an oven heated to 110° or 120° C. The transformation into dextrin is completed in about an hour and a half. (Payen.)

4. By the action of *diastase*. 400 pts. of water are heated to about 75° C. with 5 pts. of ground malt, and 500 pts. of starch added by small portions at a time. The starch dissolves, and, as soon as the solution is complete, the water is rapidly heated to the boiling point, to arrest the action of the diastase and prevent the formation of glucose. The solution is then filtered and concentrated to the consistence of syrup, in a boiler heated by steam and provided with a mechanical agitator. The second process yields the purest product.

Properties.—Dextrin is an uncrystallisable, solid, translucent substance having the aspect of gum arabic. It is soluble in *water* and in *dilute alcohol*, but insoluble in absolute alcohol. The aqueous solution is perfectly limpid and becomes gummy by concentration. Its optical rotatory power is 138.68° to the right (Payen) = 176° (Béchamp.)

Decompositions.—1. Dextrin is not coloured blue by *iodine*.—2. By boiling with *dilute acids* and with *caustic alkalis*, it is converted into glucose. When a solution of dextrin is mixed with a small quantity of *caustic potash*, and a dilute solution of *sulphate of copper* added drop by drop, the liquid acquires a deep blue colour and remains limpid in the cold; but if heated above 85° C. it quickly decomposes and deposits a red crystalline precipitate of cuprous oxide. This property distinguishes dextrin from gum arabic.—3. Dextrin heated with *nitric acid* does not yield mucic acid, but only oxalic, and perhaps a little saccharic acid.—4. A mixture of *nitric* and *sulphuric acids* converts dextrin into a nitro-compound resembling xyloidin, soluble in water, precipitable by sulphuric acid (Flores Domonte and Ménard, *Compt. rend.* xxiv. 391). According to Béchamp, this compound is dinitro-dextrin, $C^6H^8(NO^2)^2O^5$.—5. A solution of *baryta* in wood-spirit forms with dextrin a copious precipitate insoluble in wood-spirit, but soluble in excess of water, especially when hot; it contains 46.7 per cent. baryta (Payen).—6. Dextrin is also precipitated by *lime*.—7. The solution of dextrin in water or in aqueous alcohol does not precipitate either neutral or basic *acetate of lead*; but on adding ammonia, a white precipitate is formed containing $C^6H^{10}O^2.Pb^2O$. When heated to 180° C. it turns yellow and appears to lose $\frac{1}{2}$ at. water (Payen). Dextrin is precipitated by *stannous chloride*, but not by *ferrous sulphate*.

Uses.—Dextrin is applied to a variety of useful purposes; it may, indeed, be used in almost all cases in place of gum arabic. It is employed for stiffening calicos and other cotton stuffs, for the application of mordants in calico printing, for the sizing of paper, for the adhesive layer at the back of postage-stamps, &c. In surgery it is used for making bandages, which become very hard when dry, but are easily removed by means of warm water.

For these technical uses, the crude solution of dextrin is often used, just as it is obtained by the action of diastase or sulphuric acid upon starch; in the latter case, the free acid is neutralised with chalk and the liquid evaporated. The syrup of dextrin thus produced likewise contains unaltered starch, sugar and water, the relative quantities of these substances varying according to the mode of preparation. Dextrin-syrup is very liable to decomposition.

Estimation.—To estimate the quantity of dextrin in a solution likewise containing glucose, Gentele determines the total amount of both these bodies by means of a standard solution of potassio-cupric tartrate, and then estimates the glucose with an alkaline solution of ferricyanide of potassium (red prussiate), which does not act upon dextrin. The difference of the two determinations gives the quantity of dextrin.

In the viscous fermentation of saccharine liquids, a gummy matter is formed which bears considerable resemblance to dextrin. It is soluble in water, uncrystallisable, insoluble in alcohol, and precipitated by alcohol from its aqueous solution. Dried at the heat of the water-bath, it is vitreous, transparent, and exactly resembles gum-arabic, with which it likewise agrees in composition; nitric acid converts it into oxalic acid (Tilloy and MacLagan, *Phil. Mag.* [3] xxviii. 12).

Béchamp has lately shown (*Compt. rend.* xlii. 1210) that the production of dextrin by the action of dilute acids or of diastase on starch is preceded by the formation of an intermediate substance, which may be called *soluble starch*, inasmuch as it is soluble in water, but retains the power of forming a blue colour with iodine. This soluble starch possesses an optical rotatory power much greater than that of dextrin. [See STARCH.]

Cellulose dextrin.—Cellulose subjected to the action of strong sulphuric acid yields a product resembling ordinary dextrin in many of its properties, but deflecting the

plane of polarization $85^{\circ} 9'$ to the left instead of to the right, and yielding a somewhat different product with nitric acid. (Béchamp.)

DEXTRIN-SUGAR. This name is applied by Ventzke to an uncrystallisable dextro-rotatory sugar, probably a mixture of dextrin and glucose.

DEXTRIN SYRUP. See DEXTRIN.

DEXTORACEMIC or **DEXTROTARTARIC ACID.** Ordinary tartaric acid is thus designated, to distinguish it from lævo-racemic, lævo-tartaric, or anti-tartaric acid (see i. 348; also TARTARIC ACID and RACEMIC ACID).

DIABASE. This name, synonymous partly with *greenstone*, partly with *diorite*, is applied to rocks consisting of crystallo-granular mixtures of augite with felspar (oligoclase or labradorite) usually interpenetrated with earthy or scaly chlorite. Diabase has a specific gravity of 2.80 to 2.95; it is massive, coarse or fine-grained, often strongly fissured, sometimes with columnar or laminar separations, sometimes having a slaty structure. The oligoclase and labradorite in the mixture form either distinct crystals, or tabular or granular crystalline aggregates, of a white, greyish, or greenish-white colour, also reddish or brownish. The augite is granular, or in prisms of various lengths, green, brown, or black, often resembling hypersthene. The chlorite, which penetrates the entire mass and gives it a green tint, is probably not an original constituent of the rock, but a product of decomposition, inasmuch as the amount of the water found by analysis is too great to be ascribed wholly to chlorite. (Handw. d. Chem. 2^e Aufl. ii. [3] 420.)

DIABETIC SUGAR. The sugar found in considerable quantity in the urine in cases of *Diabetes mellitus*, was formerly regarded as a distinct kind of sugar, but is now known to be identical with dextro-glucose. (See GLUCOSE, SUGAR, and URINE.)

DIACLASITE. A variety of augite, intermediate in composition between diallage and hypersthene, found in the Harzburg forest in the Harz. According to Köhler's analysis (Pogg. Ann. xiii. 101), it contains 53.7 per cent. silica, 25.1 magnesia, 11.5 ferrous oxide, 3.7 water, 1.3 alumina, and 0.2 manganous oxide. Hausmann (*Handb. d. Mineral.* ii. 498) regards it as a distinct species; but the large amount of water, and the comparatively low degree of hardness of the mineral ($= 3.5$ to 4.0) indicate an advanced stage of decomposition.

DIADOCHITE. *Phosphoricisensinter.*—A mineral consisting of hydrated ferric phosphate and sulphate, from the alum-slate near Gräfenenthal and Saalfeld in Thuringia. It occurs in reniform or stalactitic masses, with curved lamellar structure and conchoidal fracture. Hardness = 3. Specific gravity = 2.03. It is translucent or opaque, with waxy lustre, and wax-yellow to yellowish-brown colour. Streak white. Heated in a tube it gives off a large quantity of acid water. Before the blowpipe it swells up and fuses on the edges to a black magnetic scoria. According to Plattner's analysis (*Rammelsberg's Mineralchemie*, p. 360) it contains 14.82 per cent. P^2O^5 , 15.4 SO^2 , 39.69 Fe^2O^3 , and 30.35 water, agreeing nearly with the formula, $3Fe^2O^3.2P^2O^5 + 4(PO)^{'''}_4$
 $2(Fe^2O^3.2SO^3) + 32H^2O = 4(SO^2)^{'''}_{f,30} O^{25} + 32H^2O$. When heated with water it gives up 12.6 per cent. SO^3 , but no ferric oxide.

DIAGOMETER. An electrical apparatus, intended for the detection of adulterations in olive oil, this oil being said to have less electric conducting power than other fixed oils. (Rousseau, J. Pharm. ix. Dec. 1833.)

DIAGONITE. Syn. with BREWSTERITE.

DIAGRYDIUM. An obsolete name of scammony.

DIALLAGES. *Schiller-spar* (in part).—A variety of augite, occurring chiefly in *gabbro*, a rock closely related to serpentine. It is thin-foliated and easily cleavable; laminae brittle. Colour, various shades of green, grey, and brown, sometimes bronze, or nearly metallic. Specific gravity 3.11 to 3.227. It is related to bronzite and hypersthene, but is distinguished from them by the large amount of lime which it contains. A specimen from Odern, analysed by Delesse (*Ann. Min.* [4] xvi. 34) gave 49.30 per cent. SiO^2 , 17.61 Mg^2O , 15.43 Ca^2O , 9.43 Fe^2O , 0.51 Mn^2O , 5.50 Al^2O^3 , 0.30 Cr^2O^3 , 0.85 loss by ignition.

(For other analyses, see *Rammelsberg's Mineralchemie*, p. 465.) Diallage heated in a tube yields water, and assumes a paler colour; on charcoal it fuses with difficulty on the edges to a grey slag; with borax it forms a glass coloured by iron. Bischof (*Chemical and Physical Geology*, ii. 331) regards diallage, bronzite, and hypersthene as altered augites, and supposes that a further alteration might convert them into serpentine.

DIALLAGITE. DIALLOGITE. DIALOGITE. Native carbonate of manganese (i. 789).

DIALLYL-UREA. See CARBAMIDE (i. 754) and SINAPOLINE.

DIALURAMIDE. *Uramil*. $\text{C}^4\text{H}^2\text{N}^3\text{O}^3 = \text{N}.\text{C}^4\text{H}^3\text{N}^2\text{O}^3.\text{H}^2$. (Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 274, 313 and 323.)—Laurent, regarding dialuric acid as dibasic, derives dialuramide from 2 at. ammonia, and writes it $\text{C}^8\text{H}^{10}\text{N}^6\text{O}^6 = \text{N}^2.\text{C}^8\text{H}^6\text{N}^6\text{O}^6.\text{H}^4$.

This compound is formed when solutions of alloxantin and chloride of ammonium, both freed from air by boiling, are mixed together; it crystallises out, and the mother-liquor contains alloxan and hydrochloric acid (see ALLOXANTIN, i. 139). It is also prepared by boiling an aqueous solution of thionuric acid, or thionurate of ammonium, with dilute hydrochloric or sulphuric acid, till it becomes turbid, and allowing it to cool; even if the solution be not concentrated, it solidifies to a crystalline magma of dialuramide:

Dialuramide forms white hard needles, united in tufts, having a silky lustre, and turning red when exposed to air containing a trace of ammonia. It is insoluble in cold water; slightly soluble in boiling water, whence it separates on cooling. Soluble in cold sulphuric acid, and precipitated unchanged by water; soluble in cold potash or ammonia, and reprecipitated by acids.

Decompositions.—1. Dialuramide treated with *nitric acid* evolves nitrous fumes, and forms a solution which yields alloxan on evaporation, nitrate of ammonium remaining in solution:

2. When a hot dilute solution of *potash* is saturated with dialuramide, ammonia is evolved, and a pale-yellow solution formed, which absorbs oxygen from the air, gradually becomes purple, and deposits gold-yellow crystals of potassic purpurate. The mother-liquor contains alloxanate and mesoxalate of potassium.—3. A solution of dialuramide in *ammonia* is decomposed by boiling, turns purple, and on cooling deposits crystals of ammonic purpurate (murexide). The same solution mixed with aqueous alloxan yields murexide. Murexide is also obtained when argentic or mercuric oxide is gradually added to dialuramide suspended in boiling water, the metal being reduced, without evolution of gas, and a purple liquid formed; the slightest excess of oxide decolorises the solution, which then contains ammonic alloxanate:

4. When a solution of dialuramide in *sulphuric acid* is diluted till it begins to be turbid, and boiled for some time, the water being renewed, uramilic acid separates on cooling, ammonio sulphate being simultaneously formed. If too much sulphuric acid be present, no uramilic acid is obtained.—5. Dialuramide heated with aqueous *cyanate of potassium*, is converted into pseudo-uric acid. (Schlieper and Baeyer, Pogg. Ann. cxii. 79.)

DIALURIC ACID. $C_4H_4N_2O_4$. (Liebig and Wöhler, [1838] Ann. Ch. Pharm. xxvi, 276.)—This acid is the final product of the action of reducing agents on alloxan. It is formed: 1. When sulphuretted hydrogen is passed through a boiling aqueous solution of alloxan until no further action takes place:

2. Together with other products, by the action of cyanide of ammonium or cyanide of potassium on aqueous alloxan :

The hydrocyanic acid does not itself enter into these reactions, but merely acts in the manner of a ferment. (Strecker, Ann. Ch. Pharm. cxiii. 49.)

Dialuric acid is prepared by dissolving dialurate of ammonium in warm hydrochloric acid; dialuric acid crystallises out on cooling. Dialurate of ammonium is thus prepared:—1. By saturating with sulphuretted hydrogen a boiling aqueous solution of alloxan, filtering from deposited sulphur, and neutralising the acid filtrate with carbonate of ammonium.—2. By treating aqueous alloxan with zinc and hydrochloric acid, decanting from the precipitated alloxantin, and adding to the solution sufficient carbonate of ammonium to redissolve the precipitated hydrate of zinc.—3. By adding hydrosulphate of ammonium to a solution of uric acid in dilute nitric acid, until the mixture is barely acid to litmus; washing the resulting precipitate with cold water, dissolving it in boiling water, and neutralising the solution with carbonate of ammonium, when it solidifies into a crystalline mass of dialurate.

Dialuric acid forms colourless needles, resembling those of alloxantin; they must be rapidly separated from the mother-liquid and dried. They redden litmus strongly; they are not very soluble in water. The acid neutralises alkalis completely, forming definite salts, dialurates, which are sparingly soluble in cold water, and in the dry state are permanent in the air. The ammonium-salt crystallises in silky needles, which become rose-coloured when dried at the ordinary temperature, and blood-red at 100° C., being converted into purpurate of ammonium:

Their solution reduces silver-salts. The barium-salt is white.

According to the above formula, dialuric acid is monobasic; Laurent regards it as dibasic, and proposes to double its formula.

Decompositions.—1. An aqueous solution of dialuric acid is decomposed by boiling, oxalic acid and other products being formed.

2. Dialuric acid (crystallised, or in aqueous solution) is converted into alloxantin by exposure to the air (see ALLOXANTIN, i. 138):

3. Aqueous dialuric acid mixed with aqueous alloxan deposits crystals of alloxantin:

F. T. C.

DIALYSIS. A term applied by Graham to the separation of certain substances by liquid diffusion. Soluble substances exhibit great diversity in their degrees of diffusive mobility, and may be divided, as regards this property, into two classes, the more diffusible being either themselves crystallisable, such as common salt and sugar, or closely related to the crystalline class, such as alcohol: hence they are called crystalloids; while the less diffusible are those which are incapable of crystallising, but exhibit a great tendency to assume the gelatinous form; these are called colloids, after gelatin (*colle*), which may be regarded as the type of the class: among these may be mentioned hydrated silicic acid, hydrated alumina and other sesquioxides of the aluminous class when in the soluble state, also starch, dextrin, gum, caramel, tannin, albumin, gelatin, and extractive matters both animal and vegetable. The diffusion of these bodies is extremely slow.

Now it is found that certain gelatinous substances, such as starch-paste, animal mucus, pectin, Payen's vegetable gelose, and other colloidal hydrates, are easily permeable, when in mass, to the more highly diffusible class of bodies, but offer great resistance to the passage of the less diffusive, and are completely impervious to colloidal substances like themselves. Hence such substances afford an easy means of separating crystalloidal from colloidal bodies, when the two exist together in a liquid: a mere film of the jelly is sufficient to produce the separation. A very convenient substance for the purpose is the vegetable or paper-parchment, obtained by immersing unsized paper for a short time in sulphuric acid of a certain strength (i. 819). A sheet of this parchment stretched on a hoop of thin wood, or gutta percha, forms a very convenient dialyser. The fluid to be dialysed is poured into the hoop to the depth of about half an inch, and the whole is floated on water. The more diffusive substances then pass through the septum, leaving the less diffusive behind.

When a mixture of sugar and gum was placed in the dialyser, $\frac{3}{4}$ of the sugar passed through the membrane in 24 hours without a trace of the gum. When a solution of silicate of sodium mixed with hydrochloric acid was treated in like manner, $\frac{7}{8}$ of the silicic acid was left upon the dialyser at the end of five days, without a trace of hydro-

chloric acid or chloride of sodium. Half a litre of urine dialysed for 24 hours gave up all its crystalloidal constituents to the water, without a trace of mucous or gelatinous matter, so that the aqueous solution, when evaporated, left a white mass, from which urea was extracted by alcohol in so pure a state as to appear in crystalline tufts when the alcohol was evaporated.

The dialytic process is exceedingly well adapted to the separation of arsenious acid and other metallic poisons from liquids containing organic matter. Milk, defibrinated blood, and other organic substances, mixed with a few milligrammes of arsenic, and introduced into the dialyser floating on water, give up the greater part of the arsenious acid to the water in the course of 24 hours, and the diffusate is quite free from organic matter, so that the arsenic may be immediately precipitated by sulphydric acid and weighed as sulphide. [For further details, see LIQUIDS, DIFFUSION OF.]

DIAMAGNETISM. Many substances, *e. g.* bismuth, antimony, tin, cadmium, and gold, when brought near either pole of a powerful magnet, are repelled from that pole; and if a bar of such a substance be suspended between the poles of a horse-shoe magnet, or the opposite poles of two bar magnets, it places itself *equatorially*, or at right angles to the line joining the two poles. Such bodies are said to be diamagnetic, in contradistinction to magnetic bodies, like iron and nickel, which are attracted by the magnet, and place themselves *axially*, that is in the line joining two opposite poles. Diamagnetism does not, however, appear to be a distinct property of matter, the true explanation of the phenomenon being that all substances, including the air, are magnetic, and that the so-called diamagnetic substances are those which are less magnetic than the air, and consequently when brought near a magnetic pole, recede from it, just as a balloon recedes from the earth, because it is less attracted by the earth than an equal bulk of the surrounding air. (See MAGNETISM.)

DIAMOND. The purest form of carbon. It is almost always crystallised; rarely massive. The crystals belong to the regular system, exhibiting the simple forms O , ∞O , $mO\infty$, mOn (figs. 149, 151, 185, 187) more rarely $\infty O\infty$ and $mO\infty$ (figs. 150, 183), and the combinations $O . \infty O\infty$ (fig. 161), $O . \infty O$ (fig. 199 &c.). The hemihedral forms of O and mOn likewise occur, the former especially in twin-crystals like fig. 321 (p. 160). Twins like fig. 319 are also found. The crystals usually have convex faces, the convexity being sometimes so great as to give them the appearance of rounded grains; they are often distorted and irregular, generally implanted singly, sometimes grown together in crystalline aggregates. Cleavage octahedral, perfect. Fracture conchoidal. The diamond has a specific gravity of 3.5 to 3.6, and its hardness (denoted by 10) is the highest known. It is colourless or white, tinged occasionally with yellow, red, orange, green, brown, or black; transparent, or, when dark-coloured, translucent. Its lustre is that known as adamantine. When rubbed, whether in the rough or polished state, it shows positive electricity. It becomes phosphorescent on exposure to the sun or the electric spark, and shines with a fiery light. In its power of refracting light it is exceeded only by red lead ore, and orpiment. Its index of refraction is 2.439. It reflects all the light falling on its posterior surface at an angle of incidence greater than $24^{\circ} 13'$, whence its great lustre is derived. Artificial gems reflect only the half of this light. Diamond is insoluble in all liquids, and infusible even before the oxy-hydrogen blowpipe; in the flame of the oxygen-blowpipe it burns away, producing carbonic anhydride, and leaving only a very trifling residue of ash. Sir H. Davy, in 1814, first showed that the diamond consists of pure carbon, by burning diamonds in an atmosphere of pure oxygen; and his conclusion has been confirmed by the experiments of Dumas and Stas (Ann. Ch. Phys. lxxvi. 1) and of Erdmann and Marchand (J. pr. Chem. xxiii. 159) made with larger quantities of diamond, and with attention to every condition necessary to ensure accuracy.

Diamonds are found chiefly at Minas Geraes in Brazil; in the Ural; in India, at Purteal between Hyderabad and Masulipatam, where the famous Kohinoor was found, also near Parma, in Bundelcund. A few also have been found in Borneo, in Georgia and North Carolina, and on the banks of the Turon in Australia.

The diamond appears generally to occur in regions which afford a laminated granular quartz-rock called *itacolunite*, which belongs to the talcose series, and owes its lamination to a little talc or mica; this rock occurs at the mines of Brazil and the Urals, also in Georgia and North Carolina. Diamonds have also been detected in a species of conglomerate composed of rounded siliceous pebbles, quartz, chalcedony, &c., cemented by a kind of ferruginous clay. At Minas Geraes in Brazil, the diamond is found in two different deposits; one called *gurgulho*, consisting of broken quartz and covered by a thin bed of sand or earth; the other, *cascalho*, of rolled quartz pebbles united by a ferruginous clay, resting usually on talcose clays, the whole being the debris of talcose rocks. The first deposit yields the finest diamonds, and both contain also gold, platinum, magnetic iron, rutile, &c.

The most highly valued diamonds are those which are colourless and perfectly transparent; but to give them the peculiar brilliancy for which they are chiefly prized, it is necessary to cut or grind them, in a peculiar way, so that the light falling on the gem in any direction may be perfectly reflected from one of its lower faces. A diamond may be split by a steel tool in the direction of the natural cleavages; but as this does not give the means of producing faces in any direction that may be required, it becomes necessary to resort to the process of abrasion, technically called "cutting." This is effected, either by rubbing two diamonds hard against each other, or by pressing the diamond against a rapidly revolving steel disc covered with diamond dust; this last method serves also for polishing. The dust for this purpose is obtained either in the process of abrasion, or by pounding rough diamonds, which are too opaque and highly coloured for gems, in a steel mortar. Such diamonds are called "bort." Diamond-dust is much used also for cutting and polishing other gems.

There are two forms given to cut diamonds, the brilliant and the rose. The rose is flat on the lower surface, while the upper portion is fashioned into a pyramid of twenty-four facets. The French brilliant consists of two truncated pyramids placed base to base: the upper portion, called the *pavilion* or *crown*, is half as thick as the lower, and terminates in a broad face, called the *table*, which has half the diameter of the entire stone and is surrounded by triangular and rhombic faces; the lower part of the brilliant, called the *culasse*, is pyramidal and terminates in a face having $\frac{1}{6}$ the diameter of the stone. (For further details on these forms, and on the methods of cutting and polishing diamonds, see *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 21.)

The weight, and consequently the value of diamonds, is estimated in carats, one of which is equal to four grains; and the price of one diamond, compared to that of another of equal colour, transparency, purity, form, &c, is as the squares of the respective weights. The average price of rough diamonds that are worth working, is about £2 for the first carat. The value of a cut diamond being equal to that of a rough diamond of double weight, exclusive of the price of workmanship, the cost of a wrought diamond of

1 carat is		£8
2 " "	$2^2 \times £8 =$	32
3 " "	$3^2 \times 8 =$	72
4 " "	$4^2 \times 8 =$	128
100 " "	$100^2 \times £8 =$	80,000

This rule, however, is not extended to diamonds of more than twenty carats. The larger ones are disposed of at prices which cannot be reduced to any fixed rule. The snow-white diamond is most highly prized by the jeweller. If transparent and pure, it is said to be of the first water.

The hardness of the diamond renders it very useful for engraving and cutting glass. The sharp point of a natural diamond will scratch glass, but the cutting is effected by the curved edges formed by the intersection of the convex-faces; such an edge penetrates the substance of the glass like a wedge. Wollaston showed that rubies and sapphires ground so as to have curved edges will cut glass just like a natural diamond; only, being inferior in hardness, they wear out sooner.

The diamond is supposed to have been formed by the slow decomposition of some vegetable or bituminous material. Numerous attempts have been made to produce it artificially. Gannal supposed that he had obtained diamonds by decomposing sulphide of carbon with phosphorus. Recently, Despretz states that he has obtained microscopic octahedrons, having the hardness of diamond dust, by the prolonged action of an induction-current on sugar-charcoal; also by the action of an electric current continued for six months on one of the chlorides of carbon (not particularly specified); warty bodies are said to have been thus produced, nearly as hard as those just mentioned and exhibiting shining faces. Artificial diamonds, if they could be prepared at a moderate cost, would be very useful for the grinding and polishing of gems, glass, and other hard bodies. Diamond dust is found to give a finer edge to cutlery than can be obtained by the use of any other material. (Handw. 2nd Aufl. ii. [3] 431.)

DIANA. The name applied by the older chemists and alchemists to silver; hence the dendritic amalgam precipitated by mercury from a solution of nitrate of silver was called *Arbor Diane*.

DIANIC ACID. Von Kobell's name for an oxide which he obtained from the tantalite of Tammela in Finland, the samarskite of the Ilmengebirg, and other similar minerals, and supposed to contain a metal different from tantalum and niobium. The oxide after boiling with water was said to be less soluble in water than tantalic or hyponiobic acid, and, when separated from its potash-solution, and treated with tin-

foil and hydrochloric acid in certain proportions, to form a dark blue liquid which became sapphire-blue on addition of a small quantity of water. According to H. Rose, Deville, and Damour, however, the so-called dianic acid does not differ essentially from the acids of niobium. Rose attributes the characters observed by Kobell to the presence of a small quantity of tungstic acid.

DIANITE. Von Kobell's name for the tantalite of Tammela in Finland.

DIAPHANITE. Syn. with DIPHANITE.

DIAPHORITE. Rhodonite or silicate of manganese mixed with quartz.

DIASPORE. *Laminated Hydrargyllite.*—Native monohydrate of alumina, Al^2HO^3 , or $\text{Al}^3\text{O}^3\cdot\text{H}^2\text{O}$. Occurs crystallised in orthorhombic prisms, exhibiting the faces ∞P : ∞P^3 : ∞P^4 : ∞P^∞ : 2P^2 : 2P^∞ (Marignac and others). Inclination of ∞P : ∞P = $130^\circ 2'$ (Dufrénoy, Compt. rend. xxxi. 185); = $130^\circ 30'$ (Shepard, Sill. Am. J. [2] xii. 215); = $129^\circ 32'$ (Kengott, Wien. Akad. Ber. ix. 610); P : P in the brachydiagonal principal section = $151^\circ 25'$ (Dufrénoy); = $152^\circ 30'$ (Shepard); = $151^\circ 36'$ (Marignac, Arch. Ph. nat. vi. 296). P : ∞P in all directions = $125^\circ 17'$ (Dufrénoy); = 125° (Shepard). Ratio of axes a : b : c = 0.3018 : 1 : 0.468 (Marignac). The crystals are usually flattened prisms, sometimes acicular, commonly implanted. Cleavage very distinct parallel to ∞P^∞ ; less distinct parallel to ∞P^2 . It occurs also foliated massive. Specific gravity 3.452 (Dufrénoy). Hardness = 6.5 to 7. Colourless, yellowish, greenish, or bluish; transparent to sub-translucent. Lustre brilliant and pearly on the cleavage-planes; vitreous elsewhere. Very brittle. Gives off water when heated in a tube; is infusible before the blowpipe; turns blue when moistened with cobalt-solution and ignited. Not attacked by acids after ignition.

Analyses.—*a.* From Schemnitz in Hungary (Löwe, Pogg. Ann. lxi. 307); *b.* from Miask in Siberia (Hesse, *ibid.* xviii. 255); *c.* from Gumuch-dagh in Asia Minor (J. L. Smith, Sill. Am. J. [2] xi. 58); *d.*, *e.*, from Siberia (Dufrénoy, Ann. Min. [2] x. 577, 1837):

	Al^3O^3	H^2O	Fe^2O	Fe^3O^3	SiO^2	Ca^2O	Mg^2O	
<i>a.</i>	85.131	15.00	= 100.131
<i>b.</i>	85.44	14.56	= 100
<i>c.</i>	83.12	14.28	0.66	.	0.32	traces	traces	= 98.88
<i>d.</i>	78.93	15.13	0.52	.	1.39	1.98	.	= 97.95
<i>e.</i>	74.66	14.58	.	4.51	2.90	1.64	.	= 98.29

The formula $\text{Al}^3\text{O}^3\cdot\text{H}^2\text{O}$ requires 85.1 alumina and 14.9 water.

Diaspore occurs in chlorite slate, near Koroibrod, district of Katherinenburg in the Ural, and at Schemnitz, in veins between dolomite and limestone; also at Broddbo, near Fahlun, Sweden; with corundum in dolomite at St. Gothard; at Gumuch-dagh and Mansen, Asia Minor, and in the Grecian islands Naxos, Samos, and Nicaria, with emery. (Dana, ii. 128.—Jahresber. d. Chem. 1847—8, p. 1163; 1850, p. 708; 1851, p. 763; 1855, p. 792; 1860, p. 763.)

DIASTASE. (Payen and Persoz, Ann. Ch. Phys. [2] liii. 73; lvi. 237; lx. 441; lxi. 351.—Guérin-Varry, *ibid.* lvii. 108; lx. 22; lxi. 22.—Bouchardat, *ibid.* [3] xiv. 61.)—The substance to which malt or germinated barley owes its property of converting starch into dextrin. It does not exist in all parts of the germinated grain being often absent in the radicles, and generally most abundant near the plumule. It exists in the tubercles of the potato near their points of insertion, but not in the roots or the shoots. It has also been found in the buds of *Adiantum glandulosa*. Neither potatoes nor cereals contain diastase before germination.

To extract diastase, malt is treated with water at 25° or 30°C ., which dissolves the diastase, together with an azotised substance. The solution is then heated to 70°C ., in order to coagulate the azotised albuminous substance, and the diastase is precipitated by absolute alcohol. It is purified by redissolving it in water and reprecipitating by alcohol. The proportion of diastase in malt does not exceed 0.002 to 0.003 per cent.

Diastase is a white amorphous substance, insoluble in absolute alcohol, soluble in water and in weak alcohol. Its aqueous solution is neutral to test-paper, has no decided taste, and is not precipitated by basic acetate of lead. Placed in contact with starch at 70°C . it quickly disorganises that substance, and converts it, first into dextrin, then into glucose. According to Payen and Persoz, 1 pt. of well-prepared diastase is sufficient for the conversion of 2000 pts. of starch. The solution of diastase quickly alters, turning acid, and losing its power of converting starch. The same decomposition takes place, though slowly, in dry diastase; on boiling it with water, the decomposition is instantaneous.

Diastase has not been obtained in a state sufficiently definite for analysis. According

to Payen and Persoz, it contains less nitrogen the more carefully it has been prepared. According to Bouchardat, the conversion of starch into glucose may also be effected by contact with putrid flesh, beer-yeast, gastric juice, and animal membranes, which seems to imply that diastase is not a peculiar principle.

The action of diastase on starch is completely prevented by nitric, sulphuric, phosphoric, hydrochloric, oxalic, tartaric, or citric acid, also by caustic potash, soda, or lime, sulphate and acetate of copper, mercuric chloride, nitrate of silver, alum, and ferric sulphate. It is retarded more or less by formic acid, arsenious acid, magnesia, ammonia, and alkaline carbonates; slightly also by acetic acid, hydrocyanic acid, strychnine, quinine, morphine, and their salts. Essential oils, creosote, alcohol, and ether, exert no retarding influence. (Bouchardat.)

DIASTASE, ANIMAL. *Diastase salivaire*.—A substance precipitated from saliva by alcohol, and supposed to be the active fermenting principle of the saliva. It does not, however, convert starch into dextrin. (Mialhe.)

DIASTASITE. A black variety of amphibole from Nordmarken in Sweden.

DIATEREBIC ACID. See TEREBIC ACID.

DIATHERMANOUS. A term applied to bodies which transmit heat in the same manner as transparent bodies transmit light. (See HEAT.)

DIAZO-COMPOUNDS. See NITROUS ACID, SUBSTITUTION-PRODUCTS FORMED BY;—also OXY-ANISAMIC, OXY-BENZAMIC, OXY-CUMINAMIC, and OXY-TOLUYLAMIC ACIDS;—also PHENOL;—also PHENYL- and TOLUYL-DIAMINES.

DICHROÏSM. The property exhibited by many double-refracting crystals, of exhibiting different colours when viewed in different directions.

DICHROÏTE. *Cordierite, Iolite, Steinheilite, Hard Fahlunite, Sapphire d'eau, Pelion, Spanish Lazulite.* $2\text{Mg}^2\text{O} \cdot \text{SiO}_2 + 2(\text{Al}^3; \text{Fe}^3)\text{O}_3 \cdot 3\text{SiO}_2 = \text{Mg}^4\text{SiO}_4 \cdot 3(\text{al}; \text{fe})^4\text{SiO}_4$.—A mineral occurring in prisms, often hexagonal, belonging to the trimetric system; $\infty\text{P} \cdot \infty\check{\text{P}}3 \cdot \infty\check{\text{P}}\infty \cdot \text{oP}$, and sometimes other faces. $\infty\text{P} : \infty\text{P} = 60^\circ 50'$; $\infty\check{\text{P}}\infty \cdot \infty\check{\text{P}}3 = 120 50'$. Cleavage indistinct, parallel to oP and $\infty\check{\text{P}}\infty$. Often in crystalline grains; also massive, compact. Specific gravity = 2.6–2.7. Hardness = 7.0–7.5. Colour bluish-white to blue, sometimes smoky blue (then called *pelion*); often deep blue along the principal axis, and brownish-yellow or yellow-grey at right angles to it. Streak uncoloured. Transparent or translucent. Fracture subconchoidal.

When heated it gives off a small quantity of water. Before the blowpipe it loses its colour, and melts with difficulty to a glass. It dissolves in borax and in phosphorus-salt, leaving in the latter case a skeleton of silica. It is but slowly attacked by acids.

Analyses.—1, 2, 3, Stromeyer (*Untersuchungen*, 329, 431.—4, 5, Schütz (Pogg. Ann. liv. 565).—6, Scheerer, *ibid.* lxxiii. 319, mean of two analyses).—7, Thomson (*Mineralogy*, i. 278).—S. Jackson (*Geol. Report of New Hampshire*, 184):

	SiO_2	Al^3O_3	Fe^3O_3	Mn^2O	Mg^2O	Ca^2O	K^2O	H^2O	
1. Bodenmais . . .	48.35	31.70	9.24	0.33	10.16	0.59	= 100.37
2. Greenland . . .	49.17	33.10	4.82	0.04	11.45	1.20	= 99.78
3. Fahlun . . .	50.25	32.42	4.45	0.76	10.85	1.66	= 100.39
4. Ostgothland . . .	48.6	30.5	11.9	0.1	8.2	1.5	= 100.8
5. Südermannland . . .	49.7	32.0	6.7	0.1	9.5	2.1	= 100.1
6. Kragerö . . .	50.44	32.95	1.07	. . .	12.76	1.12	. . .	1.02	= 99.36
7. Haddam, Conn. . .	49.62	28.72	12.86	1.51	8.64	0.23	= 101.58
8. Unity, Maine . . .	48.15	32.50	8.80	0.28	10.14	0.50	= 100.37

Dichroïte occurs in granite at Cabo de Gata in Spain, at Arendal in Norway, at Orjervi in Finland (*Steinheilite*), at Tunaberg in Sweden, and other localities; in quartz at Ujordlersoak in Greenland, in gneiss at Haddam, Connecticut, and Brinfield, Massachusetts. The smoky blue variety called *pelion* is found at Bodenmais in Bavaria, sometimes in perfect crystals $1\frac{1}{2}$ inch thick. Dichroïte is sometimes used as a gem. A transparent variety, called *Sapphire d'eau* by jewellers, is found in small rolled masses of deep blue colour in Ceylon. (Dana, ii. 214; Rammelsberg, p. 766.)

Hydrous Dichroïte.—Dichroïte alters so readily by exposure that it is commonly found in the altered state, or as a nucleus enclosed in a crust of the altered mineral. The change consists either in a simple hydration, as in *Bonsdorffite* from Abo, *Esmarkite* from Brevig in Finland, *Chlorophyllite* from Unity in Maine and Haddam in Connecticut, and *Praseolite* from Brække in Norway,—or in the removal of part of the protoxides by carbonic acid,—or the introduction of oxide of iron through carbonate of iron, or of alkalis through waters containing alkaline carbonates.

The composition of the hydrous dichroïtes formed by simple hydration, is as follows:

	SiO ₂	Al ² O ₃	Fe ² O ₃	Mg ² O	H ² O	Mn ² O					
Bonsdorffite	45.05	30.05	5.30	9.00	10.60	trace	= 100
Chlorophyllite	45.20	27.60	8.24	9.60	3.60	4.08	P ² O ₅	trace	.	.	= 98.32
Esmarkite	45.97	32.08	3.83	10.32	5.49	0.41	Ca ² O, Pb, Cu, Co, Ti	0.45	.	.	= 98.55
Praseolite	40.94	28.79	6.96	13.73	7.38	0.32	Pb ² O, Cu ² O, Co ² O, Ca ² O	0.50	.	.	= 98.62

Denoting dichroïte by D, bonsdorffite = D + 3aq.; chlorophyllite = D + aq.; esmarkite = D + 1½aq.; praseolite = D + 1½aq. (Dana, ii. 215). See also ASPASIO-LITE, FAHLUNITE, GIGANTOLITE, HURONITE, IBERITE, LIEBENERITE, PINITE, PYRARGIL-LITE, WEISSITE.

DI-COMPOUNDS. In this Dictionary, the syllable *di*, prefixed to the name of a radicle occurring in any compound, denotes that the compound in question contains two atoms of that radicle; *e. g.* di-chloride of tin = SnCl₂; di-oxide of tin = SnO₂; di-sodic phosphate = Na²HPO₄; di-ethylamine = N.H.(C²H₅)₂; di-ethylenic alcohol = (C²H₄)₂.H²O₃. The prefix *bi* is often used in the same sense. (See NOMENCLATURE.)

Individual di-compounds are described under the several general headings, *e. g.* Dichloride of Tin, under TIN, CHLORIDES OF; Disodic Phosphate, under PHOSPHATE OF SODIUM; Diethylamine, under ETHYLAMINE, &c.

DICTAMNUS ALBUS.—The root of this plant, which is the only European species of *Diosmea*, was formerly used as a vermifuge; it is resinous, bitter, and aromatic; the root-bark was said to be peculiarly efficacious.

DIDRIMITE or DIDYMITE. A mineral from the Zillertal in the Tyrol, having the aspect of microcrystalline tale. Specific gravity = 2.75. Contains 40.69 per cent. silica, 18.15 alumina, 22.74 lime and carbonic anhydride, 11.16 potash, 1.2 soda, 5.25 ferric oxide, and 0.60 water. (Kengott, Handw. d. Chem. 2^o Aufl. ii. [3] 437.)

DIDYMIUM. *Symbol* Di. *Atomic weight* 48.—This metal, discovered by Mosander in 1841 (Pogg. Ann. lvi. 504), exists, together with cerium and lanthanum, in cerite, allanite, orthite, ytrocerite, cryptolite, and a few other minerals (i. 831); it is not found in nature in the free state, or even as a pure oxide, sulphide, or other compound, but always associated with cerium and lanthanum. Its compounds greatly resemble those of lanthanum, and are very difficult to separate therefrom: hence the name didymium (from *δίδυμος*, twin). The compounds of didymium have been investigated by Mosander (*loc. cit.*), Watts (Chem. Soc. Qu. J. ii. 131), more especially by Marignac (Ann. Ch. Phys. [3] xxvii. 209; xxxviii. 148), and recently by R. Hermann (J. pr. Chem. lxxii. 385).

A pure salt of didymium is obtained by recrystallising the rose-coloured rhombohedrons which separate from an acid solution of the mixed sulphates of lanthanum and didymium by spontaneous evaporation (see LANTHANUM); and from the pure sulphate thus prepared, the other compounds of the metal may be formed.

Metallic didymium is prepared by heating potassium with an excess of chloride of didymium, and washing out the soluble chlorides with cold water. It is thus obtained, for the most part, as a grey metallic powder, but partly, also, in fused globules. The powder, thrown into the flame of a spirit-lamp, burns with bright sparks like iron-filings. The powder decomposes water at ordinary temperatures; the fused granules do not: in either form, however, the metal dissolves rapidly in dilute acids with evolution of hydrogen.

But few of the compounds of didymium have yet been examined. It forms a protoxide, Di²O, and a protochloride, DiCl, and a class of oxygen-salts of corresponding composition.

DIDYMIUM, CHLORIDE OF, DiCl, is obtained as a hydrate in rose-coloured crystals of considerable size by evaporating a solution of the oxide in hydrochloric acid. The crystals, which are very soluble in water and alcohol, contain DiCl.2H²O. The solution, when evaporated, gives off hydrochloric acid, and leaves an oxide, not however of constant composition (Marignac). According to Hermann it leaves an oxychloride.

DIDYMIUM, DETECTION AND ESTIMATION OF. The salts of *didymium* have either a pure rose-colour, like the sulphate, or slightly inclining to violet, like the nitrate in the state of strong solution. Potash, soda, and ammonia precipitate the hydrate; so does sulphide of ammonium. Carbonate of barium also throws down the hydrated oxide slowly, but completely. Oxalate of ammonium precipitates didymium completely from neutral solutions; and oxalic acid almost completely, unless the solution contains a large excess of acid. The sulphates of potassium, sodium, and ammonium form, immediately in strong, and gradually in weak

solutions, rose-white precipitates of double sulphates, slightly soluble in water, less soluble in excess of the reagent; the sodium-salt is the least soluble of the three. *Phosphoric* and *arsenic acids*, at a boiling heat, form precipitates sparingly soluble in acids. All compounds of didymium impart to *borax* and *phosphorus-salt* a very pale rose-colour. They do not colour carbonate of sodium before the blowpipe.

According to Gladstone (Chem. Soc. Qu. J. x. 319), didymium-salts are easily recognised in solution by spectral analysis. When a ray of light, after passing through such a solution, is examined by a prism, it is found that the violet rays are completely absorbed by a solution of nitrate of didymium, but not by the chloride or sulphate. All three solutions, however, form a spectrum containing two black lines, inclosing a very bright portion of the spectrum. One of these black lines is in the yellow immediately following Fraunhofer's line D; the other is situated between E and *b*. These characters can be distinctly recognised in a solution half an inch deep, containing only 0.01 per cent. of didymium-salt.

Quantitative estimation of Didymium.—Didymium is precipitated from its solutions by potash, and the precipitate is converted by ignition in a covered platinum crucible into the anhydrous protoxide, containing 85.7 per cent. of the metal.

The methods of separating didymium from other metals are the same as those adopted for cerium. The separation of didymium from cerium itself may be effected by boiling the mixed oxides in a solution of sal-ammoniac (Watts). For separating didymium from lanthanum, no method has yet been devised sufficiently accurate for quantitative analysis.

Atomic weight.—Marignac in 1848 determined the atomic weight of didymium by the quantity of chloride of barium required to precipitate a given weight of the sulphate; in this manner he obtained the number 49.6. Afterwards, in 1853 (Ann. Ch. Phys. [3] xxxviii. 148), he found that this method was inexact, because the precipitated sulphate of barium carried down with it a quantity of didymic sulphate, which was not afterwards decomposed by excess of chloride of barium. He therefore adopted two other methods: 1. By precipitating the didymium from the sulphate by oxalate of ammonia, igniting the precipitate till it turned white, and weighing the protoxide thus obtained.—2. By precipitating the chloride of didymium with nitrate of silver, estimating the chlorine as chloride of silver, and precipitating the didymium from the filtrate in the manner just mentioned. The mean of the experiments made by the first method gave for the atomic weight of didymium, on the oxygen-scale, the number 598.2; the second method gave 603.5, 598.9, and 598.3. Mean of the whole, 599 on the oxygen-scale, or 47.92 on the hydrogen-scale. Marignac considers the number 48 to be very near the truth. Hermann by igniting the oxalate obtains the number 47.48.

DIDYMIUM, OXIDES OF. Didymium forms two oxides, the protoxide, Di^2O , and a peroxide, whose atomic constitution is not exactly known.

The *protoxide* is obtained in the anhydrous state by strongly igniting the nitrate, oxalate, or the precipitated hydrate, in a covered crucible. It is perfectly white; is slowly converted into a hydrate by immersion in warm water; dissolves readily in the weakest acids; and expels ammonia from ammoniacal salts when boiled with them.

The hydrate, DiHO , is a gelatinous mass, resembling hydrate of alumina, but having a very pale rose colour. It contracts much by desiccation.

Peroxide of Didymium.—When the oxalate, nitrate, carbonate, or hydrate of didymium is ignited in contact with the air, and not very strongly, a dark brown oxide is obtained, containing from 0.32 to 0.88 per cent. of oxygen more than the protoxide. When treated with acids it dissolves readily, giving off the excess of oxygen, and forming a solution containing the protoxide. It is probably a mixture of the protoxide with a small quantity of a higher oxide of definite composition. By strong ignition in a close vessel, it is converted into the white protoxide. (Marignac.) According to Hermann, it contains $\text{Di}^{64}\text{H}^{93}$.

DIDYMIUM, SULPHIDE OF, Di^2S , is obtained by igniting the oxide in the vapour of sulphide of carbon. It is a light brownish green powder, which dissolves in acids, with evolution of sulphydric acid. A greyish-white *oxysulphide*, $\text{Di}^6\text{O}^2\text{S}$, or $\text{Di}^2\text{S} \cdot 2\text{Di}^2\text{O}$, is obtained by igniting the oxide with carbonate of sodium and excess of sulphur, and digesting the fused mass in water. (Marignac.)

DIFFLUAN. (Schlieper, Ann. Ch. Pharm. lvi. 5).—A compound formed, together with leucoturic acid, &c., when an aqueous solution of alloxanic acid is boiled for some time. (See ALLOXANIC ACID.) It separates on the addition of alcohol to the aqueous solution, and must be collected on a filter out of contact with the air, washed with alcohol and ether, and dried in vacuo over sulphuric acid. It is not crystallisable, but forms a loose white powder of a bitter saline taste, and reddens litmus strongly. It is very soluble in water, and deliquesces rapidly in the air: insoluble in alcohol. When heated it melts at 100°C ., giving off alcohol and water with intumescence, and

remains as a transparent vitreous gum, which may be rubbed to a white powder. It is decomposed with effervescence by hot nitric acid, forming alloxan. It is gradually decomposed by cold potash, ammonia being evolved, and oxalic acid formed abundantly. Its aqueous solution gives white precipitates with nitrate of silver and acetate of lead, the latter soluble in excess of the lead-solution.

The composition of this body is not accurately known. Schlieper assigns to it the formula $C^3H^4N^2O_2$, relying on an analysis which gave 32.69 per cent carbon, 3.89 hydrogen, and 25.70 nitrogen (calculation 33.33 C, 3.70 H, 25.53 N, 37.04 O).

The silver-precipitate gave on analysis 45.5 per cent. oxide of silver, which does not accord with Schlieper's formula. Laurent (Compt. rend. xxxv. 629) gives it the formula $C^8H^{10}N^6O^6$, regarding it as isomeric with dialuramide. Gmelin points out that, since alloxan is obtained from it, it probably contains 4 atoms of carbon. F. T. C.

DIFORMENE or BIFORMENE. Lallemand's name for the hydrocarbon C^2H^2 .

DIFFUSION. The mixing or mutual interpenetration of two liquids or gases which do not unite chemically one with the other. This kind of mixture takes place both when the fluids are in immediate contact, and when they are separated by porous membranes or other partitions. (See GASES and LIQUIDS, DIFFUSION OF).

DIGENITE. A variety of copper-glance from Sangerhausen in Thuringia and from Chile. Specific gravity = 4.568 to 4.68. Hardness = 2.0. Plattner found in it 70.2 per cent. copper and 0.24 silver, which approximates to the formula $Cu^{10}S^4 = Cu_2^5S_4$, or 1 atom copper-glance and 3 atoms purple copper.

DIGESTER or DIGESTOR. An apparatus for digestion, such as a sand or water-bath. *Papin's digester* is a strong iron vessel in which substances can be exposed to the action of water or other liquids at temperatures above their boiling points.

DIGESTION. The operation of exposing a substance to the action of a liquid with the aid of heat, generally below the boiling point of the liquid, for the purpose of extracting the soluble constituents. The treatment of a substance with a cold liquid is called *maceration*.

DIGESTION, ANIMAL. (Lehmann, *Lehrbuch der Physiologischen Chemie*, Leipzig 1853, iii. 216–283.—The same translated by Dr. Day, London 1854, iii. 248–324.—Gmelin's *Handbuch*, viii. 572–621.—Frerichs, *Die Verdauung. Handwörterbuch d. Physiologie*, Braunschweig, 1846, iii. 1.—Bidder und Schmidt, *Die Verdauungs-säfte und der Stoffwechsel*, Mitau und Leipzig, 1852.—Mareet, *On the Chemistry of Digestion*, Chem. Soc. J. xv. 407.)

The changes which food undergoes in the stomach and intestines consist essentially in its transformation either into soluble substances, or into emulsions, whereby it is rendered capable of passing into the blood-vessels and lacteals, and available for the purpose of nutrition. These changes are produced by the action of the saliva, gastric juice, bile, pancreatic juice and intestinal juice, fluids which are poured from time to time into the alimentary canal in very large quantities, amounting in twenty-four hours, according to the experiments of Bidder and Schmidt, to almost the sixth part of the weight of the body. If the results obtained by these physiologists from experiments on animals can be applied to man, it may be calculated that a man weighing 64 kilogrammes (or about 10 stone) will secrete in twenty-four hours:

Saliva amounting to 1.6 kilogrammes, containing 15 grms. of solid matter.

Bile	„	1.6	„	80	„	„
Gastric juice	„	6.4	„	192	„	„
Pancreatic juice	„	0.2	„	20	„	„
Intestinal juice	„	0.2	„	about 3	„	„

The chief function of the *pancreatic juice* and, in some cases, of the *saliva*, is the conversion of starch into dextrin and sugar: according to Bernard (*Leçons de Physiologie expérimentale appliquée à la Médecine*, Paris, 1856, ii. 170–453), the pancreatic juice also assists in decomposing neutral fats into glycerin and fatty acids; and this view is now generally admitted, although it is opposed to the results obtained by Frerichs and by Bidder and Schmidt. The *gastric juice* is the chief agent by which the albuminous or protein substances are rendered soluble; according to Mareet, it likewise converts the neutral fats into fatty acids. The *bile*, according to the same authority, converts into an emulsion the fatty acids thus produced. The *intestinal juice* appears to unite in itself, to a certain extent, the functions of the gastric and pancreatic fluids, having the power of rendering soluble both starch and flesh, or other protein-bodies.

The albuminous or protein-substances, *albumin*, *fibrin* and *casein*, both animal and vegetable, are, so far as their chemical composition is concerned, ready for immediate

assimilation by the animal body; in fact they do not undergo any chemical change in the process of digestion; but, under the influence of the gastric juice, they lose their coagulability by heat and by mineral acids, and likewise their property of forming insoluble combinations with most metallic salts, and are converted into soluble isomeric modifications of albumin, fibrin and casein, called by Lehmann peptones. In this state they are fit to be taken up by the absorbents. The conversion of these bodies into peptones is not, however, completed in the stomach, a large portion of the albuminous constituents of the food passing unaltered into the intestines, where their conversion into peptones is completed by the action of the intestinal juice. Indeed the quantity of gastric juice secreted is not sufficient to effect the solution of the protein-matters required for nutrition. A dog secretes about 100 grammes of gastric juice in twenty-four hours for every kilogramme's weight of its body (Bidder and Schmidt), and this quantity of gastric juice is capable of digesting about 5 grammes of albumin, reckoned as dry (Lehmann); but it appears from Schmidt's experiments, that a dog, to keep in condition on an exclusively flesh diet, should take, for every kilogramme's weight of its body, 50 grammes of flesh containing 10 grammes of dry albuminoids: hence the gastric juice secreted by the dog would only suffice for the digestion of half of the albuminoids necessary for its nutrition. That the intestinal juice is capable of digesting these bodies is proved by the experiments of Bidder and Schmidt, who found that pieces of flesh and coagulated albumin introduced into tied loops of intestine were digested in from 6 to 14 hours; also that the pure alkaline intestinal juice, as well as that secretion mixed with bile and pancreatic juice, possesses the power of dissolving protein-substances externally to the body. The transformation of the carbohydrates by the intestinal juice appears to take place wholly in the small intestine.

Gelatin and the gelatigenous tissues in general are converted in the stomach into substances which, according to Lehmann, correspond perfectly, in their physical and in most of their chemical properties, with the peptones of the protein-bodies. According to Marcet, however, the peptones produced from gelatinous tissue differ in some of their physical properties from those derived from the protein-bodies, especially in their action on polarised light. Pure gastric juice obtained by washing out the stomach of a dog with water, after it has been kept fasting for thirty hours, and then making the animal swallow pebbles, is quite destitute of optical rotatory power; so likewise is the solution of pure albumin or casein in this gastric juice; but if the dog be then fed with cartilage, a gastric juice is obtained possessing considerable lavo-rotatory power (see GASTRIC JUICE).

Many nitrogenous substances undergo decomposition in passing through the stomach and intestines—such, for example, is the case with *emulsin*. We know that when this substance acts upon amygdalin (i. 201), in presence of water, prussic acid is produced, and accordingly, when emulsin and amygdalin are introduced together into the stomach or into the blood, the animal dies with the symptoms of poisoning by prussic acid. Lehmann allowed rabbits to eat sweet almonds (which contain emulsin) and injected amygdalin into the jugular vein, one, two, four, and six hours after they had been fed; the animals remained perfectly vigorous, showing that the emulsin had not been absorbed into the circulation; but on reversing the experiment, and injecting emulsin into the vein and introducing a solution of amygdalin into the stomach, symptoms of poisoning by prussic acid soon showed themselves. In the former case, then, either the emulsin had been metamorphosed by the digestive fluids, or it was incapable of being taken up by the absorbents. To decide this point, Lehmann collected the excrements of a rabbit which had been fed for forty-eight hours on almonds, and mixed amygdalin with them, but could detect no trace of prussic acid; neither was any decomposition of the amygdalin induced by the caecal contents of the same animal: hence he infers that the emulsin was decomposed in the intestine.

Curarine, the *poison of serpents*, and those poisons which are produced in contagious diseases, as *hydrophobia*, *glanders*, *typhus*, &c., are likewise decomposed in passing through the stomach and intestines: all these substances may be taken with impunity into the alimentary canal, but produce fatal or at least morbid effects when introduced into the blood.

The mode of digestion of the *neutral fats*, such as are contained in butter, the fat of meat, olive oil, &c., has been the subject of much controversy. The generally received opinion is that these bodies do not undergo any alteration, either mechanical or chemical, by the action of the saliva or the gastric juice, but that their digestion commences in the duodenum, in passing through which, and still more in its further passage through the jejunum and ileum, the fat ceases to appear in large drops or semifluid masses, these drops becoming smaller and smaller as the fat descends in the small intestine, till at length it appears finely comminuted, and is, in fact, converted into an emulsion, a

condition which greatly facilitates its absorption by the lymphatics of the intestinal walls. The mere mechanical division of the fat is not, however, the only condition necessary for its absorption. Bidder and Schmidt have shown that bile is essential to the digestion of fats, and Wistinghausen (*Dissert. inaug.* Dorpat, Livon. 1851) has ascertained that oil cannot be made to penetrate through animal membranes without considerable pressure, but that it may be forced through with comparative ease when the membrane is saturated with a fluid which adheres to or has an affinity for the oil. When the membrane was moistened with a solution of potash, an abundance of saponified oil passed through it in the course of ten hours, under a very slight pressure (from 0.068 to 0.132 of an inch of mercury), and associated with it was free fat mechanically carried through by the soap. When a mixture of equal parts of potash-ley and albumin was used, the oil passed through the membrane, even without pressure, although in very small quantity; in this case also a soap was formed. The oil, however, passed through animal membranes without being saponified when they were saturated with a solution of soap or bile.

Marcet takes a different view of the digestion of neutral fats. He infers from his own experiments, that these fats are resolved into glycerin and fatty acids in the stomach, and are then transformed into emulsions by the action of the bile, which exerts this action upon fatty acids, but not on neutral fats. Fatty acids are altogether much more capable of forming emulsions than neutral fats. When neutral fats or fatty acids in a fused condition are agitated with water, no emulsion is formed, but large globules are seen to pervade the fluid; on standing, they immediately run into each other, and rise to the surface, the aqueous fluid remaining perfectly clear. When fused neutral fats are agitated with a solution of neutral trisodic phosphate, the same phenomenon takes place as with pure water, but when fused fatty acids are shaken in a test-tube with phosphate of sodium, or with bile, the fat is instantly divided by a mechanical process into very minute globules, just as would happen if the fat were agitated with water; but at that moment each of these very small fatty particles becomes surrounded with a layer of soap, from the surface of the globule being saponified by the sodic phosphate or the bile. From this circumstance the globules of fat lose their property of running into each other, and acquire a slight increase of specific gravity, which, however, is not sufficient to prevent them from rising slowly in the mother-liquor, and finally occupying the upper part of the liquid. Thus it is that the fluid is milky, and that the emulsion takes a much longer time to rise to the surface than pure oil would. The chemical analysis of the emulsion bears out this view, for it is found to consist invariably of free fatty acid and soap.

These facts will assist in explaining the absorption of fats, since, when in the form of an emulsion, they can no longer be in direct contact with the intestines, a layer of soap intervening between the fat and the membrane. Soaps may be conceived to pass through a membrane, whilst fat is known to be incapable of so doing; consequently we may imagine fats to be absorbed under the form of complex globules, the inside of which is free fat, and the outside soap.

These observations on the power of bile to convert fatty acids into an emulsion and afterwards into soap, are quite in accordance with the results obtained by Bidder and Schmidt, and by Wistinghausen above mentioned, though it does not appear that these observers noticed the difference existing in this respect between neutral fats and fatty acids.

The power of digesting fats does not, however, belong exclusively to the bile: for a portion of the fats taken into the stomach is not acidified, and consequently must escape the action of the bile; in this case, the pancreatic juice effects the conversion, as observed some time ago by Bernard. The absorption of fatty acids explains a fact observed by Verdeil and Marcet in 1851, viz. that the blood contains free fatty acids.

Among the so-called *carbo-hydrates*, the most important as an article of food is *starch*. This substance, being insoluble, cannot be taken up by the absorbents until it has been converted into dextrin and sugar, a change which is effected partly by the saliva, partly by the pancreatic and intestinal juices. The action of saliva upon starch is not the same in all animals. Odling found that pure parotid saliva, obtained from a man who had a fistulous opening in the parotid duct, converted boiled starch quickly, and raw starch more slowly, into sugar, whereas saliva obtained in like manner from a young donkey had no effect on starch, either boiled or unboiled. According to Bernard, the saliva of horses is likewise without action on starch. In ruminating animals, which retain their food for a long time in the paunch, where it is exposed to the continuous action of the saliva, a great portion of the starch contained in the food is probably transformed into sugar; and the same is the case in the crop of birds; but in all other animals, the action of the saliva during the short time that the food remains in the mouth, must be very slight, so that the greater part of the starch passes unchanged into the stomach, where the further action of the saliva upon it is

to a certain degree suspended by the gastric juice, when secreted in sufficient quantity. On passing into the duodenum, the starch is brought in contact with the powerfully acting pancreatic juice, and afterwards in the ileum, with the intestinal juice, which acts upon it in a similar manner, but less strongly. As the starch passes on, the granules become softened on their surface, diminish in size, and are gradually dissolved in the form of dextrin and glucose; the dextrin is the first product of the transformation, but is so rapidly converted into sugar, that it is rarely found in the intestine, and even then only in very small quantity.

Inulin is affected by the digestive fluids in the same manner as starch; but, according to Lehmann's experiments, its transformation is much more rapid.

Glucose or *grape-sugar*, whether formed from starch in the manner above described, or introduced directly into the alimentary canal, is partly taken up directly by the intestinal absorbents, and passes into the blood without alteration, and is partly converted, by the action of the bile and intestinal juices, into lactic acid, and in that state passes into the circulation. *Cane-sugar* appears to be converted into glucose before it is absorbed into the circulation. *Milk-sugar* appears to comport itself in the intestinal canal in the same manner as glucose; it distributes itself very rapidly throughout the small intestine, and in about an hour after it has been swallowed, may be traced as far as the cæcum; but, like glucose and cane-sugar, it occasions an intensely acid reaction in the jejunum and ileum, which remains for three or four hours after the injection of the sugar.

Pectin and the allied substances are totally unaffected by the digestive fluids. (Blondlot, Frerichs.)

Gum, although an easily soluble substance, does not play an important part in the process of animal nutrition; indeed it rarely occurs as a constituent of nutritive matters, even of the food of the herbivora. It is not affected by the digestive fluids, and, when given to animals, is not subsequently found in the blood or in the urine, but passes unchanged into the solid excrements. Boussingault caused a duck to swallow fifty-two grammes of gum-arabic, and in the course of nine hours forty-six grammes were recovered from the excrements. The fact of gum not being taken up in perceptible quantity by the intestinal absorbents, is related to its low diffusibility, which, according to Graham, is only half that of starch-sugar, and four or five times less than that of chloride of sodium.

Cellulose, or *woody-fibre*, resists the action of all the digestive fluids: hence all vegetable substances essentially consisting of cellulose pass unchanged into the excrements of most herbivorous and omnivorous animals. In some animals, however, which swallow very large quantities of woody fibre, it appears probable that some means must exist of rendering this substance soluble. In the beaver, the whole stomach, and more especially the cæcum, are often found plugged, as it were, with fragments of wood and bark, amongst which, according to Lehmann, no easily soluble nutrient substance can be detected. Now, in this animal, the organs whose secretions contribute more especially to the metamorphosis of the carbo-hydrates, are developed in a remarkable degree—the salivary glands amounting, according to Weber, to $\frac{1}{118}$ of the whole weight of the body, whereas in man they do not exceed $\frac{1}{805}$ of the entire weight. The pancreas in the beaver is also very bulky, and there is a large gastric gland, peculiar to the animal, which may perhaps have some relation to its power of digesting cellulose. It is well known that cellulose is converted into dextrin, or a similar substance, by the action of alkalis, even when very dilute—and it is by no means improbable that the alkaline juices of the salivary glands, the pancreas, and the cæcal glands of the beaver may effect this transformation.

The relative digestibility of different kinds of food is a subject on which it is very difficult to obtain precise results, inasmuch as the facility with which any substance is digested depends very much on its state of mechanical division or aggregation, and on the condition of the digestive organs at the time when the food is taken; food taken into the empty stomach, after fasting for some hours, will be digested much more quickly than the same kind of food introduced into the stomach partly full or immediately after it has been emptied. The point to which observation has been chiefly directed is the time during which different kinds of food remain in the stomach, those being considered the most digestible which pass out most quickly, in intervals varying from an hour to an hour and a half. Such observations are made either by feeding animals with different kinds of food, and killing them at various intervals after the meals—or by introducing portions of food enclosed in muslin bags into the stomachs of animals bearing gastric fistulæ. A series of observations of this latter kind were made by Beaumont (*Experiments and Observations on the Gastric Juice and Physiology of Digestion*, Boston, 1834), on a man having a large fistulous opening into the stomach resulting from a gun-shot wound. It is clear, however, that such observations can give but an imperfect idea of the relative digestibility of different articles of food,

inasmuch as the digestion, even of albuminous substances, is not completed in the stomach, and that of most vegetable substances does not even commence till they reach the intestine.

The digestibility of the *albuminous bodies* depends very much on their state of aggregation. Soluble coagulable *albumin*, like unboiled white of egg, is much more digestible than the same substance when coagulated. Soluble *casein*, as it exists in milk, is one of the most indigestible of the unboiled albuminous substances, inasmuch as it is very quickly coagulated by the acid gastric juice, and then but slowly dissolved. A considerable difference is, however, observable, according to the denser or more porous condition of the coagulum. The casein of human milk, which forms a gelatinous coagulum, is much more rapidly digested than that of cows' milk, which forms in the stomach a compact lump, generally coagulated into a solid ball.

Syntonin, or *muscle-fibrin*, is, according to Lehmann, very easily digested, more easily than the blood-fibrin of the ox. The digestibility of muscle varies, however, greatly with its conformation. The smooth muscular fibre, like that of the stomach and intestines, is much more digestible than the striated muscles, because the former is not provided with the dense and insoluble, although thin integument, which encloses the primitive bundles, and consequently the syntonin, in the latter,—but is for the most part surrounded only by loose connective tissue, which is easily permeated and dissolved by the digestive juices. The flesh of young animals is more easily digestible than that of older animals, because the primitive bundles of the former are much thinner than those of the latter, and consequently present, in relation to their mass, a larger extent of surface to the action of the gastric juice. Frerichs found that the flesh of old animals required for digestion an hour or an hour and a half longer than that of young animals.

Raw flesh is generally regarded as more difficult of digestion than boiled or roast meat; the difference is not, however, very great, and has been estimated by Frerichs at only half an hour. In fact, the advantage derived from the loosening of the connective tissue and the partial destruction of the organic structure by boiling or roasting, is partly counteracted by the coagulation of the albumin in the muscular juice and the hardening of the syntonin.

Gelatin, in its pure state, is one of the most easily digestible substances. In Beaumont's experiments, the gelatinous character of this substance disappeared after it had remained twenty minutes in the stomach, and after an hour no trace could be found of 120 grammes of jelly which had been taken. The digestibility of the *gelatinous tissues* depends, however, very much upon their state of aggregation, and is greatly increased by boiling. Tendons and cartilage, and all those tissues which are abundantly intersected with elastic fibres, belong to the least easily digested class of substances, inasmuch as true elastic tissue and elastic fibres completely resist the action of the digestive fluids.

The *fats* belong to the least digestible class of substances; indeed fat, when taken in large quantity, either alone or with other food, usually remains for a long time in the stomach, sometimes even for $5\frac{1}{2}$ hours. It is not only not digested in the stomach, but often exerts an impeding action on the digestion of other substances, since it is liquefied by the heat of the stomach, and, encasing the particles of food, prevents them from coming in contact with the gastric juice; moreover, it becomes rancid during its long retention in the stomach, and forms volatile acids, which exert a very deleterious, though not well understood action on digestion. The true digestion, that is, the emulsifying of fat, does not, indeed, commence till it reaches the small intestine, where it comes in contact with the bile (p. 325). Small quantities of fat appear, however, to be easily digested; and, according to Lehmann, fat, when not mixed in too large quantity with the food, essentially promotes the digestion both of albuminous and amylaceous substances.

Starch, the principal nutrient matter of most vegetable food, is much more easily digested in the boiled than in the raw state, the effect of the boiling being to burst the envelopes of the starch-granules and thus expose the starch to the action of the saliva and the pancreatic and intestinal juice, whereby it is converted into sugar. When raw starch is eaten in large quantity, a considerable portion of it passes away unchanged in the solid excrements.

The digestibility of *vegetables* depends very much on the nature of the cells in which the starch and the albuminous matters are enclosed; if the cells are still invested with epidermis, no portion of them is dissolved, the epidermis of plants being completely proof against the digestive fluids. Boiling usually renders vegetable food more digestible, by thoroughly loosening the intercellular substance, and thus allowing the digestive juices to make their way more readily into the cells.

DIGESTIVE SALT. *Sal digestivum Sylvi.* Syn. with CHLORIDE OF POTASSIUM.

DIGESTOR. See DIGESTER (p. 323).

DIGITALACRIN. *Digitalicrin.* This name was applied by Walz (Jahrb. pr. Pharm. xxi. 29) to an acrid substance which he obtained from crude digitalin by exhaustion with ether, and to which he assigned the formula $C^{22}H^{20}O^6$. Subsequently this product has been found to be a mixture of several substances. When its alcoholic solution is mixed with basic acetate of lead, which takes up the colouring matter, the filtrate evaporated, and the residue washed, first with ammoniacal water, then with cold alcohol, and dissolved in boiling alcohol, white nacreous laminæ are obtained, consisting of Walz's digitaloic acid $C^{22}H^{22}O^4$, soluble in ether and in alcohol, but insoluble in water.

Crude digitalacrin likewise contains a resin or fat precipitable by basic acetate of lead. By decomposing the lead-precipitate under alcohol with sulphydric acid, and leaving the filtrate to evaporate, the resin called digitalin-fat or digitaloin is obtained, in white crystalline scales, which melt to an oil at a gentle heat, and are said to consist of $C^{23}H^{22}O^4$. Walz regards the compound as a glyceride, but does not state whether glycerin can be obtained from it.

DIGITALEIN. *Digitaline.* A substance said by Kossmann (Buchn. Repert. xcii. 348) to be contained in the precipitate thrown down by basic acetate of lead from the aqueous extract of foxglove (*Digitalis purpurea*). The precipitate is first exhausted with ether, which dissolves digitoleic acid, the residue is boiled with alcohol, and the solution evaporated: it then deposits the digitalein in the crystalline form. This body is slightly soluble in water, easily in alcohol, insoluble in ether. The aqueous solution is precipitated by lead-salts, but not by ferrous sulphate or silver-salts.

DIGITALETIN. Walz's name for pure digitalin.

DIGITALIC ACID. (P. Morin, J. Pharm. [3] vii. 294.)—An acid contained in foxglove (*Digitalis purpurea*). To obtain it, an aqueous infusion of the leaves is evaporated to the consistence of an extract, and gradually mixed with alcohol of 92 or 94 per cent. as long as anything separates from it. The mixture is left to clarify, and the alcohol is decanted and distilled in the water-bath, till the residue acquires the consistence of a thick extract. This residue is boiled several times with ether, which dissolves digitalic acid and digitalin, and the ethereal solution is shaken up with baryta till it acquires an alkaline reaction, whereby the digitalic acid is precipitated as a barium-salt, while the digitalin remains in solution. This salt is washed with ether and strong alcohol to remove digitalin, and then decomposed by dilute sulphuric acid, care being taken not to convert all the baryta into sulphate. The filtered liquid is concentrated by evaporation out of contact of air, then mixed with strong alcohol to separate the undecomposed barium-salt, and the alcoholic filtrate is evaporated in vacuo. Throughout the whole process, great care must be taken to prevent access of air to the material.

Digitalic acid crystallises in needles. It has a peculiar odour, which becomes strong when the acid is heated, and a decided acid taste; it reddens litmus. It is not volatile, but melts easily, becoming coloured and charred at a higher temperature, without evolution of ammonia. It is very soluble in water, but the solution soon becomes coloured, the change being accelerated by light and heat. It is moderately soluble in alcohol, and the solution keeps better; less soluble in ether. It has not been analysed.

It expels carbonic acid from alkaline carbonates, but its salts are decomposed by contact with the air, even more easily than the free acid. The digitalates of potassium, sodium, barium, calcium, strontium, magnesium, zinc, and ferrium are soluble in water; the copper-salt, the ferrous salt, and the lead and silver-salts are obtained by precipitation.

The name digitalic acid is also applied by Kossmann to a product, $C^{54}H^{96}O^{33}$, obtained by boiling digitalin with moderately dilute soda-ley or with lime. It is precipitated by acids from the alkaline solution in white flocks, may be crystallised from alcohol, and forms crystalline salts with bases. By boiling with acids it is resolved into digitaliretin and glucose.

DIGITALICRIN. See DIGITALACRIN.

DIGITALIN. (Le Royer, Bibl. Univ. xxvi. 102.—Lancelot, Ann. Ch. Pharm. xii. 251.—Trommsdorff, *ibid.* xxiv. 240; and Arch. Pharm. x. 113.—Homolle, J. Pharm. [3] vii. 57.—O. Henry, *ibid.* vii. 460.—Homolle and Quevenne, *Mémoires sur la Digitaline*, Paris, 1851; abstr. Repert. Pharm. [3] ix. 2.—Walz, Jahrb. pr. Pharm. xiv. 20; xxi. 29; xxiv. 86; Gerh. Traité, iv. 286.—N. Jahrb. Pharm. viii. 332; ix. 302; x. 319; Jahresber. d. Chem. 1847, p. 646; 1851, p. 567; 1852, p. 679;

1853, p. 568; 1857, p. 520; 1858, p. 528. — Delffs, N. Jahrb. Pharm. ix. 26; Jahresber. d. Chem. 1858, p. 528. — Kossmann, J. Pharm. [3] xxxviii. 5.) — The active principle of *Digitalis purpurea*. It is obtained by exhausting the comminuted leaves of foxglove with alcohol; concentrating the extract by evaporation; treating the syrupy residue with acetic acid; decolorising with animal charcoal; treating the resulting solution, which contains acetate of digitalin, with tannin, whereby the digitalin is precipitated as tannate; and decomposing this precipitate with oxide of lead, which sets the digitalin free. It is then decolorised with animal charcoal and crystallised from ether.

On the large scale, digitalin may be directly precipitated from the aqueous decoction of the plant by tannin.

According to Delffs and Walz, digitalin prepared as above is not pure. Delffs purifies it from an admixed resinous body by washing it with cold alcohol of 70 per cent., and dissolving the residue in boiling alcohol of 85°, from which the pure digitalin separates on cooling. Walz treats the impure digitalin with ether, which extracts digitalacrin, and the residue with water, which dissolves digitasolin and leaves pure digitalin. (Walz's *Digitaletin*.)

Digitalin is white, difficult to crystallise, inodorous, has a bitter taste, is very sparingly soluble in *water*, to the extent of only $\frac{1}{1000}$ at the boiling heat, moderately soluble in *ether*, freely in *alcohol*; according to Delffs, only when it is contaminated with resin. Digitalin exerts a powerful action on the animal economy, even a small dose of it producing poisonous effects. The smallest quantity of it introduced in the state of powder into the olfactory organs produces violent sneezing.

The composition of digitalin has not been determined with certainty; according to Delffs, it is $C^{22}H^{19}O^9$; according to Kossmann, $C^{54}H^{45}O^{50}$, or $C^{54}H^{50}O^{30}$.

Digitalin becomes coloured at 180° C., and decomposes with much tumefaction when heated above 200°. *Sulphuric acid* dissolves it, acquiring thereby a brown colour, which soon changes towards crimson. The solution poured into water colours it greenish. *Hydrochloric acid* dissolves digitalin, forming a yellow liquid, which gradually changes to a dark green. *Tannin* precipitates digitalin from its aqueous solution. It is not precipitated by nitrate of silver, mercurous nitrate, acetate of copper, or acetate of lead, either neutral or basic.

According to Ludwig and Delffs, digitalin boiled with *mineral acids* yields a liquid which reduces an alkaline cupric solution. According to Kossmann, digitalin ($C^{51}H^{50}O^9$) boiled with *dilute sulphuric acid* yields glucose and digitaliretin, $C^{30}H^{50}O^{10}$.

According to Walz, pure digitalin, called by him *digitaletin* ($C^{22}H^{38}O^9$), is resolved by boiling with dilute sulphuric acid, partly with abstraction of 2 at. water, into paradigitalletin ($C^{22}H^{31}O^7$), partly into digitaliretin ($C^{16}H^{26}O^3$) and glucose:

Digitalin boiled with moderately dilute soda-ley, or with lime, takes up water, and is converted into Kossmann's digitalic acid (p. 328).

DIGITALIN-FAT. See DIGITALACRIN.

DIGITALIRETIN. A product of the decomposition of digitalin by dilute sulphuric acid. Its formulæ, as determined by Kossmann and by Walz, have just been given. According to Kossmann, it is sparingly soluble in ether, easily in alcohol, and crystallises from hot alcohol in shining grains.

DIGITALIS. A genus of plants belonging to the natural order *Scrophulariaceæ*. The best known species is the common foxglove, *Digitalis purpurea*, the herb of which is used in medicine, both as a diuretic and for its retarding effect on the circulation. From the results of numerous chemical investigations, this plant has been found to contain the following more or less problematical compounds, besides the ordinary vegetable constituents, starch, sugar, albumin, oil, &c.: — *Digitalin*, already described. *Picrin*, obtained by agitating the aqueous extract of the plant with ether. *Scaptin*, an acid extractive substance, not separated from the aqueous extract by ether (Radig). Morin found, besides digitalin, a volatile acid, *antirrhinic acid* (i. 348), and a non-volatile acid, *digitalic acid* (p. 328). Walz has obtained, as volatile principles, *digitalosmin* and *digitalissic acid* (valeric acid); and as non-volatile principles, *digitalin*, *digitasolin*, *digitalacrin*, *digitaloin*, and *digitaloic acid*. Whether all these bodies are really distinct, or whether they have been obtained quite pure, is a

point not yet quite decided; but Walz's analyses certainly agree very well with his formulae.

According to Buchner (Repert. [3] ix. 38), the seeds of foxglove contain about 3 per cent. of digitalin, more indeed than the herb, and 40 per cent. of their weight of a drying oil, which is said to hold the digitalin in combination. The seed-capsules and calices contain but a small quantity of digitalin, about 0.3 per cent.

From *Digitalis lutea*, Walz obtained, by distillation, digitalosmin, and a peculiar volatile fatty acid, isomeric with valeric acid; also formic acid, acetic acid, digitalin, digitalacrin, and digitasolin. (Hand. d. Chem. 2^{te} Aufl. ii. [3] 465.)

DIGITALISSIC ACID. See DIGITALIS.

DIGITALOSMIN. The odoriferous principle of *Digitalis purpurea* and *D. lutea*, obtained as a fatty film by distilling either of these plants with water. It is a camphoroïdal substance insoluble in cold water, soluble in alcohol and in ether, melts when heated with water, and is not dissolved by ammonia. (Walz.)

DIGITASOLIN. (Walz, N. Jahrb. Pharm. ix. 302; Jahresber. d. Chem. 1858, p. 529.)—This substance, now called by Walz, *digitalin*, constitutes, according to his observations, the principal portion and the active principle of commercial digitalin. Its formula, according to Walz's latest determination, is $C^{25}H^{48}O^{14}$. When commercial digitalin is exhausted with ether (to remove digitalacrin), the dry residue treated with water, and the aqueous extract either purified with animal charcoal and evaporated, or treated with oxide and basic acetate of lead, then freed from lead by sulphuric acid, neutralised with ammonia, and precipitated by tannin, digitasolin is obtained as a yellowish amorphous mass, which is soluble in 120 pts. of cold and 40 pts. of boiling water, differing therein essentially from the compound usually called digitalin. (Walz's *Digitalatin*, p. 328.)

Digitasolin is decomposed by boiling with dilute sulphuric acid, yielding digitaliretin, $C^{16}H^{26}O^3$, soluble in alcohol and ether, and melting at 60° C., and paradigitalletin, $C^{22}H^{34}O^7$, insoluble in ether, soluble in alcohol, and remaining solid at 100° C. (p. 328.)

DIGITOLEIC ACID. (Kossmann, J. Chim. méd. [3] ii. 377.)—A kind of fatty acid contained in the leaves of *Digitalis purpurea*. It is obtained by exhausting the leaves with cold water, precipitating with acetate of lead, decomposing the precipitate with carbonate of sodium, treating the filtered solution with hydrochloric acid, which precipitates the digitoleic acid, and crystallising the product from strong alcohol. The acid crystallises in slender needles grouped in stars or grains and having a green colour. Taste bitter, odour agreeably aromatic. Sparingly soluble in water, very soluble in alcohol and ether. Reddens litmus and expels carbonic acid from alkaline and earthy carbonates.

The *digitoleates* are yellow or greenish yellow; those of the alkalis are soluble; the rest insoluble. The solutions of the alkaline salts froth like soap-water.

DIHYDRITE. $Cu^2PO_4 \cdot 2CuHO$.—A basic phosphate of copper from Nischne-Tagilsk in the Ural. (See PHOSPHATES.)

DIKA-BREAD. A vegetable substance somewhat resembling cocoa, prepared from the fruit of the *Mangifera Gabonensis*, a tree growing abundantly on the west coast of Africa, from Sierra Leone to the Gaboon. The fruit, which is about as large as a swan's egg, contains a white almond having an agreeable taste. These almonds, when coarsely bruised and warm-pressed, form dika-bread, which has a grey colour, with white spots, smells like roasted cocoa and roasted flour, has an agreeable, somewhat bitter and astringent taste, and is greasy to the touch. It is a valuable article of food, and is used abundantly by the natives of the country.

Dika-bread contains a large quantity of fat. O'Rorke (J. Pharm. [3], xxxi. 275) obtained from it from 79 to 80 per cent. solid fat, melting at 30° C. Oudemans (J. pr. Chem. lxxxi. 356) obtained by exhaustion with ether, 66 per cent. fat, melting at 33° C. The fat has an agreeable odour, and is easily saponified by potash, yielding myristic and lauric acids, but no volatile acid.

DILATATION. See HEAT.

DILATOMETER. This name is given by Kopp to a thermometric apparatus for measuring the expansion of liquids (see HEAT); by Silbermann to an instrument which he uses for measuring the expansion of a mixture of two liquids, and thence determining their relative quantities; e.g. for determining the strength of aqueous alcohol.

DILITURIC ACID. *Nitrodilitic acid*. (Schlieper, Ann. Ch. Pharm. lvi. 23.)

When aqueous alloxantin is boiled with hydrochloric acid; the mixture of allituric acid and alloxantin which separates on cooling, treated with nitric acid, to dissolve out the latter; the nitric acid solution treated with sulphuretted hydrogen, and filtered; and the filtrate mixed with nitric acid, and evaporated to one-third;—a yellowish powder is obtained, which, by recrystallisation from hot water yields yellow laminæ. Schlieper assigns to this compound the formula $C^4H^6N^4O^5$, and regards it as the ammonium-salt of a peculiar acid, which he has not succeeded in isolating, which he calls Dilituric acid. The compound is nearly insoluble in cold, sparingly soluble in hot water; insoluble in ammonia; soluble in sulphuric acid, and reprecipitated unchanged by water; neither dissolved nor decomposed by nitric acid. It is soluble in dilute potash, with evolution of ammonia: from the solution acids precipitate acid dialurate of potassium. The acid appears to be dibasic. Besides the potassium-salt, Schlieper has analysed its silver-salt.

F. T. C.

DILLNITE. $4Al^2O^3 \cdot 3SiO^2 + 8H^2O$. (Haidinger, Pogg. Ann. xxviii. 575.—Jahresber. d. Chem. 1849, 259.)—The compact argillaceous mass in which the diaspore of Schemnitz is imbedded, consists of three varieties, one of which (*a*) is agalmatolite, while the other two (*b* and *c*) contain a mineral not previously observed, to which Haidinger gives the name of *Dillnite*, from the locality, Dillna, near Schemnitz, where it occurs. The agalmatolite (*a*) is translucent, with grey or greenish colour, fatty lustre and splintery fracture. Hardness = 2·5 to 3; specific gravity = 2·735. Dillnite (*b*), called *collyrite* at Schemnitz, has the composition above stated: it is white, opaque and dull, earthy, and adheres strongly to the tongue. Hardness, 1·8 to 2. Specific gravity 2·574. The variety *c*, called *Bildstein* at Schemnitz, is also white, opaque and dull, but has a flat conchoidal or uneven fracture; hardness 3·5 and specific gravity 2·835: it is dillnite mixed with a hydrate of aluminium, $Al^3H^6O^7$ or $Al^2O^3 \cdot 4H^2O$. The following are the analyses of these minerals:

	SiO ²	Al ² O ³	Ca ² O	Mg ² O	Fe ² O	K ² O and Na ² O	H ² O	Total.
<i>a</i> .	49·5	27·5	5·6	0·7	1·0	10·2	5·1	= 99·0
<i>b</i> .	23·5	53·0	0·9	1·8	trace	trace	20·05	= 99·25
<i>c</i> .	22·4	56·4	trace	0·4	21·1	= 100·4

The diaspore is found most abundantly in the second variety.

DILL, OIL OF. *Oil of Celery, Oleum anethi.* The volatile oil of *Apium* (or *Anethum*) *graveolens*. It has a pale yellow colour, becoming brownish by age, the same pungent odour as the seeds, and a sweetish taste. Specific gravity 0·88 to 0·91; of old oil, according to Zeller, 0·95. Sparingly soluble in water, easily in alcohol and ether. Boils at about 190° C. (Handw. d. Chem. 2^e Aufl. ii. [3] 468.)

DIMAGNETITE. A mineral consisting mainly of ferroso-ferrie oxide, which occurs in rhombic prisms at Monroe, Orange County, New York, and is regarded by Shepard (Sill. Am. J. [2] xiii. 392) as a distinct species. According to Dana, however (*Mineralogy*, ii. 206), it is a pseudomorph of magnetite after lievrite.

DIMETAPHOSPHORIC ACID. See PHOSPHORUS, OXYGEN-ACIDS OF.

DIMORPHINE. A sulphide of arsenic from the Solfatara, Pozzuoli. It forms minute trimetric crystals of very complicated form, and is regarded by Scacchi (*Mém. géol. sulla Campania*, Napoli, 1849) as a distinct species. It has not, however, been analysed, and is perhaps a mere variety of orpiment, which it very much resembles.

DIMORPHISM, and TRIMORPHISM. Many substances, both simple and compound, crystallise in forms which belong to two or three different systems of crystallisation, or which, even if they belong to the same system, yet exhibit such difference in their corresponding angles as to render it quite impossible to reduce them to the same form: this was first shown by Mitscherlich in 1823 (Ann. Ch. Phys. [2] xxiv. 264). Such bodies are said to be dimorphous and trimorphous. The difference of crystalline form which they exhibit is associated with difference of specific gravity, hardness, colour, and other properties. Whether a body shall crystallise in one system or another seems to depend chiefly on temperature. Crystals formed at one particular temperature, and then exposed to that temperature at which crystals of a different kind are produced, often lose their transparency, and, without alteration of external form, become changed into an aggregate of small crystals of the latter kind: examples of this alteration of structure are afforded by sulphur, carbonate of calcium, mercuric iodide, and many other bodies. Sometimes the form of the crystal varies according to the solvent from which it separates; thus, arsenious anhydride crystallises from water or hydrochloric acid in regular octahedrons, from alkaline solutions in trimetric prisms.

The most important cases of dimorphism hitherto observed, are as follows:

1. In *elementary bodies*.

Carbon, in the diamond, forms crystals belonging to the monometric system; in graphite, to the hexagonal system. If the amorphous varieties, charcoal, anthracite, &c., are likewise taken into account, carbon may be regarded as trimorphous.

Arsenic, antimony, phosphorus, bismuth, palladium, iridium, copper, and probably *iron*, likewise crystallise in the monometric and hexagonal systems.

Tin exhibits forms belonging to the monometric and dimetric systems.

Sulphur crystallises on cooling from a state of solution in sulphide of carbon in rhombic octahedrons belonging to the trimetric system, exactly like those of native sulphur; if, on the other hand, melted sulphur be allowed to cool slowly till a portion of it has become solid, and the still liquid portion be then poured out, the solidified portion exhibits oblique rhombic prisms belonging to the monoclinic system. These are at first perfectly transparent, of a deep yellow colour, and somewhat harder and denser than those of sulphur crystallised in the cold; but after being kept for a few days at ordinary temperatures, they become opaque, and of a straw-yellow colour.

According to Frankenheim (J. pr. Chem. xvi. 5), sulphur assumes the form of the oblique rhombic prism when precipitated from solutions, or sublimed, at temperatures near its melting point.

2. In *compound bodies*. A compound is said to be dimorphous, only when the two forms which it assumes are perfectly identical in chemical composition. Thus, a salt which crystallises in two forms is not dimorphous, if these forms belong to different hydrates; thus the two hydrates of sulphate of nickel, viz. $\text{Ni}^2\text{SO}^4 + 6 \text{ aq.}$, which is dimetric, and $\text{Ni}^2\text{SO}^4 + \text{aq.}$, which is trimetric, do not afford an instance of dimorphism.

Cuprous oxide occurs in ordinary red copper ore in regular octahedrons and other forms belonging to the monometric system, but in copper-bloom it exhibits forms of the trimetric system.

Protoxide of lead crystallises after fusion, as well as from a saturated solution in hot concentrated caustic potash, in yellow rhombic octahedrons. If, however, the solution is not fully saturated with oxide of lead, so that crystallisation does not take place till after complete cooling, red crystalline scales are deposited on the yellow rhombic octahedrons just formed: if the red crystals are heated, they turn yellow on cooling, in consequence of passing into the first form. (Mitscherlich, J. pr. Chem. xix. 451.)

Titanic oxide, TiO^2 , occurs in nature in the three forms of anatase, rutile, and brookite. Anatase and rutile are both dimetric, but their angles are incompatible, so that they cannot be reduced to the same primitive form; moreover, the specific gravity of anatase is 3.826, that of rutile 4.249. Brookite is trimetric.

Arsenious oxide, As^2O^3 , generally crystallises in regular octahedrons; but Wöhler (Pogg. Ann. xxvi. 177) found it also in the form of native oxide of antimony, Sb^2O^3 (valentinite), which belongs to the trimetric system. Wöhler also obtained artificially crystallised oxide of antimony in regular octahedrons. Consequently As^2O^3 and Sb^2O^3 are *iso-dimorphous*; i. e. they are capable of crystallising in two different forms which are similar each to each.

Cuprous sulphide, Cu^2S , appears in copper-glance in crystals of the trimetric system; but Mitscherlich (Pogg. Ann. xxviii. 157), by melting together large quantities of copper and sulphur, obtained it in regular octahedrons. These two forms are similar to those of the red oxide of copper.

Disulphide of iron occurs in nature as iron pyrites in crystals belonging to the regular system, and as marcasite, in forms of the trimetric system, the latter being of a paler yellow and much softer,

Mercuric iodide separates from solution, and likewise sublimes at a very gentle heat, in scarlet tables belonging to the dimetric system, but when sublimed at a higher temperature, in sulphur-yellow rhombic tables of the monoclinic system. The red crystals turn yellow when heated, and resume their red tint on cooling. The yellow crystals obtained by sublimation retain their colour when cooled; but on the slightest rubbing or stirring with a pointed instrument, the part which is touched turns scarlet, and this change of colour extends, with a slight motion, as if the mass were alive, throughout the whole group of crystals as far as they adhere together.

Carbonate of calcium, Ca^2CO^3 , in the form of calespar, whose specific gravity = 2.721, belongs to the rhombohedral; in arragonite, whose specific gravity is 2.931, to the trimetric system. An explanation of this difference was formerly sought in the fact discovered by Stromeyer, viz., that arragonite usually contains small quantities of carbonate of strontium. The same peculiarity is presented by *carbonate of iron* (i. 359), which in sparry iron ore (of 3.872 specific gravity) has the form of calespar, in junkerite (of 3.815 specific gravity) that of arragonite. Hence Ca^2CO^3 , and Fe^2CO^3 are *isodimorphous*. If a solution of carbonate of calcium in water containing carbonic acid be left

to evaporate at the ordinary temperature, nothing is obtained but calcspar, in microscopical and, for the most part, truncated primitive rhombohedrons; if, on the contrary, the solution be evaporated over the water-bath, arragonite is obtained in small six-sided prisms, mixed with a few crystals of calcspar, because the temperature of the solution is lower at first than it afterwards becomes, and the specific gravity of the liquid is not higher than 2.803. When an aqueous solution of chloride of calcium is mixed at ordinary temperatures with an aqueous solution of carbonate of ammonium, a voluminous flocculent precipitate of chalky (amorphous?) carbonate of calcium is first produced, which, if immediately collected on a filter, washed and dried, remains unaltered, possessing a specific gravity of 2.716, and appearing under the microscope to consist of small opaque granules; but if this same precipitate be left for some time in the saline liquid from which it has been precipitated, it collects into microscopical crystals of calcspar, of specific gravity 2.719. If the same saline solutions be mixed boiling, the carbonate of ammonium being added to the chloride of calcium, arragonite is obtained, mixed with a small portion of calcspar. If, on the contrary, the chloride of calcium be added to the carbonate of ammonium, arragonite is obtained alone, in exceedingly small crystals of specific gravity 2.949. If, however, these crystals are not immediately collected on a filter, washed, and dried, but allowed to remain in the liquid, they gradually change after the liquid has cooled, and in about a week are completely converted into calcspar; in pure water this transformation goes on much more slowly. When carbonate of calcium is fused under strong pressure, it invariably crystallises on cooling in the form of calcspar. A tolerably large crystal of arragonite falls to pieces at a low red heat without losing weight, and forms a white, opaque, coarse powder, having a specific gravity of only 2.706. Hence it follows that carbonate of calcium crystallises at about 100° C. in the form of arragonite, but at a lower temperature, or at a red heat, in the form of calcspar. The arragonite which occurs in the caverns of volcanic districts must have been formed by infiltration while the mass was yet warm. (H. Rose, Pogg. Ann. xlvii. 353.)

Nitrate of potassium usually crystallises in prisms of the form of arragonite: but if a drop of the aqueous solution of this salt be left to evaporate on a glass plate and the crystallisation observed under the microscope, it will be found that, side by side with the prismatic crystals at the edges of the drop, a number of obtuse rhombohedrons of the calcspar form are produced, just like those in which nitrate of sodium crystallises. As the two kinds of crystals increase in size and approach one another, the rhombohedrons become rounded off and dissolve, because they are more easily soluble than the others, while the arragonite-shaped prisms go on increasing in size. When the two kinds of crystals come into immediate contact, the rhombohedral ones instantly become turbid, acquire an uneven surface, and after a short time throw out prisms from all parts of their surfaces. Contact with foreign bodies also brings about the transformation of the rhombohedrons while they are wet. If the drops are so shallow that the liquid dries round the rhombohedrons before they are disturbed, they will remain for weeks without disintegrating, and bear gentle pressure with foreign bodies without alteration; but stronger pressure, or scratching, or the mere contact of a prismatic crystal of saltpetre, causes them to change, a delicate film proceeding, as it were, from the point of contact and spreading itself over their surfaces; they then behave towards foreign bodies like a heap of fine dust, but retain their transparency. The rhombohedrons are also transformed, without alteration of external appearance, when heated considerably above 100° C.: they then become much harder, because the fine powder first produced bakes together into prismatic crystals. A hot solution of saltpetre yields, when slightly cooled, nothing but prismatic crystals; but at 10° C. prismatic and rhombohedral crystals appear together; if alcohol be added, the latter are formed most abundantly; the addition of potash, nitric acid, or nitrate of sodium, produces no alteration. (Frankenheim, Pogg. Ann. xl. 447; also J. pr. Chem. xvi. 1.)

Sal-ammoniac, which commonly crystallises in regular octahedrons, appears at higher temperatures to assume forms belonging to the trimetric system. (Frankenheim, J. pr. Chem. xvi. 3.)

Iodide of potassium, which usually crystallises in cubes, likewise forms square prisms, with truncated summits, which cannot be regarded as cubo-octahedrons, because their octahedral faces are not equally inclined to all the adjacent prismatic faces; $P : oP = 120^\circ$; $P : \alpha P =$ about 150° . (Kane, Phil. Mag. [3] xvi. 222.)

Chromate of lead occurs in red lead spar in the form of monoclinic prisms; but in chromate of lead from the Bannat, the same substance presents forms belonging to the dimetric system, having the same angles as molybdate of lead. (Johnston, Phil. Mag. [3] xii. 387.)

Sulphate of nickel, $NiSO_4 + 7 aq.$, crystallises (a) below 15° C. in trimetric prisms, (b) between 15° and 20° C. (59° and 68° Fahr.) in acute dimetric octahedrons, and (c) above 30° C. (86° Fahr.) in monoclinic prisms; it is therefore *trimorphous*. The right

rhombic prisms (*a*) when exposed to sunlight for a few days, neither liquefy nor lose their form or water of crystallisation, but when broken are found to be made up of square-based octahedrons, often several lines in length.

The following salts, isomorphous with sulphate of nickel, have hitherto been obtained in only two out of the three forms just mentioned. *Sulphate of zinc*, $\text{Zn}^2\text{SO}^4 + 7 \text{ aq.}$, crystallises below 52°C. in form *a*; below 52°C. , as observed by Haidinger in less transparent crystals, like *c*; if a crystal *a* be heated in oil or in a glass tube above 52°C. , it becomes soft at certain points without losing water, excepting any that may be adhering to it mechanically, and from these points bundles of milk-white crystals *c* shoot out towards the inside of the transparent crystal, until the whole is completely transformed. If the crystals obtained above 52°C. be slowly cooled after drying, they remain tolerably clear; but when cooled quickly before drying, they become opaque, and when broken are often found to consist of an aggregate of crystals *a*, these having been first formed in the adhering mother-liquid, and subsequently extended through the crystals already formed. *Sulphate of magnesium*, $\text{Mg}^2\text{SO}^4 + 7 \text{ aq.}$, like sulphate of zinc, yields trimetric prisms *a* below 52° , and monoclinic prisms *c* above 52° ; and the crystals *a* when heated above 52° are immediately converted into an opaque aggregate of crystals *c*, which proceed from the surface of the crystals and meet in the middle. *Selenate of zinc*, $\text{Zn}^2\text{SeO}^4 + 7 \text{ aq.}$, crystallises at a lower temperature like *a*, at a higher temperature like *b*, and the crystals *a* undergo an alteration of internal structure when exposed to sunshine. (Mitscherlich, Pogg. Ann. vi. 19, and xii. 144.)

Acid phosphate of sodium, $\text{NaH}^2\text{PO}^4 + \text{aq.}$ crystallises in two series of forms, both of which belong to the trimetric system, but have incompatible angles. (Mitscherlich.)

DINITE. A fossil resin found in the lignite of Lunigiana in Tuscany. Cleavage, none. Has the appearance of ice, with a yellow tinge. Inodorous and tasteless. Fragile and easily reduced to powder. Insoluble in water, sparingly soluble in alcohol, very soluble in ether and in sulphide of carbon. The ethereal solution, on standing, deposits large crystals of the resin. It melts with the warmth of the hand. Heated in a close vessel, it distils over without perceptible decomposition.

DINITRAMMONYL, and **DIBROMONITRACETONITRILE.** See TRINITRACETONITRILE.

DINITROETHYLIC and **DINITROMETHYLIC ACIDS.** See NITROUS ETHERS.

DIOPSIDE. A variety of augite M^2SiO^3 , containing calcium and magnesium, with little or no iron. The crystals appear rectangular in the basal section from predominance of the faces $\infty\text{P}\infty$ and $[\infty\text{P}\infty]$, and are acuminated at the ends with the faces $+ \text{P}$, $- \text{P}$, $- 2\text{P}$, and several others, the pyramids being also frequently truncated by oP . Inclination of ∞P : $\infty\text{P} = 87^\circ 6'$; $+ \text{P}$: $+ \text{P}$ in the clinodiagonal principal section = $131^\circ 29'$; $- \text{P}$: $- \text{P} = 120^\circ 39'$; $- 2\text{P}$: $- 2\text{P} = 96^\circ 36'$. Cleavage distinct parallel to ∞P ; less distinct parallel to $\infty\text{P}\infty$ and $[\infty\text{P}\infty]$. The crystals are implanted, or less frequently imbedded, and often distorted into fusiform, scaly, or granular aggregations. The granular variety, if coarse and somewhat friable, is called *white coccolite*. Specific gravity = 3.2 to 2.3. Hardness = 5.5 to 6.0. Colour, generally light green or grey; white, if quite free from iron. Lustre, vitreous on the crystalline faces, nacreous on the cleavage faces. Transparent or translucent in various degrees, sometimes on the edges only; the more transparent sorts are sometimes cut for gems. Before the blowpipe, diopside melts to a whitish or grey glass. It is insoluble in acids.

Analyses.—*a.* From Tammare, Finland (Bonsdorff, Schw. J. xxxi. 158).—*b.* From Brazil (Kussin, *Rammelsberg's Mineralchemie*, p. 452).—*c.* From the Zillerthal (Wackenroder, Kastn. Arch. xiii. 84).—*d.* From Reichenstein, in Silesia; partly asbestiform (R. Richter, Pogg. Ann. lxxxiv. 383).—*e.* From Pargas in Finland; large grey-green crystals (Arppe, *Anal. af. Finsk. min.* p. 22).—*f, g.* From Schwarzenstein in the Tyrol (T. S. Hunt, Phil. Mag. [4] vii. 501).—*h.* From the Saassgrat between the Rimfischhorn and the Strahlhorn; white, translucent. (Brunner, Jahrb. Min. 1855, p. 186.)

A transparent colourless variety of diopside called *alalite*, found at Ala in Piedmont, is cut for gems. *Massite* is a variety from Massa in Piedmont of greyish-green colour, with lamellæ parallel to the base, and sometimes contorted. These two varieties contain very little iron.

Diopside has also been found as a furnace-slag (Hausmann, J. pr. Chem. lvi. 186), and is produced artificially by passing vapour of chloride of silicon over a mixture of lime and magnesia at a red heat. (Daubrée, Compt. rend. xxxix. 153.)

DIOPTASE. *Emerald Copper, Emerald Malachite, Smaragdochalcite, Achirite*, $\text{Cu}_2\text{SiO}_3 + \text{H}_2\text{O}$ or $(\text{Cu}_2\text{H}_2)\text{SiO}_4$.—This mineral crystallises in rhombohedral combinations derived from a primary form R, for which the length of the principal axis is 0·5295, and the angle R : R in the terminal edges = $126^\circ 17'$. Ordinary combination $-2\text{R} \cdot \infty \text{P}2$ (fig. 369); $-2\text{R} : -2\text{R}$ in the terminal edges = $95^\circ 48'$. Cleavage very distinct parallel to R. It occurs in single crystals and implanted in geodes. Specific gravity = 3·278 — 3·348. Hardness = 5. Colour emerald-green. Streak green. Lustre vitreous. Transparent to sub-translucent. Fracture conchoidal, uneven. Brittle. When heated in a tube, it gives off water and turns black. Infusible before the blowpipe; turns black in the outer, red in the inner flame. Gives with phosphorus-salt a skeleton of silica and the reactions of copper; and with soda a button of copper. Dissolves in hydrochloric acid, with separation of gelatinous silica.

Fig. 369.

Analyses.—*a, b*, Damour (Ann. Ch. Phys. [3] x. 485); — *c, d*, Hess (Pogg. Ann. xvi. 360).

<i>c.</i>	36·85	45·10	11·52	·	·	·	2·36	3·39	0·22	= 99·44
<i>d.</i>	36·60	48·89	12·29	2·00	·	·	·	·	·	= 99·78

Diopside occurs at Altyn Tubé, Berghes-Karkalinsk, and Oni in Siberia, and in the Duchy of Nassau between Oberlahnstein and Braubach.

DIORITE. Greenstone, containing soda- instead of potash-felspar. (See GREENSTONE.)

DIOSCOREA. A genus of plants of the Smilacæous order, the tubers of which, called yams, are very rich in starch, and are much used as food in the West Indies and other tropical countries. In a root of *Dioscorea alata* from the Antilles weighing eleven kilogrammes, Payen (Compt. rend. xxv. 182) found 79·6 per cent. water, and

	In the middle.	At the end of the root.
Non-azotised substance	85·0	74·5
Azotised substance	9·5	16·4
Mineral constituents	5·5	9·0

The tubers of *D. bulbifera* were found to contain 10·5 per cent. starch (Pharm. J. Trans. vi. 23). The tubers of *D. Batatas* (the *Chinese yam, Igame de Chine*), grown in the neighbourhood of Paris, have been analysed by Frémy (Compt. rend. xl. 128); the same from Algeria, by Boussingault and by Payen; the same grown in the Botanic Garden at Bonn by Grouven (Chem. Centralbl. 1857, p. 686). The tubers, after drying over the water-bath, yield by trituration, a powder which may be kneaded with water to a dough, like wheat-flour. The fresh tubers yield in 100 parts:

	Frémy.	Boussingault.	Payen.	Grouven.
Starch	16·0	13·1	16·7	8·0
Albuminous substance	1·5	2·4	2·5	1·1
Fat, sugar, &c.	1·1	0·2	0·3	6·0
Cellulose	1·0	0·4	1·4	0·7
Mineral salts	1·1	1·3	1·9	1·1
Water	79·3	82·6	77·1	83·0

The albuminous substance does not coagulate till after long continued boiling (Frémy). Suersen (Scheerer's Journ. [1802] viii. 600), found in the tubers of *Dioscorea sativa*, 23 per cent. starch, 68 woody fibre, gum, &c.

DIOSMA CRENATA. *Buchu.* The leaves of this plant, a native of the Cape of Good Hope, contain about 0·7 per cent. of volatile oil, 21·2 gum, and 2·15 resin. According to Brandes (*Arch. Pharm.* xxii. 242) they also contain a bitter principle, *diosmin*, which is yellowish-brown, bitter, and soluble in water.

DIOXYLITE. Syn. with LANARKITE.

DIPHANITE. A variety of margarite, occurring in the emerald mines of the Ural, together with chrysoberyl and phenacite, in hexagonal prisms with perfect basal cleavage. Specific gravity = 3·04 — 3·97. Hardness = 5 — 5·5. Colour, white to bluish. Before the blowpipe it becomes opaque, and fuses with intumescence in the inner flame to a white enamel. With a little soda it forms a blebby glass. Contains, according to Jewreinow's analysis, 34·02 per cent. SiO_2 , 43·33 Al_2O_3 , 13·11 Ca_2O , 3·02 Fe_2O_3 , 1·05 Mn_2O_3 and 5·34 water = 99·87, whence approximately the formula $(\text{M}^2\text{O} \cdot \text{SiO}_2) \cdot (2\text{Al}^3\text{O}_3 \cdot \text{SiO}_2) + \text{H}_2\text{O}$ or $\text{Mal}^2\text{SiO}_4 \cdot \text{al}^3\text{HO}^2$. (*Nordenskiöld*, *Petersb. Acad. Bull.* v. 17; *Rammelsb. Mineralch.* p. 843.)

DIPHENIN. $\text{C}_6\text{H}_6\text{N}^2$ or $\text{C}^{12}\text{H}^{12}\text{N}^4$. (Laurent and Gerhardt, *Compt. chim.* 1849, 417.) Dinitrazobenzene (i. 478) is boiled with alcohol and sulphide of ammonium till most of the alcohol is driven off; the liquid is diluted with water, mixed with a slight excess of hydrochloric acid, filtered hot, and precipitated by ammonia; and the crystalline precipitate is purified, either by recrystallisation from ether, or by converting it into sulphate, which is washed with cold water and alcohol, dissolved in boiling dilute hydrochloric acid, and precipitated by ammonia. Diphenin is a yellow crystalline body, dissolving with red colour, in hydrochloric or nitric acid; the former solution gives with dichloride of platinum a dark carmine precipitate of *chloroplatinate*, $\text{PtCl}^3\text{C}^6\text{H}^4\text{N}^2$. The *sulphate* is insoluble in water. F. T. C.

DIPLOBASE. Syn. with ALSTONITE (i. 149).

DIPLOITE. *Latrobite.* A variety of ANORTHITE (i. 308).

DIPPEL'S OIL. *Purified Hart's-horn oil*, or *Animal oil*, *Oleum animale Dippelii*, *Ol. cornu cervi rectificatum*. An oil originally prepared as a medicine by Dippel, an apothecary of the seventeenth century, from crude fetid animal oil (*Ol. cornu cervi fetidum*) by submitting it to repeated rectification *per se*, till it no longer left any black residue. The oil thus obtained is colourless, highly refractive, has a not unpleasant odour, somewhat like that of cinnamon, and a burning taste, with sweetish after-taste, like a mixture of pepper and cinnamon: its specific gravity is 0·865. When kept for some time it turns yellow, especially if exposed to light.

Animal oil is now more generally purified by rectifying it with addition of sand, lime, or water. That which is rectified with water is very mobile, has a very pungent disagreeable odour, a nauseous burning taste, and a specific gravity of about 0·75.

Nearly all the animal oil of commerce is now obtained by the destructive distillation of bones, in fact as a by-product in the preparation of bone-black.

The composition of animal oil varies greatly according to the mode of preparation; but in all cases it consists of a basic and non-basic portion, the former being a mixture of numerous volatile bases, including ammonia and pyrrol, and the latter consisting mainly of benzene and its homologues. (See BONE-OIL, i. 625.)

DIPYRE. *Schmelzstein*, *Leucolithe de Mauléon*. A silicate found with talc and chlorite in an unctuous argillite near Mauléon in the lower Pyrenees, crystallised in four-sided prisms, with rounded ends, apparently dimetric like scapolite, with lateral and diagonal cleavage. Specific gravity = 2·646. Hard enough to scratch glass. Colour whitish or reddish, lustre vitreous. Transparent to translucent; opaque when weathered. Before the blowpipe it becomes opaque and melts with intumescence to a white blebby glass. Melts easily with phosphorus salt, excepting a skeleton of silica. Forms a limpid glass with soda. Attacked with difficulty by the strongest acids, even when pulverised. According to an analysis by Delesse (*Compt. rend.* xviii. 994, 1844), it contains 55·5 per cent. SiO_2 , 24·8 Al_2O_3 , 9·0 Ca_2O , 9·4 Na_2O , 0·7 K_2O , whence approximately the formula $4(2\text{M}^2\text{O} \cdot 3\text{SiO}_2) + 3(2\text{Al}^3\text{O}_3 \cdot 3\text{SiO}_2)$.

DISACRONE. See DISACRYL.

DISACRYL. (Redtenbacher, *Ann. Ch. Pharm.* xlvii. 114.) Acrolein when kept for some time, even in close vessels, changes, sometimes into a flocculent substance called *disacryl* or *disacrone*, sometimes into a resinous matter, *disacryl resin*.

Disacryl is a white, amorphous, tasteless, inodorous powder, which becomes strongly electrical by friction. It is insoluble in water, acids, alkalis, sulphide of carbon, and oils, either fat or volatile. It dissolves slowly in melted potash, and is precipitated by acids from the solution of the product. It gives by analysis 61·2 per cent. carbon,

and 7.43 hydrogen, whence Redtenbacher deduces the formula $C^3H^7O^2$ (carbon 60.6, hydrogen 7.1). It is perhaps isomeric with acrolein.

Disacryl-resin is a white powder which melts at $100^\circ C$., and forms on cooling a diaphanous brittle mass. It is insoluble in water, but soluble in alcohol and in ether; the alcoholic solution reddens litmus and is precipitated by water. It dissolves in aqueous alkalis and is precipitated by acids. The alcoholic solution precipitates the salts of copper, lead, and other metals. The resin gives by analysis 66.6 C and 7.4 H, whence Redtenbacher deduces the formula $C^{10}H^{13}O^3$. (Carbon 66.3, hydrogen 7.2.)

DISCRASITE. Syn. with ANTIMONIAL SILVER (i. 317).

DISOMOSE. Syn. with NICKEL-GLANCE.

DISTERRITE. See CLINTONITE (i. 1026).

DISTHENE. See KYANITE.

DISINFECTANTS. See *Ure's Dictionary of Arts, Manufactures, and Mines* (ii. 27).

DISTILLATION is the conversion of a substance into vapour, and the condensation of the vapour in another part of the apparatus by cooling, the object of the operation being generally to separate an easily vaporised body from one which is less volatile. It is called especially *distillation*, when the vapour condenses into a liquid, and *sublimation* when it condenses into a solid. In either case the body to be vaporised is enclosed in an alembic flask, retort, or still, and the vapour is conducted through a tube or series of tubes kept cool into a *receiver*. In distillation on the large scale, the conducting tube is in the form of a worm enclosed in a tub, through which cold water is constantly flowing. For laboratory experiments, sufficient cooling power may sometimes be obtained by simply immersing the receiver in cold water, or by directing a stream of cold water on the neck of the retort, surrounded for the purpose with bibulous paper. To obtain greater cooling power, Liebig's condenser is used, which consists of a glass tube enclosed within a metal cylinder, through which cold water is continually flowing in a direction contrary to that of the vapour. For details and figures of apparatus, see *Ure's Dictionary of Arts, Manufactures, and Mines* (ii. 36).

DISTILLATION, DRY or DESTRUCTIVE. These terms are applied to the decomposition which organic substances undergo when heated out of contact with the air, or at all events, in such a manner that the constituents of the air take no part in the reaction. Some organic compounds boil at so low a temperature that, when heated in a retort, they pass over unchanged, especially if the air be excluded; *e. g.*, alcohol, ether, volatile oils; others, on the contrary, which would not boil till raised to a higher degree of heat, undergo decomposition before they attain the boiling temperature.

Compounds whose boiling points are not much above the temperatures at which their decomposition begins, pass over to a certain extent undecomposed; because the vapours and gases produced by the decomposition of the one part, take up the other part of the compound below the boiling temperature in the form of vapour, just as water evaporates in the air considerably below its boiling point. Thus, oxalic acid, margaric acid, and other fatty acids, also pinic acid, and certain other resins, indigo-blue, &c., undergo but partial decomposition. Such compounds may therefore be volatilised without decomposition, if they are heated in open vessels to a temperature somewhat below that at which they decompose; or in a wide distillatory apparatus filled with air: or in a tube or a conical enlargement of it, through which is passed a stream of air—or if the air exerts an oxidising action—of hydrogen, nitrogen, or carbonic acid gas; also when carefully heated in *vacuo*.

A contrary action is exerted by sand, brickdust, &c., mixed in large quantities with the organic compound, even if the boiling point of that compound be below the temperature at which it decomposes: for the bubbles of vapour are mechanically retained by the pulverulent mixture, and raised by the heat which penetrates the containing vessel, to the degree at which their decomposition takes place. Alcohol is partially decomposed by this treatment, and benzoic acid almost completely.

The apparatus used for destructive distillation consists of retorts of glass, earthenware, or metal, according to the temperature required, filled with good-sized exit-tubes, and communicating with well-cooled receivers of considerable capacity. For operating on small quantities of substances, Greville Williams, who has worked extensively on the subject, uses a small still made from a glue-pot, and having a copper head fitted to it. The luting for all temperatures not exceeding $700^\circ F$. may be a mixture of $\frac{3}{4}$ linseed and $\frac{1}{4}$ almond meal, made into a mass of the consistence of putty. For quantities of material not exceeding 15 or 20 lbs., a stout semi-cylindrical cast-iron pot may be used, having a broad flange round the edge and a cover fitting it like a saucepan-lid.

For operations on the manufacturing scale, large retorts of cast iron or fire-clay are employed, as in gas-works. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 44.)

Volatile organic compounds are decomposed by passing them through a red-hot tube, usually filled with fragments of glass or pumice, to increase the heating surface.

The causes of decomposition by heat are as follows:—The affinity of the oxygen for the hydrogen and the carbon, tending to form water, carbonic oxide and carbonic anhydride, is greater than that by which the elements in the organic compound are held together. These strong affinities are brought into action by heat. Hence those compounds which contain most oxygen decompose at much lower temperatures than those which contain little or none. To this rule, however, there are many exceptions; Acetic acid, $C^2H^4O^2$, is a body rich in oxygen; but its vapour is but little altered in composition by passing through a tube at a low red heat; acetate and cyanate of potassium also, are not decomposed when heated to low redness out of contact with air.

In compounds containing nitrogen, the affinity of that element for hydrogen likewise assists the decomposition. The ammonia which is then abundantly formed, does not, however, pass over in the free state, but in combination with an acid, as with carbonic, acetic acid, &c.

If the compound contains chlorine, bromine, iodine, or sulphur, these elements, if they do not separate in the free state, or enter into volatile organic compounds, are given off in combination with hydrogen, in the form of hydrochloric, hydrobromic, hydriodic, or sulphydric acid. Part of the sulphur and chlorine may also be evolved in the form of sulphide or chloride of carbon.

At high temperatures, moreover, decomposition is facilitated by the great tendency of certain elements to assume the gaseous form; hence part of the hydrogen and nitrogen are given off in the state of gas, the quantity thus evolved increasing with the temperature; for even the hydrocarbons formed at a moderate heat may be resolved at higher temperatures into hydrogen gas and sooty carbon. The heat may also induce a disposition to the formation of volatile organic compounds, which, when once produced, pass over, and are thus withdrawn from the decomposing action of a stronger heat.

By the formation of the inorganic compounds above mentioned, and by the escape of hydrogen and nitrogen gas, the organic compound (unless it be one of the more highly oxygenised acids, such as oxalic or formic acid) loses oxygen in the greatest *relative* quantity, hydrogen and nitrogen in smaller quantity, while the residue becomes continually richer in carbon.

Hence those volatile organic compounds which are richest in oxygen, such as acids and alcoholic liquids, pass over principally at the beginning of the distillation. Among *acids*, the most frequent is acetic acid. It is formed in especial abundance in the distillation of compounds, such as sugar, gum, or wood, which contain oxygen and hydrogen in about the proportion to form water, so that it only requires the addition of a certain number of carbon-atoms to form acetic acid, $C^2H^4O^2$, which, being volatile, is withdrawn from the further decomposing action of the heat. Many organic compounds yield other acids, which in some cases are quite peculiar to them (*vid. inf.*). The *alcoholic liquids* produced in the dry distillation of a few organic compounds are, wood-spirit, lignone, aldehyde, and acetone.

But as the distillation proceeds, compounds containing little or no oxygen appear in continually greater abundance, *viz.*: 1. *Gaseous hydrocarbons*, such as marsh-gas, CH^4 , olefiant gas or ethylene, C^2H^4 , and tetrylene, C^4H^8 . The last two hydrocarbons are evolved chiefly from compounds containing but little oxygen, such as fats and resins; the greater their proportion in the gaseous mixture, the more brilliant is its flame and the better is it adapted for illumination.—2. *Volatile oils* generally having an offensive odour, and designated, from their mode of formation, *empyreumatic oils*. They are sometimes pure, sometimes slightly oxidised hydrocarbons. To this class of products belong the two empyreumatic oils which Faraday obtained from fat; also eupione, creosote, picamar, and capnomor, obtained by Reichenbach; pyrrol, by Runge, and several oils obtained from resins by Frémy, Couerbe, Laurent, and others; &c. &c.—3. *Camphoroidal compounds*, which may be called *empyreumatic camphors* or *stearoptenes*; they consist wholly of carbon and hydrogen; but some of them appear to be produced from other volatilised compounds, which are subjected to the further action of a red heat within the apparatus.—4. *Resins*, which may be called *empyreumatic resins*, containing but little oxygen, and generally dark-coloured; according to Unverdorben, some of them dissolve both in alcohol and in potash, others only in alcohol, others again only in potash.—5. If the original compound contains nitrogen, ammonia and *volatile alkaloïds* are also given off, *viz.* ethylamine and its homologues, together with pyridine, picoline, lutidine, collidine, pyrrhol, and others. (See BONE-OIL, i. 625.)

Coal yields by dry distillation, especially at low temperatures, a very complex distillate, consisting of an acid portion containing phenic or carbolic acid, with smaller quantities of rosolic and brunolic acids, a basic portion containing ammonia, phenylamine, benzylamine, and the volatile bases above mentioned, and a neutral portion consisting of benzene and its homologues, together with the hydrides of the alcohol-radicles, amyl, hexyl, and heptyl, which are liquids,—also the solid compounds naphthalene, anthracene or paranaphthalene, chrysene, pyrene, and the paraffins, which probably consist of the hydrides of the higher terms of the series of alcohol-radicles.

As the more volatile products escape, substances of continually diminishing volatility remain behind; and these, as the temperature rises, are either evolved unaltered in the gaseous form, or resolved into more volatile matters and residual products of still greater fixity.

The hydrogen, nitrogen, and oxygen, which finally remain, are either sufficient to form, with the whole of the residual carbon, a compound which is volatile at a higher temperature, in which case nothing remains in the retort; or, the relative quantity of the carbon is too great to enter wholly into such a state of combination; and then, as the heat approaches to redness, this excess remains behind in the form of charcoal, still combined with small quantities of the other substances, which, however, are separated the more completely as the residue is finally subjected to a stronger heat.

Compounds containing a medium quantity of oxygen, such as sugar, gum, wood, and glue, leave, if they are not volatile, the largest quantity of charcoal; because a large portion of the hydrogen, which would otherwise volatilise the carbon, is converted by the oxygen into water. These compounds leave more charcoal in proportion as they are heated more slowly, because the quantity of water formed is then likewise greater. When the proportion of oxygen is large, this element also tends to volatilise the carbon, in the form of carbonic anhydride and carbonic oxide. When the quantity of oxygen is comparatively small, the hydrogen combines chiefly with the carbon, forming volatile compounds, such as gases, oils, camphors, and resins.

If the compound, during dry distillation, passes into a fused or softened state, which is most frequently the case, the charcoal appears inflated, like that formed from resin and sugar, or at all events very porous, like that from tartaric acid and cork. But if the compound, wood, for example, remains solid while subjected to heat, the charcoal still exhibits the original form and internal structure, but is contracted in volume.

Spongy platinum, inasmuch as it favours the formation of vapour in liquids, may cause an organic compound to be completely resolved into volatile products at a lower temperature than it would if heated alone. Thus, tartaric acid mixed with spongy platinum and carefully heated, yields nothing but carbonic acid and a transparent and colourless, crystallisable distillate. (Reiset and Millon.)

The products of dry distillation may be arranged in the following classes, according to their external forms:

1. *Gases*.—Hydrogen and nitrogen;—carbonic oxide, carbonic anhydride, hydrochloric, hydrobromic, hydriodic, and sulphydric acid gases, marsh-gas, olefiant gas, and tetrylene. In this gaseous mixture, the vapours of empyreumatic oils and of sulphide of carbon are also diffused.

2. *Watery distillate*.—The water contained in this distillate was either attached as such to the organic compound, or it has been formed at the high temperature to which that compound has been subjected, from the oxygen and hydrogen contained in it. In this water are dissolved:—*a*. In some few instances, alcoholic fluids, such as aldehyde, wood-spirit, lignone, and acetone.—*b*. Almost always acids, of which the most frequent is acetic acid. Hence the watery distillate obtained in the dry distillation of non-azotised organic bodies almost always has an acid reaction (see ACETIC Acm, i. 9).—*c*. The watery distillate obtained from azotised substances contains small quantities of hydrocyanic acid and large quantities of ammonia, often mixed with compound ammonias, such as methylamine, ethylamine, &c. When the quantity of ammonia is but small, it is completely saturated by the acetic acid or any other stronger acid that may be present, and the watery distillate still exhibits an acid reaction, or is neutral; but in the distillate obtained from most azotised bodies, these stronger acids are not present in sufficient quantity to neutralise the large quantity of ammonia, the excess of which, therefore, unites with the carbonic acid, and in the form of carbonate of ammonia, imparts an alkaline reaction to the liquid. By this character, a non-azotised organic compound may be distinguished from one which contains nitrogen. The former yields an acid distillate, which does not give off ammonia even on the addition of potash; the latter gives either an alkaline distillate, or, if it contains but little nitrogen, a neutral or acid distillate which gives off ammonia when treated with potash. But a non-azotised organic compound likewise yields ammonia by destructive distillation, if it be previously mixed with nitre. Thus, gum-arabic distilled with one-tenth of its weight of nitre yields ammonia

and a pyrophoric charcoal containing cyanide of potassium (Vauquelin, Ann. Chim. lxxii. 59).—*d.* The watery distillate likewise holds in solution a small quantity of the tarry matter next to be considered, which gives it a brown colour.

3. *Oily or Tarry Distillate, Empyreumatic Tar.*—Generally a brown and fetid mixture of different empyreumatic oils, camphors, and resins, which may likewise contain volatile alkaloïds, a brown mouldy substance, and another brown substance soluble in water and alcohol, and forming with potash, baryta, and lime, compounds which are soluble in water, and, with the other earths, compounds which are insoluble. The most fetid tar is that obtained from the more highly azotised compounds, such as gelatin and white of egg. The offensive odour of most empyreumatic tars is ascribed by Unverdorben (Pogg. 253, 297, and 477) to a peculiar oily acid which he calls *empyreumatic acid*, which, however, varies with the nature of the original compound, being sometimes lighter, sometimes heavier, than water.

4. *Sublimed Products.*—These products consist sometimes of an acid, *e. g.* pyrogallie acid, sometimes of a camphor, sometimes of carbonate of ammonia.

5. *Charcoal.*

Some organic compounds yield all these products, viz. gases, watery liquid, tar, sublimate, and charcoal. Such is the case with gelatin, albumin, &c., in which the sublimate consists of carbonate of ammonia. Other compounds, as sugar, woody fibre, &c., yield gases, a watery liquid, tar, and charcoal, but no sublimate. (See ACETIC ACID, BONE-OIL, CINCHONINE, COAL.)

The nature of the products obtained by the destructive distillation of any substance, often varies considerably with the temperature to which it is subjected; thus coal, when distilled at bright red heat, yields a large quantity of gaseous, and a comparatively small quantity of liquid hydrocarbons, whereas, when the distillation is conducted at a low red heat, the proportion of liquid products is much greater. The paraffin oils now so largely used for illumination and for lubricating machinery, are prepared by distilling Boghead coal at a low red heat.

We have hitherto spoken chiefly of the decomposition of bodies of complex or indefinite constitution, such as wood, coal, animal matter, &c. The more simply constituted organic compounds, such as acids, bases, and salts, yield by dry distillation, especially if carefully conducted, a small number of products, bearing a definite and, generally speaking, a simple ratio to the original substance. The following are examples:—

a. Decomposition of non-azotised organic bodies.—Many acids are wholly resolved into water or carbonic anhydride (or both together), and one or more acids, called *Pyro-acids*, containing less oxygen.

Malic acid, when quickly heated to 200 C., is almost completely resolved into water and maleic acid, which distil over:

At 150° C., it yields, as principal product, a residue of fumaric acid, which is polymeric with maleic acid, and may be regarded as a dibasic acid = $C^4H^4O^4$. At a more intense heat, the products are carbonic oxide, marsh-gas, empyreumatic oil, and charcoal.

Mucic acid is resolved into 1 at. carbonic anhydride, 3 at. water, and pyromucic acid:

Citric acid, when heated in a retort, gives off 1 at. water, and leaves a residue of aconitic acid:

This *aconitic acid*, if more strongly heated in the retort, gives off 1 at. carbonic anhydride and distils over as itaconic acid:

At the same time, another portion of the citric acid is decomposed in a different manner, being resolved into carbonic oxide, acetone, empyreumatic oil, and charcoal.

Gallic acid, heated to 210° C., yields carbonic anhydride and a distillate of pyrogallie acid:

but at 250°, it gives off water and carbonic anhydride and leaves metagallic acid:

Meconic acid gives off carbonic anhydride, and yields a sublimate of pyromeconic acid :

Oxalic acid partly sublimes undecomposed; another portion is resolved into water, carbonic oxide, and carbonic anhydride :

and a third part into formic acid and carbonic anhydride :

Salicylic acid, when quickly heated, is resolved into carbonic anhydride and phenylic alcohol :

Orsellic acid yields carbonic anhydride and orcin :

In some cases, the whole of the oxygen of the organic compound is eliminated in the form of water and carbonic anhydride, and hydrocarbons of various composition are produced : thus,

Acetic acid.

Marsh gas.

Cinnamic acid.

Cinnamene.

Monobasic acids are, for the most part, resolved by dry distillation into 1 molecule of carbonic anhydride, together with a hydrocarbon (*e. g.* acetic, cinnamic, benzoic acid, &c.), or into carbonic anhydride and an alcohol (like salicylic acid); dibasic acids yield 1 molecule of carbonic anhydride and a monobasic pyro-acid (oxalic acid yields carbonic anhydride and formic acid),—or two mol. CO^2 and a hydrocarbon, sometimes also water (phthalic acid, $C^8H^6O^4$, yields $2CO^2$, and 1 at. benzene, C^6H^6);—and tri-basic acids yield either 1 mol. carbonic anhydride and a dibasic pyro-acid (citric acid yields CO^2 and itaconic acid), or 2 mol. CO^2 and a monobasic acid, or 3 mol. CO^2 and a hydrocarbon.

Under the influence of strong chemical reagents, the decomposition by heat often takes a different form. Thus, organic bodies heated with caustic *alkalis* yield acids as their chief products of decomposition, formic, oxalic, and carbonic acids being frequently produced in this manner; monobasic acids heated with lime or baryta yield acetones, together with a carbonate of the earth-metal, *e. g.*

Acetate of calcium.

Carbonate of calcium.

Acetone.

Benzoate of calcium.

Benzophenone

Sometimes a more complex decomposition takes place, resulting in the formation of hydrocarbons, together with aldehydes, or compounds isomeric therewith, *e. g.* butyral from butyric acid (i. 689).

In many cases, when a considerable quantity of lime or baryta, or an excess of hydrate of potassium or sodium is present, the whole of the oxygen of the acid is converted into carbonic anhydride, and a hydrocarbon is given off:

Acetate of potassium.

Marsh gas

Benzoate of calcium.

Benzene.

In other cases, organic acids of more simple constitution are produced; thus, oleic acid heated with hydrate of potassium, yields palmitate and acetate of potassium, together with free hydrogen :

Oleic acid.

Palmitate of potassium.

Acetate of potassium.

Dibasic acids frequently yield monobasic acids, together with carbonic anhydride: thus,

Under the influence of sulphuric acid, phosphoric acid, or chloride of zinc, the elements of water are often withdrawn, and a hydrocarbon produced: thus alcohol, $\text{C}^1\text{H}^6\text{O}$, is resolved into water, H^2O , and ethylene, C^2H^4 ; and borneol, $\text{C}^{10}\text{H}^{18}\text{O}$, into H^2O and borneene, $\text{C}^{10}\text{H}^{16}$.

6 *Decomposition of azotised bodies.*—When azotised organic bodies are heated *per se*, the greater part of their nitrogen is given off in the form of ammonia, a volatile organic base, or a cyanogen compound; sometimes also in part as free nitrogen, and in the case of compounds containing nitril (NO^2), as an oxide of nitrogen. A small portion of the nitrogen usually remains united with the charcoal, which is left behind when all the volatile products have escaped. The following are examples of some of the modes of decomposition just mentioned:

Certain nitrogen-compounds (ammonium-salts), when gradually heated, give off all their oxygen in the form of water, and are converted into amides, or nitriles.

Oxalate of ammonium, $\text{C}^2(\text{NH}^1)^2\text{O}^4$, is resolved in like manner into 2 at. cyanogen (C^2N^2) and $4\text{H}^2\text{O}$; formate of ammonium, $\text{CH}(\text{NH}^1)\text{O}^2$, into hydrocyanic acid (formonitrile), HCN , and $2\text{H}^2\text{O}$; benzoate of ammonium, $\text{C}^7\text{H}^3(\text{NH}^1)\text{O}^2$, into cyanide of phenyl (benzonitrile) $\text{C}^7\text{H}^5\text{N}$, and $2\text{H}^2\text{O}$.

If the nitrogen-compound likewise contains sulphur, this element unites partly with the ammonium and ammonium-bases evolved, forming sulphides, partly with carbon and the ammonium-bases, forming sulphocyanates of those bases, partly with carbon alone, in the form of sulphide of carbon.

Nitrogen-compounds heated with the hydrates of the alkali-metals, either alone or mixed with lime (potash- or soda-lime), generally give off the whole of their nitrogen as ammonia; in some cases, however, volatile organic bases are likewise given off. Thus, caffeine boiled with potash, gives off methylamine, and cinchonine heated with hydrate of potassium, yields pyrrol, pyridine, picoline, lutidine, collidine, chinoline and lepidine.

DISULPH-ANISOLIC, -BENZOLIC, -ETHOLIC, -METHOLIC, and -PROPOLIC ACIDS. See SULPHUROUS ETHERS.

DITETRYL. The name given by Berzelius to the hydrocarbon C^1H^8 , now called *Butylene* or *Tetrylene*.

DITHIONIC ACID. See SULPHUR, OXYGEN-ACIDS OF.

DIURET. Syn. with BIURET (i. 600).

DIVI-DIVI or *Libidibi*. The husks of *Cæsalpinia coriaria*, Willd., imported from South America, in the form of dark brown rolls containing a few flat seeds. The outer rind of the husk contains a large quantity of tannin, together with ready-formed gallic acid; the tannin easily yields pyrogallie acid by distillation. (Stenhouse.)

DOCIMASY (from δοκιμάζω, to test). A term synonymous with assaying.

DOEGLAL. A compound obtained from dögling train oil, and said by Scharling to be analogous to æthal (hydrate of cetyl).

DOEGLIC ACID. See the next article.

DOEGLING TRAIN OIL. (Scharling, J. pr. Chem. xliii. 257; Jahresber. d. Chem. 1847-8, p. 367.)—The oil obtained from the bottle-nosed whale, *Balæna rostrata*,

called "dögling" in the Faroë isles, where it is caught. The oil has a specific gravity of 0.868 at 20° C., 0.981 at 11°, becomes turbid at 8°, and deposits a crystalline fat at 0°, more abundantly at -8°. It contains, according to Scharling, 79.9 p.c. carbon, and 13.4 hydrogen, and consists mainly of doeglate of doeglyl, with but a small proportion of glycerides, and no iodine. It dissolves in 2 pts. of boiling absolute alcohol, and in 22 pts. weak alcohol. When exposed to the air it takes up oxygen, becomes heavier and more viscid, and ultimately dries up. It forms a better fuel for lamps than common train oil, and may be freed from offensive odour by leaving it exposed to the sun in contact with water, by shaking it up with thin milk of lime, or by dissolving it in boiling alcohol.

Doegling train oil is a mixture of several fats. On leaving it for some time exposed to a temperature of -8° C., it separates into a liquid oil and a fat which melts at 24° C., contains a small quantity of spermaceti, and yields by saponification a turbid soap containing a small quantity of a fatty acid, isomeric or identical with capric acid, $C^{10}H^{20}O_2$. When saponified with oxide of lead, it yields chiefly a lead-salt soluble in ether, with but a small quantity of a lead-salt insoluble therein.

The lead-salt insoluble in ether contains a mixture of a body melting at 49° C. with a smaller quantity of a substance which melts at 100° C. without decomposing. The lead-salt soluble in ether yields, when decomposed by acids, yellow doeglic acid $C^{19}H^{36}O_2$, which belongs to the oleic series, is perfectly clear and fluid at 16° C., and solidifies a little above 0° C. It reddens litmus, forms a liquid ethyl-compound, $C^{19}H^{35}(C^2H^5)O_2$, and a crystalline barium-salt, $C^{19}H^{35}BaO_2$, which dissolves in boiling alcohol and does not melt at 100° C.

Doegling train oil yields by dry distillation a large quantity of a colourless liquid which is a mixture of several fatty acids (including volatile acids like butyric acid), with numerous hydrocarbons. By treating this liquid with carbonate of sodium and water, rectifying it *per se*, treating it with potassium, and again rectifying, a colourless liquid hydrocarbon, $C^{12}H^{24}$, is obtained, having a strong aromatic odour, and vapour-density = 5.8 (2 vol.). According to Scharling, this hydrocarbon is formed by the decomposition of *oxide of doeglyl*, $C^{24}H^{50}O$, contained in the oil ($C^{24}H^{50}O - H^2O = 2C^{12}H^{24}$).

Doegling train oil treated with nitrous acid, assumes a darker colour and solidifies; and the solidified oil may be separated by alcohol into a reddish-yellow easily soluble substance, and a colourless, crystallisable, less soluble mass, neither of which has been examined.

DOG-TOOTH SPAR. The scalenohedral form of calespar (i. 722).

DOLERIN. A gneissoïd rock in the Alps, consisting of talc and felspar.

DOLERITE. A rock nearly allied to basalt, and consisting of a crystallo-granular mixture of felspar (labradorite) and augite, with a small quantity of titaniferous magnetic iron ore: it differs from basalt by not containing olivine, and generally also by the absence of zeolites. Its structure varies from small- and fine-grained to compact, seldom coarse-grained. It often contains distinct crystals of augite or labradorite, or both, and then becomes porphyroidal; it likewise acquires an amygdaloid character by the presence of cavities, and is sometimes porous. Specific gravity = 2.75 to 2.99. The essential constituents of dolerite are silica, alumina, lime, magnesia, ferrous and ferric oxide, with small quantities of potash and soda. Dolerite from Iceland, analysed by Auerbach, gave 38.18 per cent. labradorite and 61.32 augite. Dolerite from Meissner, analysed by Heusser (Pogg. Ann. lxxxv. 298), gave 47.60 labradorite and 49.60 augite, and by ultimate analysis 48.00 SiO_2 , 16.28 Al_2O_3 , 15.55 Fe_2O_3 , 9.50 CaO , 3.85 MgO , 2.01 Na_2O , 2.01 K_2O , 2.80 water (loss included).

Dolerite occurs as an eruptive rock in enormous masses, streams, veins, beds, and crusts; it generally weathers somewhat easily; it is but slowly attacked by acids. A very fine formation of coarse-grained dolerite is found at Meissner in Hesse. See D'Aubisson (*Traité de Géognosie*, ii. 558, note).—On the dolerites of the left bank of the Rhine (Bergemann, Karsten's Archiv. xxi. 3; Rammelsberg's Handw. 4, suppl. 49; Jahresber. d. Chem. 1849, 803).—On the dolerite of Guadeloupe (Deville, Bull. géolog. [2] viii. 425; Jahresber. 1851, 862).—On the dolerites of the Siebengebirg (Dechen, Verhändl. d. naturalist. Vereins d. preuss. Rheinl. 1852, 3, 4, Heft, 289); Jahresber. 1852, 949).—On the products of decomposition of dolerite (R. Ludwig, Jahresber. 1851, 831).

DOLOMITE. The compact and granular varieties of magnesio-calcic carbonate ($Ca; Mg^2CO_3$), the crystallised varieties being called Bitter-spar (i. 600). The following sub-varieties have been distinguished:

1st. *Granular Dolomite.*

a. *White granular.* It occurs massive, and in fine granular distinct concretions, loosely aggregated. Lustre glimmering and pearly. Fracture in the large, imperfect

slaty. Faintly translucent. As hard as fluor-spar. Brittle. Specific gravity, 2·83. Effervesces feebly with acids. Phosphorescent on heated iron, or by friction. Its constituents are, 46·5 carbonate of magnesium, 52·08 carbonate of calcium, 0·25 oxide of manganese, and 0·5 oxide of iron (Klaproth). Beds of dolomite containing tremolite occur in the island of Iona, in the mountain-group of St. Gothard, in the Apennines, and in Carinthia. A beautiful white variety, used by ancient sculptors, is found in the Isle of Tenedos.

The *flexible* variety was first noticed in the Borghese palace at Rome; but the other varieties of dolomite, and also common granular limestone, may be rendered flexible by exposing them in thin and long slabs to a heat of 480° Fahr. for six hours.

b. Brown Dolomite, or magnesian limestone of Tennant.

Colour, yellowish-grey and yellowish-brown. Massive, and in minute granular concretions. Lustre, internally glistening. Fracture, splintery. Translucent on the edges. Harder than calcareous spar. Brittle. Specific gravity of crystals, 2·8. It dissolves slowly, and with feeble effervescence; and when calcined, it is long in reabsorbing carbonic acid from the air. Its constituents are, lime 29·5, magnesia 20·3, carbonic acid 47·2, alumina and iron 0·8 (Tennant). In the north of England it occurs in beds of considerable thickness and great extent, resting on the Newcastle coal formation. In the Isle of Man, it occurs in a limestone which rests on greywacke. It occurs in trap-rocks in Fifeshire.

To the preceding variety we must refer a *flexible dolomite* found near Tinmouth Castle. It is yellowish-grey, passing into cream-yellow. Massive. Dull. Fracture earthy. Opaque. Yields readily to the knife. In thin plates, very flexible. Specific gravity, 2·54; but the stone is porous. It dissolves in acids as readily as common carbonate of calcium. Its constituents are said to be 62 carbonate of calcium, and 36 carbonate of magnesium. When made moderately dry, it loses its flexibility; but when either very moist or very dry, it is very flexible.

2nd, *Columnar Dolomite*. Colour pale greyish-white. Massive, and in thin prismatic concretions. Cleavage imperfect. Fracture uneven. Lustre vitreous, inclining to pearly. Breaks into acicular fragments. Feebly translucent. Brittle. Specific gravity 2·76. Its constituents are 51 carbonate of calcium, 47 carbonate of magnesium, 1 carbonate of iron. It occurs in serpentine in Russia.

3rd, *Compact Dolomite*, or *Gurhoffite*. Colour snow-white. Massive. Dull. Fracture flat conchoidal. Slightly translucent on the edges. Semi-hard. Difficultly frangible. Specific gravity 2·76. When pulverised, it dissolves with effervescence in hot nitric acid. It consists of 70·5 carbonate of calcium and 29·5 carbonate of magnesium. It occurs in veins in serpentine rocks, near Gurhoff, in Lower Austria.

U.

DOME. A term used in crystallography to designate a trimetric, monoclinic, or triclinic prism, whose faces and edges are parallel to one of the secondary axes, in contradistinction to those which are parallel to the principal axis, the term *prism* being for the most part restricted to these latter. (See CRYSTALLOGRAPHY, pp. 145, 151, 157.)

DOMKEYITE. *Arsenical Copper*, *Weisskupfererz*.—An arsenide of copper, Cu⁶As, found in the district of Copiapo and the province of Coquimbo, in Chili, in reniform and botryoidal concretions, also massive and disseminated. Hardness = 3 to 3·5. Lustre metallic. Colour tin-white, with a slight yellowish or iridescent tarnish. Fracture uneven. Melts easily before the blowpipe, emitting an odour of arsenic.

Analyses.—*a.* Copiapo, province of Coquimbo (Domeyko, Ann. Min. [4] iii. 5).—*b.* Cordilleras of Copiapo (Field, Chem. Soc. Qu. J. x. 289).—*c.* Coquimbo (Field).—*d.* San Antonio mine, Copiapo, mixed with iron pyrites (Domeyko).

	<i>a.</i>	<i>b.</i>	<i>c.</i>	<i>d.</i>
Copper . . .	71·64	71·56	71·48	70·70
Iron . . .	·	·	·	0·52
Arsenic . . .	28·36	28·44	28·26	23·29
Sulphur . . .	·	·	·	3·87
	100·00	100·00	99·74	98·38

A similar mineral from Michipicoten Island, Lake Superior, of reddish-white to bronze-yellow colour, and specific gravity 7·35 to 7·40, is, according to T. S. Hunt (Sill. Am. J. xxv. 406), perhaps a mixture of domeyite and nickelin.

Condurrite (i. 1110), must be regarded as a product of the decomposition of domeyite.

DOMITE. A greyish variety of clinkstone from the Puy de Dome in Auvergne.

DONARIA. The name given by Bergemann (Pogg. Ann. lxxxvii. 608), to an earth which he obtained from the orangite of Brevig in Norway, and supposed at the

time to be peculiar; later investigations, however, by Bergemann himself and by Berlin and Damour, have shown that it is identical with thorina.

DOPPLERITE. A pitch-like substance occurring in layers in the peat near Aussee in Styria (Haidinger, Wien. Akad. Ber. ii. 287). It is gelatinous, elastic like caoutchouc, brownish-black, translucent on the edges, has but little lustre, is very soft, and has a specific gravity of 1·089. When exposed to the air, it quickly gives off a large quantity of water, and splits up into black, highly lustrous, sharp-edged brittle lumps, like jet, having a hardness of 2 to 2·5, and specific gravity of 1·466. In this state it burns away but slowly when heated, leaving a white ash. It is insoluble in alcohol and ether, but dissolves almost entirely in caustic potash. According to an analysis by Schrötter (Wien. Akad. Ber. 1849, p. 285), it contains 51·43 carbon, 5·34 hydrogen, and 48·03 oxygen (= 100): according to another analysis by Schrötter, quoted by Kennigott (Handw. d. Chem. 2^{te}. Aufl. ii. [3] 484), it contains 48·06 per cent. carbon, 4·98 hydrogen, 1·03 nitrogen, and 40·07 oxygen. The fresh substance, at 18° C., contains 68·22 per cent. water, and after being heated to 100° C., 78·5 per cent. water.

The same substance appears to occur in the peat deposits at the Gonten baths, near Appenzel (v. Tschudi, Wien. Akad. Ber. ii. 274), and in the peat of Berechtsgarden (Gumbel, Jahrb. J. Min. v. Leonhard, 1858, p. 278). The substance from Hagnetswyl in the Canton of St. Gall, described as dopplerite by J. Deicke (Berg. v. Hüttenm. Zeitg. xvii. 383), does not exhibit the same properties.

DRACENINE, DRACINE, or DRACONINE. See DRAGON'S BLOOD.

DRACO MITIGATUS. An old name of calomel.

DRACOL. Laurent's name for ANISOL.

DRACONIC ACID. Syn. with ANISIC ACID (i. 300).

DRACONIDE.} See DRAGON'S BLOOD.
DRACONINE.}

DRACONYL. A product of decomposition of dragon's blood, identical, according to Blyth and Hofmann, with metastyrol or metacinnamene (i. 982).

DRACONYL, or DRAGONYL, CHLORIDE OF. Laurent's name for a product of the action of chlorine on oil of tarragon (i. 299).

DRACYL. A product of decomposition of dragon's blood, identical, according to Hofmann, with toluene or hydride of benzyl (i. 573).

DRACONITE, DRAGONITE. Syn. with ROCK-CRYSTAL.

DRAGONIC ACID. Syn. with ANISIC ACID.

DRAGON'S BLOOD. *Sanguis Draconis.*—A resin, so called on account of its red colour, which exudes from various trees, either spontaneously or from incisions. Three kinds are distinguished in commerce—1. *East Indian dragon's blood*, which is found on the ripe fruits and leaves of several palms of the genus *Calamus*, viz. *C. Rotang*, *C. pectreus*, *C. draco*. 2. *American*, from incisions in *Pterocarpus draco*, indigenous in the West Indies. 3. *Canary dragon's blood*, from *Dracæna draco*. According to Pereira, it occurs, in commerce, in sticks or in the reed (*Sanguis draconis in baculis*); in oval masses or drops (*in lachrymis*); in powder; in the tear (*in granis*); in lumps (*in massis*); and in cakes.

Dragon's blood is dark red-brown, opaque, tasteless and scentless, brittle, and yields by trituration a cinnabar or carmine-red powder. When pure, it dissolves, with fine red colour, in *alcohol*, also in *ether*, and in *oils* both fixed and volatile. *Alkalis* also dissolve it more or less completely.

The composition of dragon's blood varies with its origin; the several commercial varieties are probably mixtures of different compounds. According to Johnstone, (Phil. Trans. 1839, p. 134), the portion of cake dragon's blood which is soluble in alcohol and ether has the composition $C^{20}H^{20}O^4$. Herberger (Buchn. Repert. xxxvii. 17; xl. 138) found in 100 pts. of dragon's blood *in granis*: 90·7 red, amorphous, acid resin, which he designates as draconide, 2·0 fatty matter soluble in ether, 3·0 benzoic acid, 3·7 phosphate of calcium, and 1·6 oxalate of calcium.

The alcoholic solution of dragon's blood forms red or violet precipitates with metallic salts (Herberger). The same turns yellow when mixed with sulphuric or hydrochloric acid, and on addition of water deposits a yellow or reddish compound of the acid with the resin. This compound dissolves in a small quantity of water, forming a yellow solution, which is reddened by alkalis. Melandri (Brandes' Archiv. [1828] xxv. 193) regarded the resin combined with sulphuric or hydrochloric acid as an alkaloid, and designated it as draconine, dracenine, or dracine.

Dragon's blood is decomposed by *nitric acid*. With acid of specific gravity 1·33 it yields oxalic acid; if the acid has been previously diluted with an equal weight of

water, it forms, when heated with the resin, nitrobenzoic acid, together with a non-volatile acid.

Dragon's blood, when gradually heated, melts and gives off, up to 210°C ., a small quantity of acid watery distillate containing acetone and benzoic acid; as the heat increases, the resin swells up and gives off carbonic anhydride and carbonic oxide, while water is formed, and thick white vapours are evolved, which condense in the receiver to a reddish black liquid. The oily distillate contains two hydrocarbons, dracyl and draconyl, the former of which, according to Hofmann, is identical with toluene or hydride of benzyl (i. 573), the latter with metacinnamene or metastyrol (i. 982). Benzoic acid is also obtained, together with a colourless, mobile, oxygenated oil, which is heavier than water, insoluble therein, but soluble in alcohol and ether, and boils at 200°C .; with potash, this oil yields benzoic acid and a compound not further examined. (Glénard and Boudault, *Compt. rend.* xvii. 503; xix. 505.)

Dragon's blood is used chiefly for colouring varnishes, for preparing gold lacquers, for tooth tinctures and powders, and for staining marble, to which it imparts a fine red colour; it is also used, though rarely, in medicine. A spurious kind of dragon's blood is said to be found in commerce, consisting of a mixture of different resins coloured with sandarach.

DRAWING SLATE. *Black chalk.*—Colour greyish-black. Massive. Lustre of the principal fracture, glimmering; of the cross fracture, dull. Fracture of the former slaty, of the latter fine earthy. Opaque. It writes. Streak same colour, and glistening. Very soft. Sectile. Easily frangible. It adheres slightly to the tongue. Feels fine, but meagre. Specific gravity, 2.11. It is infusible. Its constituents are, silica 64.06, alumina 11, carbon 11, water 7.2, iron 2.75. It occurs in beds in primitive and transition clay-slate, also in secondary formations. It is found in the coal formation of Scotland, and in most countries. It is used in crayon-painting. The trace of bituminous shale is brownish and irregular; that of black chalk is regular and black. The best kind is found in Spain, Italy, and France. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 57.)

DREELITE. *Dreelite.*—A baryto-calcic sulphate, occurring in small unmodified rhombohedral crystals, disseminated on the surface and in the cavities of a quartzose rock at Beaujeu, Dep. of the Rhone, also at Badenweiler in Baden. R : R in the terminal edges = 93° or 94° . Cleavage rhombohedral in traces. Specific gravity = 3.2 to 3.4. Hardness = 3.5. Lustre pearly; splendent on the fractured surfaces. Streak and colour white. According to Dufrénoy (*Ann. Ch. Phys.* [2] lx. 102) it contains 61.73 per cent. Ba^2SO^4 , and 14.275 Ca^2SO^4 , agreeing with the formula $\text{Ca}^2\text{SO}^4.3\text{Ba}^2\text{SO}^4$, or $\left. \begin{matrix} \text{Ca} \\ \text{Ba} \end{matrix} \right\} \text{S}^2\text{O}^8$, together with 8.05 carbonate of calcium, 9.71 silica, 2.405 alumina, 1.52 lime, and 2.31 water.

DRUPACIN. Buchner (*Repert.* xli. 237) gave this name to a yellow substance deposited from old bitter almond oil. It was said to dissolve in acids and to be precipitated by bases, and was perhaps benzamide.

DRUSE, or *Geode*. A rounded nodule of stone containing a cavity lined with crystals.

DRYABALANOPS CAMPHORA. The camphor tree of Borneo and Sumatra, which yields borneol and borneene (i. 626). The borneol or Borneo camphor is a white crystalline substance found in cavities of old trees. The borneene is a liquid hydrocarbon, isomeric with oil of turpentine, $\text{C}^{10}\text{H}^{16}$, which exudes from incisions in the younger stems.

The tree likewise contains another oil, described by Lallemand, which is obtained by boiling the different parts of the tree, cut up into small pieces, with water, and collecting the oily layer which floats on the surface. It is a viscid reddish oil, having a strong balsamic odour, and turning the plane of polarisation of a luminous ray to the right. It begins to boil at about 180°C . (borneene boils at 165°), but the boiling point quickly rises to about 255° and then to 300° , at which temperature the whole of the volatile portion has passed over, and there remains a resin amounting to about half the weight of the original oil. The distilled oil is further resolved by repeated fractional distillation (mostly conducted under diminished pressure) into a more volatile oil, boiling from 180° to 190°C ., and a less volatile oil, boiling at about 260° . Both have the composition $\text{C}^{10}\text{H}^{16}$. The crude oil was not found to contain borneol. (Lallemand, *Études sur la Composition de quelques Essences*, *Ann. Ch. Phys.* [3]; lvii. 404.—G m. xiv. 354.)

DRYMIS WINTERI, or *Wintera aromatica*. The bark of this tree, growing in Brazil, is said to be the *Cortex Winteranus*, formerly used as a tonic. It contains, according to Henry (*J. Pharm.* v. 481), in 100 pts. 1.2 volatile oil, 10 hard

acid resin, 9 extractive matter with a little tannin, 1.6 starch, also woody fibre, salts, &c.

According to more recent investigations by Weissbecker, *Cortex Winteranus* is obtained from *Winteranus Canella*, L. (*Canella alba*, M.), or from some other plant nearly related thereto.

DSCHUT. See JUTE.

DUCKTOWNITE. The name given by C. U. Shepard (Sill. Am. J. xxviii. 129) to a mineral found in the copper mine near Ducktown, East Tennessee, having a steel-grey colour inclining to bronze, hardness = 5.5, specific gravity = 4.55 to 4.66, and containing, according to R. A. Fisher, 30.7 pts. iron and 26.0 copper, together with sulphur. According to G. J. Brush, it is a mixture of pyrite, chalkosin, malachite, quartz, limonite, &c.

DUCTILITY. That property or texture of bodies, which renders it practicable to draw them out in length, while their thickness is diminished, without any actual fracture of their parts. This term is almost exclusively applied to metals.

The words malleability, laminability, and ductility, though often confounded together, and used in a loose indiscriminate way, are really very different. Malleability is the property of a body which enlarges one or two of its three dimensions by a blow or pressure very suddenly applied. Laminability belongs to bodies extensible in dimension by a gradually applied pressure: and ductility is properly to be attributed to such bodies as can be rendered longer and thinner by drawing them though a hole of smaller area than the transverse section of the body so drawn. U.

DUFRENITE. *Green Iron ore, Kraurite.*—A basic ferric phosphate, $2\text{Fe}^{\text{IV}}\text{O}^3 \cdot \text{P}^2\text{O}^5$, or $3\text{Fe}^{\text{IV}}\text{O}^3 \cdot 2\text{P}^2\text{O}^5$, occurring in indistinct trimetric crystals ($\infty\text{P} : \infty\text{P}$ about 123°), with brachydiagonal cleavage, or in spherical, botryoidal, or kidney-shaped masses, with radiated fibrous structure, and drusy surface. Hardness = 3.5 to 4. Specific gravity = 3.2 to 3.4. Lustre silky, weak. Colour dull leek-green or blackish-green, changing to yellow and brown on exposure. Streak siskin-green. Subtranslucent. Melts easily to a slag before the blowpipe.

Karsten (Arch. f. Bergb. v. Hüttenw. xv. 243) found in a specimen from Siegen in Saxony, 27.72 p. c. P^2O^5 , 63.45 $\text{Fe}^{\text{IV}}\text{O}^3$ and 8.56 water; Vauquelin (Ann. Ch. Phys. xxx. 202) found, in a specimen from Haute Vienne, France, 27.85 P^2O^5 , 56.20 $\text{Fe}^{\text{IV}}\text{O}^3$, 6.76 $\text{Mn}^{\text{IV}}\text{O}^3$, and 9.29 water, whence the formula $2(2\text{Fe}^{\text{IV}}\text{O}^3 \cdot \text{P}^2\text{O}^5) + 5\text{H}^2\text{O}$; (calc. 28.0 P^2O^5 , 63.1 $\text{Fe}^{\text{IV}}\text{O}^3$, 8.9 water).—From a more recent analysis by Pisani (Sill. Am. J. [2] xxiii. 423), the formula appears to be $2(2\text{Fe}^{\text{IV}}\text{O}^3 \cdot \text{P}^2\text{O}^5) + 7\text{H}^2\text{O}$.

DUFRENOYSITE. A sulphide of copper and arsenic occurring, together with binnite, in the dolomite of the Binnenthal, in the Ober-Wallis, Switzerland. It forms small monometric crystals, sometimes with numerous faces, of dark steel-grey to iron-black colour, opaque, and with metallic lustre. Hardness = 4.5. Specific gravity = 4.6. Heated in a test-tube, it yields a sublimate of sulphide of arsenic; when roasted, it yields arsenious oxide. Before the blowpipe it gives off arsenical fumes, and melts to a black button. With soda, it yields a button of copper.

The composition of this mineral is variously stated. Uhrlaub (*Kennigott's Uebers.* 1856–1857, p. 173) found in it:

S	As	Cu	Pb	Ag	Fe
27.54	30.06	37.74	2.75	1.23	0.82 = 100.14;

which, when the lead, silver, and iron are replaced by their equivalents in copper, agrees approximately with the formula $3\text{Cu}^{\text{I}}\text{S} \cdot 2\text{As}^{\text{I}}\text{S}^{\text{I}}$ or $\text{Cu}^{\text{I}}\text{As}^{\text{I}}\text{S}^{\text{I}}$ (calc. 29.70 S, 31.03 As, 39.27 Cu).—Stockar-Escher, on the other hand (*ibid.* p. 175), found in the pure crystals:

S	As	Cu	Ag
32.73	18.98	46.24	1.91 = 99.86;

which agrees nearly with the formula of normal cuprous sulpharsenate, $3\text{Cu}^{\text{I}}\text{S} \cdot \text{As}^{\text{I}}\text{S}^{\text{I}}$, or $\text{Cu}^{\text{I}}\text{As}^{\text{I}}\text{S}^{\text{I}}$ (calc. 32.60 S, 19.10 As, 48.29 Cu). The latter formula is the same as that of enargite, and if established for dufrenoyite, would show that cuprous sulpharsenate is dimorphous.

The name *dufrenoyite* has sometimes also been applied to binnite (i. 588).

DULCAMARIN. Wittstein's name for a base obtained from the stems of the common nightshade, *Solanum Dulcamara*, which he regards as peculiar, and represents by the formula $\text{C}^{65}\text{H}^{50}\text{NO}^{20}$ (Vierteljahresschrift, f. prakt. Pharm. i. 364, 495).

DULCARIN. Syn. with BITTERSWEET (i. 600).

DULCIN. Syn. with DULCITE.

DULCINAN. Syn. with DULCITAN.

DULCITAN. *Dulcinan.* $C^6H^{12}O^5$. (Berthelot, *Chimie organique fondée sur la Synthèse*, Paris, 1860, ii. 207.)—The anhydride of dulcite ($C^6H^{11}O^6 - H^2O$), obtained by heating dulcite for some time to near $200^\circ C$., or by the decomposition of the dulcitanides. It is a very viscid neutral syrup, which volatilises perceptibly at $120^\circ C$., and is partially converted into dulcite by prolonged contact with water, or by heating with water and baryta-crystals. It is soluble in water and in absolute alcohol, but not in ether. The composition of its salts, the dulcitanides, shows that it may be regarded as a tetratomic alcohol, $(C^6H^8O)^{iv} \left\{ \begin{smallmatrix} H^4 \\ O^4 \end{smallmatrix} \right\}$.

DULCITANIDES. Compounds of dulcitan with acids, analogous to the mannitanides and glycerides. They may be regarded as dulcitan, in which 2 or 4 at. H are replaced by acid radicles, or as compounds of dulcitan *minus* H^2O , with the corresponding anhydrides; thus, *butyro-dulcitan* $C^{14}H^{21}O^7 = \frac{(C^6H^8O)^{iv}}{H^2.(C^4H^7O)^2} \left\{ O^4 \right\} = C^6H^{10}O^4.C^8H^{11}O^3$.

They are prepared by heating dulcite with acids in sealed tubes, maintaining the temperature for some time at $100^\circ C$., or more easily by raising it to $200^\circ - 220^\circ$. The fused mass is mixed with excess of a strong solution of carbonate of sodium and a little caustic potash, then repeatedly exhausted with ether; the ethereal solution is digested with animal charcoal; and the filtrate evaporated over the water-bath. If the residue is still not quite neutral, it must be again treated with carbonate of sodium and ether.

Benzodulcitan, $C^{20}H^{20}O^7 = \frac{(C^6H^8O)^{iv}}{H^2.(C^4H^7O)^2} \left\{ O^4 \right\}$.—Resinous, of the consistence of turpentine, decomposed by boiling with a mixture of alcohol and hydrochloric acid, yielding benzoate of ethyl; by hydrate of calcium into benzoate of calcium, and a mixture of dulcite and dulcitan.

Butyrodulcitan, $C^{14}H^{21}O^7 = \frac{(C^6H^8O)^{iv}}{H^2.(C^4H^7O)^2} \left\{ O^4 \right\}$.—Colourless, viscid oil, having a bitter and buttery taste; neutral, sparingly soluble in water, easily in absolute alcohol and in ether. Boiled with alcohol and hydrochloric acid, it yields dulcitan and butyric ether.

Stearodulcitan. a. Neutral. $C^{42}H^{80}O^7 = \frac{(C^6H^8O)^{iv}}{H^2.(C^{18}H^{35}O)^2} \left\{ O^4 \right\}$.—Nearly white, crystalline, neutral. Closely resembles monostearin, both in its physical and in its chemical characters.

b. Acid. $C^{78}H^{148}O^9 = \frac{(C^6H^8O)^{iv}}{(C^{18}H^{35}O)^4} \left\{ O^4 \right\}$.—Obtained by heating dulcite to $220^\circ C$. with a large excess of stearic acid. It is white, neutral, and very much like tristearin.

DULCI-TARTARIC ACID. $C^{14}H^{20}O^{15} = \frac{(C^6H^8O)^{iv}}{H^2.(C^4H^7O)^2} \left\{ O^4.C^4H^6O^6, \text{ or } \frac{(C^6H^8O)^{iv}}{2(C^4H^7O)^2} \right\} O^4 + 2H^2O$. (Berthelot, *loc. cit.*)—Known only as a calcium-salt, which is obtained by heating a mixture of equal parts of dulcite and tartaric acid to $100^\circ - 120^\circ C$. for five hours in an open vessel, triturating the resulting glutinous mass with chalk and a little water till it becomes neutral, then filtering, precipitating with alcohol, and purifying by repeated solution in water and precipitation with alcohol. This salt, dried in vacuo, has the composition $C^{14}H^{18}Ca^2O^{15} + 4 aq.$, and gives off its water at $100^\circ C$.

DULCITE. *Dulcin, Dulcose, Melampyrite, Melampyrrin.* $C^6H^{11}O^6 = \frac{(C^6H^8O)^{iv}}{H^1} \left\{ O^4 \right\} + H^2O$. (Laurent, *Compt. chim.* 1850, p. 364; 1851, p. 29.—Jacquelain, *ibid.* 1851, p. 21.—Hünefeld, *J. pr. Chem.* vii. 233; ix. 47.—Eichler, *Ueber das Melampyrrin*, Moskau, 1855; *Rep. Chim.* pure ii. 103.—L. Gilmer, *Ann. Ch. Pharm.* cxxiii. 372.—Erlenmeyer and Wanklyn, *Chem. Soc. J.* xv. 455.)—A saccharine substance similar to and isomeric with mannite. The plant from which it was originally obtained is unknown. It was first sent to Paris in 1848 from Madagascar, in lumps more or less rounded, crystallised throughout their entire mass, and covered externally with earthy particles. It is easily purified by means of boiling water, the filtered solution depositing crystals of dulcite, an additional quantity of which separates from the mother-liquor on standing, while a nearly colourless, uncrystallisable syrup remains.

Quite recently Gilmer has shown that *melampyrite*, the saccharine substance obtained by Hünefeld from *Melampyrum nemorosum*, and by Eichler from *Scrophularia*

nodosa and *Rhinanthus Crista Galli*, and hitherto regarded as $C^{12}H^{15}O^{13}$, or $C^{12}H^{30}O^{13}$, is really identical in composition and properties with dulcite, a result confirmed, so far as the composition is concerned, by the experiments of Erlenmeyer and Wanklyn. It is convenient, however, to retain the name melampyrite, to indicate the origin of the substance.

Preparation of Melampyrite.—1. The decoction of the dried herb of *Melampyrum nemorosum*, taken at the flowering time, is mixed with milk of lime till it exhibits an alkaline reaction, then boiled up, filtered, concentrated to a small bulk, and acidulated with hydrochloric acid. On cooling and further crystallisation, melampyrite crystallises out, and may easily be obtained pure by recrystallisation from water (Eichler).—2. The dried herb is boiled with water containing hydrochloric acid; the decoction is strained, mixed with milk of lime till it exhibits a slight alkaline reaction, then concentrated, whereupon it deposits succinate of calcium; and the calcium-compound of melampyrite, which passes into the filtrate, is decomposed with hydrochloric acid; it then deposits crystals, which may be purified by recrystallisation (Eichler).—3. Hünefeld evaporates the decoction to a syrup, and leaves the melampyrite to crystallise out; removes from the mother-liquors the substances precipitable by neutral and basic acetate of lead, and the excess of lead by sulphydric acid; and again evaporates. Eichler, instead of proceeding in this manner, precipitates the decoction with neutral acetate of lead, boils the filtrate with lead-oxide, removes dissolved lead by sulphydric acid, and evaporates.

Properties.—Dulcite (from Madagascar) crystallises in colourless highly lustrous prisms of the monoclinic system, having their obtuse edges symmetrically truncated, together with the octahedral and basal end-faces. $\infty P. \cdot \infty P \infty. + P. - P. \cdot \infty P$. Inclination of $\infty P : \infty P = 112^\circ$; $+P : -P = 115^\circ 26'$; $\infty P : +P = 134^\circ 42'$ (Laurent). Melampyrite (from *Melampyrum nemorosum*) crystallises from moderately warm aqueous solution in transparent colourless, shining, monoclinic prisms, with octahedral summits, the faces of which are truncated by an orthodiagonal dome. $\infty P. + P. - P. + P \infty. - P \infty.$ Inclination of $\infty P : \infty P = 112^\circ$; $+P : -P = 115^\circ 45'$; $\infty P : +P = 134.5^\circ$ (Gilmer). The crystals from both sources are usually aggregated in crusts. Both are inodorous, have a slightly sweet taste and neutral reaction, and are destitute of optical rotatory power.

Dulcite dissolves in 31 pts. water at $15^\circ C$. (Gilmer); melampyrite in 25.5 pts. of water at $15^\circ C$., easily in boiling water (Eichler); in 29.41 pts. water at $16^\circ C$. (Gilmer); in 34.41 pts. at $16.5^\circ C$. (Erlenmeyer and Wanklyn). Both are but slightly soluble in alcohol, even at the boiling heat, in which respect they differ essentially from mannite. Melampyrite is slightly soluble in *acetone*, *wood-spirit*, *chloroform*, and *acetic ether*.

Dulcite melts at about $190^\circ C$. (Laurent), at 182° (Jacquelain); melampyrite at 186° (Eichler), at 180° (Gilmer).

The identity in composition between dulcite and melampyrite is shown by the following analyses:—

	<i>Calculation.</i>	<i>Dulcite.</i>		<i>Melampyrite.</i>	
		Laurent.	Jacquelain.	Gilmer (<i>mean</i>).	Erlenmeyer and Wanklyn.
C ⁶	12	39.56	39.20	39.6	39.33
H ¹⁴	14	7.69	7.61	7.9	7.90
O ⁶	96	52.75	53.19	52.5	52.77
C ⁶ H ¹⁴ O ⁶	112	100.00	100.00	100.0	100.00

Eichler found in melampyrite 37.79 per cent. carbon and 7.83 hydrogen, whence he deduced the formula $C^{12}H^{15}O^{13}$ [or $C^6H^{14}O^6 + \frac{1}{2}H_2O$]. The substance analysed was perhaps not thoroughly dried.

Decompositions.—1. Dulcite heated to $200^\circ C$. gives off water, and is converted into duleitan (p. 348), at $275^\circ C$. it decomposes and gives off carbonic oxide without much colouring, and at higher temperatures gives off large quantities of gas, smelling of acetic acid and acetone, and distils without residue (Laurent, Jacquelain). Melampyrite begins to decompose at $180^\circ C$. (Eichler), at 275° (Gilmer).—2. Dulcite in solution is slowly decomposed by *chlorine*, yielding an acid, the barium-salt of which is soluble, but not crystallisable.—3. Dulcite boiled with *nitric acid* is converted into mucic, oxalic, and racemic acids (Laurent; Carlet, *Compt. rend.* li. 137; liii. 343). Melampyrite treated in like manner yields mucic and oxalic acids (Eichler, Gilmer); the formation of racemic acid was not observed, probably because the quantity operated upon was insufficient (Gilmer).—4. *Fuming nitric acid* converts dulcite into hex-nitrodulcite (see below). Melampyrite treated with a mixture of *nitric* and *sulphuric acids* also yields a nitro-compound.—5. Dulcite and melampyrite both dissolve

in strong *sulphuric acid*, and on heating the solution an acid is formed, which yields a soluble barium-salt (Laurent, Eichler).—6. Melampyrite heated with *hydriodic acid* in an atmosphere of carbonic acid yields iodide of hexyl, together with water and free iodine (Erlenmeyer and Wanklyn):

7. Dulcite is not decomposed by dilute *potash*; but when heated with strong potash-ley, it is converted into a thick, syrupy, colourless mass, the solution of which is not precipitated by alcohol.—8. Dulcite heated with *butyric, benzoic, or stearic acid* to 200° C. is converted, with elimination of water, into compounds called dulcitanides (p. 348), analogous to the mannitanides, which are decomposed by water into dulcitan and the acid, and by alcohol into dulcitan and the corresponding ether. (Berthelot.)

Melampyrite is not decomposed by boiling with dilute acids or alkalis, or by potassium-cupric tartrate. It is not altered by boiling with dilute sulphuric acid and acid chromate of potassium, and when mixed with potash does not reduce mercuric oxide. (Eichler.)

9. Neither dulcite nor melampyrite ferments with *yeast* (Jacquelain, Eichler, Gilmer). Dulcite left for some weeks at 40° C. in contact with chalk and *cheese*, is resolved, like mannite, into alcohol, lactic acid, and butyric acid; in contact with *testicular tissue*, it forms a peculiar sugar. (Berthelot, Ann. Ch. Phys. [3] i. 348, 372.)

Dulcitates.—These compounds are formed by the substitution of metals for a portion of the hydrogen in dulcite or melampyrite. Those containing the alkali- and alkaline-earth-metals are soluble in water, the lead- and copper-compounds are insoluble. The aqueous solution of dulcite or melampyrite does not precipitate metallic salts.

Ammonium-salt.—Melampyrite crystallises unaltered from aqueous ammonia or after being heated with it to 120° C.; but when nitromelampyrite (see above) is decomposed by sulphide of ammonium, or when the barium- or calcium-compound of melampyrite is decomposed by carbonate of ammonia, the concentrated filtrate yields transparent, colourless, rectangular prisms, which have an alkaline reaction, do not give off ammonia at 100° C., but become carbonised at higher temperatures, with loss of ammonia, and without previous fusion, and are decomposed by acids into melampyrite and an ammonia-salt. These crystals are easily soluble in water. (Eichler.)

Barium-compound. $\text{C}^6\text{H}^{12}\text{Ba}^2\text{O}^6 + 8\text{H}^2\text{O}$ or $\text{C}^6\text{H}^{14}\text{O}^6.\text{Ba}^2\text{O} + 7\text{H}^2\text{O}$.—When dulcite or melampyrite is heated with water and baryta-crystals, a clear solution is formed, which on cooling deposits prismatic crystals. Easily soluble in warm water, less soluble in alcohol, which, however, does not precipitate the aqueous solution. The crystals give off 27.4 per cent. water at 170° C., and contain 29.7 per cent. barium, agreeing with the formula $\text{C}^6\text{H}^{14}\text{O}^6.\text{Ba}^2\text{O} + 7 \text{ aq.}$, which requires 27.33 water and 29.71 barium (Laurent). According to Eichler, they give off 26.73 per cent. water at 120° C., and contain 28.5 per cent. barium, whence he deduces the formula $\text{C}^{12}\text{H}^{15}\text{O}^{13}.2\text{BaO} + 14\text{HO}$ (calc. 26.78 water and 29.16 barium). It was doubtless the same as Laurent's compound, the two formulæ differing indeed only by HO or $\frac{1}{2}\text{H}^2\text{O}$.

Calcium-compound.—Aqueous melampyrite dissolves lime.

Copper-compound.—Melampyrite boiled with cupric sulphate and potash yields a clear blue solution. From aqueous melampyrite an ammoniacal solution of cupric sulphate throws down a light blue precipitate, which, after washing with weak aqueous ammonia, turns green at 100° C., and contains 55.25 per cent. cupric oxide, agreeing therefore with the formula $\text{C}^{12}\text{H}^{15}\text{O}^{13}.\text{CuO}$, which requires 55.49 per cent. CuO (Eichler), probably $\text{C}^6\text{H}^{13}\text{CuO}^6 + \text{H}^2\text{O}$.

Lead-salt.—Aqueous solutions of dulcite and melampyrite are not precipitated by acetate of lead either neutral or basic. From an ammoniacal solution of the neutral acetate, aqueous melampyrite throws down a white precipitate which, after drying at 100° C. in a stream of hydrogen, contains 77.68 per cent. PbO , answering to the formula $\text{C}^{12}\text{H}^{15}\text{O}^{13}.6\text{PbO}$ (calc. 77.84 PbO) (Eichler); probably $\text{C}^6\text{H}^{12}\text{Pb}^2\text{O}^6.2\text{Pb}^2\text{O} + \text{aq.}$

Potassium-salt.—Warm alcoholic potash dissolves melampyrite, and the solution when left to itself deposits needles which have a caustic alkaline taste, are easily soluble in water, absorb water and carbonic acid from the air, and are converted into a mixture of melampyrite and carbonate of potassium. (Eichler.)

Sodium-salt.—Small flat needles resembling the potassium-salt, but less soluble in alcohol. (Eichler.)

Nitro-derivatives of Dulcite.

HEXNITRODULCITE, $C^6H^8N^6O^{18} = C^6H^8(NO_2)^6O^6$.—A solution of dulcite in 5 pts. fuming nitric acid is mixed with 10 pts. oil of vitriol, and the mixture, which becomes turbid, is immediately thrown into a large quantity of water. The semifluid precipitate solidifies slowly to a buttery mass, which, after washing with water, may be crystallised from alcohol. It forms beautiful, colourless, flexible needles, which melt between 68° and 72° C., give off nitric acid vapours continuously, and are in the end wholly converted into tetranitrodulcite. When heated to 90° C. it is converted, with regular emission of red vapours, into a pasty mass, and then into a hard, friable, white acid product. (Béchamp, *Compt. rend.* li. 257.)

TETRANITRODULCITE, $C^6H^{10}N^4O^{14} = C^6H^{10}(NO_2)^4O^6$.—Hexnitrodulcite is completely converted into this compound, without alteration of crystalline form, by the spontaneous decomposition which it undergoes, with evolution of nitrous vapours, when kept for a month between 30° and 45° C.

Tetranitrodulcite forms needles harder and less flexible than those of hexnitrodulcite, and crystallises from alcohol in beautiful translucent prisms, melts to a pasty mass at 130° C., completely at 140° , and gives off red fumes at 145° .—It is reduced by ferrous salts and forms a non-crystallisable syrup, probably dulcitan. (Béchamp, *loc. cit.*)

Dulcisulphuric Acid. *Melampyro-sulphuric acid.*—Melampyrite dissolves in strong sulphuric acid; and the solution diluted with water, saturated with carbonate of lead, filtered from sulphate of lead, and decomposed by sulphydric acid, then filtered from the sulphide of lead and evaporated, yields melampyro-sulphuric acid in the form of a syrup which has a faint yellow colour, a sour and bitter taste, and carbonises when heated, with evolution of sulphurous anhydride.

Barium-salt. Obtained by neutralising the acid with carbonate of barium and evaporating the filtrate at a very gentle heat. In the moist state it is a mass having the consistence of turpentine; after drying in vacuo, it forms a transparent gun, which dissolves in water, is precipitated by alcohol, and decomposes at 100° C. According to Eichler's analysis, it contains 36.45 per cent. baryta, and 37.79 sulphuric anhydride, whence he deduces the formula $C^{12}H^{12}Ba^3O^{13}.6SO^3$ (calc. 36.26 BaO and 37.86 SO^3); probably $C^6H^{11}Ba^3O^6.3SO^3$.

The *calcium-salt* resembles the barium-salt, but is not precipitated by alcohol from its aqueous solution. The solution does not precipitate acetate of lead, mercurous nitrate, or nitrate of silver. (Eichler.)

Similar results are obtained with dulcite (p. 349).

DULCOSE. Syn. with DULCITE.

DUMASIN. *Pyroacetic oil.* $C^6H^{10}O$.—A volatile oil, isomeric with oxide of mesityl, obtained, together with acetone, by the destructive distillation of acetates. It was discovered by Kane (*Pogg. Ann.* xlv. 494), who assigned to it the formula $C^{10}H^8O$, further examined by Heintz (*ibid.* lxviii. 277), who regarded it as identical with oxide of mesityl, and afterwards by Fittig (*Ann. Ch. Pharm.* cx. 21), who confirmed Heintz's formula, but showed that dumasin is not identical, but only isomeric, with oxide of mesityl.

Dumasin cannot be completely separated from the acetone which accompanies it by fractional distillation. Heintz obtains it by distilling 2 pts. acetate of lead with 1 pt. lime; agitates the distillate repeatedly with water, to remove acetone; dries it over chloride of calcium; then decants, and boils it for some minutes in contact with the air; distils till the boiling-point, which is 130° C. at first, rises to 200° , a blackish tar then remaining; and again distils, separating the more volatile portion, which is pure dumasin.

Dumasin is an oil boiling between 120° and 125° C., lighter than water and insoluble therein, but dissolving in alcohol in all proportions. It forms crystalline compounds with the acid sulphites of the alkali-metals, whereby it is distinguished from oxide of mesityl. The sodium-salt contains, according to Fittig, $C^6H^9NaSO^3 + 3$ aq.

Strong nitric acid converts dumasin into oxalic acid; the dilute acid scarcely acts upon it. Dumasin distilled with hydrochloric acid and peroxide of manganese yields a colourless chlorinated oil, $C^6H^9Cl^2O$, heavier than water, boiling between 150° and 155° C., not capable of uniting with acid sulphites of alkali-metals.

DUMASITE. Delesse's name for a mineral found in the Vosges, in green scales resembling chlorite. (Dufrénoy, *Traité de Minéralogie*, iii. 790.)

DUMERILLIA. The root called *Raíz del Pipit-ahuac*, used in Mexico as a purgative, is obtained according to Ramon de la Sagra (*Compt. rend.* xlii. 873,

1072) from *Dumerillia Humboldtii*, Less. It contains a peculiar acid called by him rioloic, by Weldt (Ann. Ch. Pharm. xcv. 188) pipitzahoic acid.

DYEING. The art of dyeing consists in fixing upon cloth of various kinds any colours that may be required, in such a manner that they shall not be easily altered by those agents to which the cloth will most probably be exposed.

The most remarkable general fact in the art of dyeing consists in the different degrees of facility with which animal and vegetable substances attract and retain colouring matter, or rather the degree of facility with which the dyer finds he can tinge them with any intended colour. The chief materials of stuff to be dyed are, wool, silk, cotton, and linen, of which the former two are more easily dyed than the latter. This has been usually attributed to their greater attraction to the tingeing matter.

Wool is naturally so much disposed to combine with colouring matter, that it requires but little preparation for the immediate processes of dyeing, nothing more being required than to cleanse it, by scouring, from a fatty substance, called the yolk, which is contained in the fleece. For this purpose an alkaline liquor is necessary; but as alkalis injure the texture of the wool, a very weak solution may be used; if more alkali were present than is sufficient to convert the yolk into soap, it would attack the wool itself. Putrid urine is therefore generally used, as being cheap, and containing a volatile alkali, which, uniting with the grease, renders it soluble in water.

Silk, when taken from the cocoon, is covered with a kind of varnish, which, because it does not easily yield either to water or alcohol, is usually said to be soluble in neither. It is therefore usual to boil the silk with an alkali, to disengage this matter. Much care is necessary in this operation, because the silk itself is easily corroded or discoloured. Fine soap is commonly used, but even this is said to be detrimental; and the white China silk, which is supposed to be prepared without soap, has a lustre superior to that of Europe, Silk loses about one-fourth of its weight by being deprived of its varnish. (See BLEACHING.)

The intention of the previous preparations seems to be of two kinds. The first, to render the stuff or material to be dyed as clear as possible, in order that the aqueous fluid to be afterward applied may be imbibed, and its contents adhere to the minute internal surfaces. The second is, that the stuff may be rendered whiter and more capable of reflecting the light, and, consequently, enabling the colouring matter to exhibit more brilliant tints.

Substances which serve to fix colouring matters on vegetable or animal fabrics are called mordants. An essential quality of a mordant is, that it be soluble in water; the mordants most frequently used are the solutions of certain metallic salts.

A mordant acts either by forming an insoluble compound with the colouring matter, which compound is precipitated on or within the fibre, or by modifying the surface of the fibre in such a manner as to enable it to retain the colour.

The decoctions of many dye-stuffs, as well as the solutions of the pure colouring matters prepared from them, form with certain saline solutions coloured precipitates called lakes, consisting of the colouring matter combined with the base of the salt. Many of these lakes are prepared on the large scale and used as pigments. The salts chiefly used for their preparation are the salts of aluminium and the stannic salts; the oxides precipitated from these salts being colourless, the lakes which they produce take exactly the tints of the colouring matters used. Ferric salts are also used for the preparation of lakes, but the precipitates which they form differ considerably in colour from the colouring matters used, being for the most part of duller hue.

In the aluminic, stannic, and ferric salts, the base and acid are held together by a comparatively feeble affinity, so that the precipitation of the base by a colouring matter is generally effected without much difficulty. This however depends upon a variety of circumstances, among which the nature of the acid is of considerable importance; acetate of aluminium or ferric acetate, for example, is much more easily decomposed by colouring matters than the corresponding sulphate. Hence a mixture of alum with acetate of lead is often used as a mordant. Precipitation is often greatly accelerated by heat; many mixtures of metallic solutions with colouring matters, which remain clear in the cold, yield precipitates on boiling. In many cases, however, the addition of a precipitant is necessary to produce the required decomposition; thus a solution of alum mixed with certain colouring matters remains clear, but on adding an alkali, a precipitate is formed consisting of an alumina lake. By this means, lakes may be formed from metallic solutions, which would not yield them with colouring matters alone, such as salts of magnesia, zinc, lead, and mercury.

The formation of insoluble lakes is the principal function of the mordants used in dyeing and calico-printing: nevertheless the number of metallic salts that can be used as mordants is much smaller than that of the salts which are capable of forming lakes, because the applicability of any salt as a mordant depends also on the effect which the

saline solution produces on the fibre to be dyed, and on the behaviour of the fibre saturated with the mordant in the subsequent stages of the process.

Metallic salts are sometimes separated from their solutions by animal or vegetable fibres immersed in them and deposited thereon without decomposition. Wool or silk immersed in a solution of alum takes up a considerable quantity of the salt without decomposing it, so that the alum may be afterwards dissolved out by boiling water, though only after being treated therewith ten times or more in succession. Linen and cotton likewise take up alum from its solution, but only in very small quantity.

The direct separation of a salt from its solutions by organic fibre, is however of much less importance in dyeing than the decomposition of the salt into an acid and a basic salt, and the precipitation of the latter on and within the fibre while the former remains in solution. Stannic chloride is resolved, by boiling its aqueous solution, and under other circumstances, according to the mode of its preparation, into hydrochloric acid and a precipitate of stannic hydrate. Easily soluble ferrous salts are converted, by absorption of oxygen, into insoluble basic ferric salts, which also attach themselves to the fibre. Aluminium-salts containing weak acids, such as the acetate, are easily converted into sparingly soluble basic salts, either by the evaporation of a portion of their acid on exposure to the air (as with the acetate), or by precipitation with the aid of heat. It is this disposition to form basic salts, added to the tendency of the bases to unite with colouring matters, that renders the salts of aluminium, tin, and iron so peculiarly adapted for the fixing of colouring matters. Other substances are however used as mordants, viz. soap, acids, albumin, gluten, tannin, &c.

It is evident that when a mordant is applied over the whole surface of a fabric, and this is afterwards immersed in a dye-bath, it will receive a tint all over its surface; but if the mordant is applied only in parts, the colour will be fixed on those parts only. The former process constitutes the art of dyeing, properly so called; the latter the art of printing colours on stuffs, usually called calico-printing. To produce this topical fixation of the colour, either the mordant is first applied to the entire surface, and then removed in parts by the application of a suitable solvent; or, more frequently, the mordant is mixed with a thickening material, such as gum, starch, paste, albumin, &c., and printed on the parts which are to take the colour; or thirdly, the mordant, thickening materials, and colouring matter, are mixed and printed together on the cloth.

The mordanted cloth has to be submitted to certain preliminary operations before it is ready for dyeing,—first to fix the mordant on the fibre, and secondly to remove superfluous mordant. For fixing the mordant the chief agent employed is heat, which, as already observed, facilitates the separation of the base of the mordant from the acid. Cotton goods are subjected to a treatment called “ageing,” which formerly consisted in hanging them up for several days in a warm room, whereby the acetic acid of the mordant was volatilised, and in the case of iron mordants, the iron was brought to the state of sesquioxide. The change is now however much more quickly effected by the joint action of heat and moisture, the pieces of calico being passed over and under a series of rollers, in a narrow room into which a small quantity of steam is suffered to issue, the temperature being kept at 80° to 100°, or rather more, of Fahrenheit, by means of steam pipes. The aqueous vapour perhaps acts by facilitating the volatilisation of the acid.

The removal of the unfixed or superfluous mordant (and thickening matter in the case of printed goods), is a very important operation, as the excess, if suffered to remain, would consume to no purpose a certain portion of the dye-stuff, and moreover, in printed goods, it would, on immersion in the dye-bath, spread itself over the ground or unprinted portion of the surface, and cause it to take up the colour when it ought to be left white. The cleansing is effected sometimes by simple washing in water, either hot or cold; this is especially the case with fabrics which are to receive a uniform colour, and do not require the mordant to be dried before dyeing. For printed stuffs this simple washing will not suffice; for the superfluous mordant, as it dissolved in the water, would be likely to impregnate the ground and render the pattern indistinct. Hence it is necessary to wash the piece with a solution which will at once decompose the superfluous mordant. This is effected by various means, viz. by the chalk-bath, bran-bath, cowdung-bath, &c. Chalk acts simply by precipitating the alumina or other oxide in the mordant. The action of cowdung, which is especially used for madder goods, has been ascribed to a peculiar acid, also to phosphates, silicates, and other salts. That the latter is the more correct view is proved by the fact that the dung-bath is now almost wholly superseded by the solutions of certain salts, viz. the double phosphate of soda and lime, arsenite and arsenate of soda, and silicate of soda,—all of which act by precipitating the base of the mordant in the form of an insoluble salt which will not unite with the colouring matter or with the fibre.

The manner in which colouring matters are fixed on organic fibres by means of mordants is well illustrated by the following observations of Walter Crum (Chem. Soc. J., vol. xvi. Jan. 1860) on the dyeing of cotton.

When ripe cotton fibre, which consists of an aggregate of fine cylindrical tubes, is immersed in a solution of ferric acetate, a portion of the solution enters the tubes, and on subsequent exposure to a warm moist atmosphere, the acetic acid evaporates and oxide of iron is deposited within the fibre; when the cotton thus mordanted is immersed in a madder bath, a portion of the solution enters the fibre, and the colouring matter unites with the oxide of iron. A similar action takes place when acetate of alumina is used as the mordant. When the cotton is first immersed in subacetate of lead and then exposed to moist warm air, a deposition of oxide of lead takes place within the fibre, and on subsequently dipping it in a solution of chromate of potassium a yellow deposit of chromate of lead is obtained. In like manner, by first steeping the cotton in a solution of tannin, then, after exposure to the air, in a ferric salt, a black precipitate of ferric tannate is formed within the fibre. A piece of dyed cotton may, in fact, be described as a set of colourless bags containing coloured substances, and in so far resembling the natural colours of flowers.

Cotton fibre in the unripe state, in which it has the appearance of flattened blades, but really consists of flattened tubes with extremely narrow bore, is impervious to liquids, and therefore will not take a dye. Such cotton is called dead cotton. White fibres consisting of it may frequently be observed in the middle of the coloured portions of printed calicoes.

Various methods are resorted to for forming precipitates within the fibre. Sometimes the fibre is first made to absorb tannin, then treated with an acid solution of tin; in this manner a precipitate of tannate of tin is formed within the fibre, which forms a good mordant for Lima or Brazil wood. When cotton is soaked in a cold weak solution of oxychloride of tin, or better in a mixture of stannous and stannic chlorides, and then immersed in basic ferric chloride or nitrate, a large quantity of iron is deposited within the fibres, probably as ferric stannate. This mordant, when dyed in ferroproussic acid, forms a prussian blue of the greatest richness and brilliancy.

Some colours fix themselves within the fibre without the aid of mordants. Blue indigo, which is insoluble in water, is converted into soluble white indigo by the action of reducing agents, such as ferrous sulphate, orpiment, &c. The solution thus obtained is absorbed by the fibre, and accumulates or becomes precipitated on or within it in the insoluble state; and on subsequent exposure to the air the white indigo is reconverted into blue indigo by oxidation.

Besides the precipitation which takes place within the fibre, there is likewise a considerable quantity of dye deposited in the interstices between the fibres. This portion is less firmly fixed than the former, and is removed by the process of soaping, to which some dyed and printed goods, the madder-purples for instance, are subjected; but in the numerous class of colours which do not require, and indeed would not bear, the soaping process, this external dye is allowed to remain, and contributes greatly to the richness of the tone; such is the case with goods dyed with garancin, the indigo-dye, and all colours fixed by steam. (Crum.)

Steam-colours.—This is a style of calico-printing in which one or more mordants are mixed with dye-wood decoctions or other coloured solutions, and printed on the cloth, and then subjected to the heat of a steam-bath, which causes the mordant to unite with the colouring matter and both with the cloth. Superior colours are produced by mordanting the cloth first so as to fix oxide of tin on the fibre.

Pigment-printing.—In this style of calico-printing, the same pigments may be used as in oil-painting, and are mechanically fixed to the cloth by a species of cementing. The first fixing agent used was a solution of caoutchouc in naphtha, but this was soon abandoned, chiefly on account of the danger of fire which it occasioned. The fixing materials now used are *albumin*, either of eggs or of blood; *lactarin*, which is prepared from buttermilk by separating the solid part, purifying it from butter and free acid, and then drying it; *gluten*, which is the residue of starch-making from wheat-flour by the simple washing process, the gluten being afterwards dried at a gentle heat; and *tannin*. The albumin coagulates readily at the steam-heat; lactarin and gluten require a small quantity of alkali to dissolve them: they then coagulate by heat like albumin.

Formerly but few colours were printed in this manner, chiefly ultramarine blue and carbon-drab; lately, however, Guignet's chrome-green has been used for pigment-printing, and likewise the aniline colours, which may be fixed with tannin. (See p. 357.)

The various colours which the dyer has to produce are either the primitive colours,

red, blue, and yellow, or combinations of them. Many of the compound tints may however be produced directly by the use of particular dyes—purple, for example, by archil, and by some of the aniline dyes. The following is a brief summary of the principal methods of producing the various colours.

RED.

Red of various shades is produced by madder and the products obtained from it, garancin, alizarin, flower of madder, &c., with a mordant of acetate of alumina. (See Madder.)

Turkey-red is a madder colour. To produce it, the tissue is first heated in a bath of oil, water, and carbonate of soda (2 parts of the salt to 100 oil), which forms on the surface a modified oil capable of acting as a mordant. It is then dried, freed from excess of fatty matter by pearlash mordanted in a bath of gall-nuts and alum, then immersed in a hot bath containing chalk. After this it is dipped in the madder-bath for 3 hours, the bath being kept at the boiling heat for the first quarter of an hour only. It is next washed, again treated with galls and alum, and dipped in a second bath of chalk and madder, after which it is submitted to the *clearing* operation (*avivage*). For this purpose it is first boiled in a bath of soap and pearlash contained in a closed vessel, then twice in a bath of soap and protochloride of tin. Lastly it is passed through a bath of sour bran, and then exposed to the air. (Pelouze and Frémy.)

Scarlet is produced by cochineal with a mordant of stannic chloride, obtained by treating tin-foil with dilute nitric acid and sal-ammoniac.

Brazil-red.—Brazil-wood with an aluminous mordant. It is applied chiefly to silks, but is rather fugitive, being destroyed by acids and changed to amaranth by alkalis.

Lac-dye is a splendid scarlet imported from India, and prepared from stick lac. Messrs. Haworth and Brooke of Manchester obtained a superior colour by treating stick lac with weak ammonia, and mixing this solution with chloride of tin, whereby a fine red insoluble matter is precipitated.

For the aniline reds, see page 356.

BLUE.

Indigo.—This blue dye-stuff is first converted into white indigo and rendered soluble, by the action of alkalis and reducing agents, such as protosulphate of iron, opium, glucose, &c.; the cloth or fibre is then immersed in the solution, and afterwards exposed to the air, the white indigo being thereby oxidised and converted into blue indigo, which thus becomes fixed upon the tissue. To produce white patterns on a blue ground, the pieces are printed before dyeing with what is called a "reserve," that is a composition which prevents the colour from fixing itself on the fibre; the substance most frequently used for the purpose is sulphate of copper, which acts by prematurely oxidising the indigo.

Indigo combined in various proportions with sulphuric acid forms *Sulphindigotic acid*, *Indigo-carmin*, *Saxony blue*, &c.

Prussian Blue, *Turnbull's Blue*, &c.—The stuff or fibre is immersed first in a solution of an iron-salt, then in a bath of yellow or red prussiate (pp. 227, 244). In calico-printing, the pattern is sometimes printed with a mixture of yellow prussiate and tartaric acid, or sulphuric acid and alum, and exposed to the action of a hot steam-bath. By this treatment, ferroprussic acid is first set free, and then decomposed by the heat, yielding Prussian blue (p. 227).

Logwood-blue.—Produced by decoction of logwood on stuffs mordanted with alum and cream of tartar. The colour is not very stable. Sometimes a light sky-blue tint is first given with a weak bath of indigo, and the colour afterwards deepened by logwood, and brightened by immersion in a bath of protochloride of tin, alum, and tartar.

Coal-tar blues.—1. *Azuline*. This fine colour, which was first prepared by Messrs. Guinon, Marnas, and Bonnet of Lyons, is obtained from phenic or carbolic acid by a process which is kept secret. When pure it forms copper-bronze crystals, soluble in alcohol, to which it imparts a splendid blue colour, slightly tinged with red. To dye silk or wool with this colour, the alcoholic solution is added to an acidulated lukewarm bath of water, and the silk or wool is worked in it till it acquires a purple shade of a certain depth. It is then transferred to another bath of boiling water strongly acidulated with sulphuric acid, whereby the purple colour is dissolved, and a most brilliant and permanent blue is left on the material. The dyed silk or wool is then washed repeatedly, passed through a bath containing a little tartaric acid, and dried.

2. *Bleu de Paris* is produced from aniline by the action of corrosive sublimate;—

3. *Bleu de Mulhouse* from *rosaniline* (*Magenta*) by the action of reducing agents.

4. *Chinoline blue* is a finelight blue obtained by the action of iodide of amyl on chinoline, a base contained in coal-tar naphtha, and also produced by the destructive distilla-

tion of cinchonine (i. 869). The chinoline blue obtained from the cinchonine base is a fast colour; but unfortunately that obtained from coal-tar cinchonine is very unstable. (Greville Williams.)

Ultramarine.—This splendid blue colour is not used as a dye, properly so called, but only as a pigment in calico printing (p. 354).

YELLOW.

Weld.—A bright yellow dye is produced by *weld*, the colouring matter of *Reseda luteola*. Cotton to be dyed with it is mordanted with acetate of alumina: silk and wool with alum and tartar.

Fustic.—There are two distinct yellow dyes known by this name, viz. *old fustic*, the *bois jaune* of the French, which is obtained from dyer's mulberry (*Morus tinctoria*), and *young fustic*, from the Venetian sumach (*Rhus cotinus*). The former yields, with aluminous mordants, a yellow colour, which is durable, but not very bright; it is used chiefly for mixed tints; the latter yields, with alum or stannic chloride mixed with tartar, a beautiful bright yellow dye, much used in calico-printing. It is changed to a fine purple by alkalis, and the decoction forms an orange-red precipitate with acetate of copper or lead.

Quercitron.—The decoction of quercitron (*Quercus nigra*) produces on cotton and wool mordanted with stannic chloride or alum, a yellow colour, which is apt to change to a rusty red; it is also applied as a steam colour, thickened with gum-arabic and mordanted with alum.

Chromate of Lead.—The stuff or fibre is immersed first in a bath of basic acetate of lead, then, after washing, in a rather dilute solution of chromate of potassium. The yellow colour thus produced is heightened by immersion in dilute acetic acid, which removes any excess of basic acetate of lead. The neutral acetate and nitrate of lead are also used, and produce at once a fine yellow dye. By immersing the stuff thus dyed in lime water, a basic chromate of lead is formed of a fine orange colour (i. 934).

Picric Acid.—This compound, produced by the action of nitric acid on indigo, phenic acid, aloes, gum-resins, &c., was first introduced as a yellow dye about six years ago by Messrs. Guinon, Marnas, and Bonney, silk-dyers of Lyons; it forms a very beautiful and permanent colour.

Colours intermediate between Blue and Red: CRIMSON, PINK, CHERRY-COLOUR, &c.

Wool mordanted with alum and cream of tartar may be dyed *crimson* by immersion in a bath of cochineal containing a little tartar. For *amaranth*, which inclines more to blue, the wool is first dyed with logwood mordanted with alum and tartar or chloride of tin, and then with cochineal.

The special dyes for producing these colours are:

1. *Safflower*, the red colouring matter of the flowers of *Carthamus tinctorius*. It is chiefly used for silk, and produces very beautiful but rather fugitive colours. For the mode of applying it, see page 808, vol. i.

2. *Madder* mordanted with a mixture of acetate of alumina and acetate of iron.

3. *Rosaniline*, *Fuchsine*, or *Magenta*.—This splendid dye, which has nearly superseded all others for the production of rose or cherry colour, is obtained from aniline by the action of certain oxidising agents, viz. stannic chloride or mercurous nitrate. It is an organic base, which forms several definite and beautifully crystallised salts. The acetate, which is the salt chiefly used, crystallises in beautiful dark green octahedrons, having a lustre like the wing-cases of beetles. Silk or wool is dyed with it by simply adding some of the colour to a slightly acidulated bath. Its dyeing power is so great that 10 grains will dye 2 square yards of silk. (See ROSANILINE.)

Roseine is another crimson or rose-coloured dye, produced, though in small quantity, in the preparation of aniline purple. It may be prepared by the action of peroxide of lead or of manganates on aniline.

VIOLETS AND PURPLES.—These colours may be produced by the successive use of logwood and cochineal, the cloth or fibre being first dyed blue with logwood, then passed successively through two cochineal baths mordanted with alum and tartar. The special dye-stuffs for producing them are:

1. *Madder*, *garancin*, or *alizarin*, mordanted with dilute iron-liquor.

2. *Archil* or *Orchil*.—This dye-stuff, obtained from various lichens by maceration in putrid urine or other alkaline liquors, has long been used for the production of violets, mauves, &c., of various shades, but the colours obtained with it were fugitive. It has, however, been shown by M. Marnas of Lyons that a fine purple colour, capable of withstanding the action of acids and of light, may be obtained by treating the lichens with milk of lime, filtering the lime-liquor, and precipitating the colouring matter from it with hydrochloric acid, washing the precipitate on a filter, dissolving it in

caustic ammonia, and keeping this ammoniacal liquor at a temperature of 153° to 160° F. for twenty to twenty-five days. The colouring principles of the lichens then fix ammonia and oxygen, and are transformed into a new series of products, which may be separated from the coloured liquid by chloride of calcium. A fine purple lake is then deposited, which, after being washed and dried, is sold as *French purple*. Salts of alumina, tin, &c., might also be used as precipitants instead of chloride of calcium. French purple dyes silk and wool more readily than common archil. The lake is mixed with an equal quantity of oxalic acid, boiled with water and filtered, oxalate of calcium then remaining on the filter, while the colour passes into the filtrate. This liquid is then added to a slightly ammoniacal dye-bath, and the silk, wool, or cotton mordanted with albumin, or cotton prepared for Turkey-red, is immersed in it, these fabrics then becoming dyed with magnificent fast shades of purple or mauve.

Murexide or Roman Purple.—This substance, produced by the action of ammonia on alloxan, was first used as a dyeing material for silk and wool by MM. Depouilly, Lauth, Meister, Petersen, and A. Schlumberger, in 1856. When mixed with corrosive sublimate, acetate of sodium, and acetic acid, it produces various shades of red and purple. For printing, a mixture of murexide with nitrate of lead and acetate of zinc, properly thickened, is applied to cotton fabrics, which are then left to dry for a day or two, when the colour is fixed by passing the fabric through a mixture of corrosive sublimate, acetate of sodium, and acetic acid. The uric acid, the raw material whence the murexide is prepared, is extracted from guano.

Alous, the resin obtained from the *Aloe socotrina*, has of late been used by the French dyers for producing violets, pinks, maroons, and other shades.

Aniline-purple, or Mauve-dye (also called *Tyrian purple, Phenamine, Indisine*).—This colouring matter, which has to a great extent superseded all other purple dyes, was discovered by Mr. W. H. Perkin in 1856. It is prepared by the action of acid chromate of potassium on sulphate of aniline. When pure, it is a brittle substance, with a bronze-coloured surface, sparingly soluble in cold water, to which, however, it imparts a deep purple colour, more soluble in hot water, freely soluble in alcohol and in aniline. It is slightly basic, dissolves in strong sulphuric acid, and is precipitated from its aqueous solution by alkalis and saline substances. With tannin it forms a precipitate insoluble in water, soluble in sulphuric acid. Its colour is not affected by light, or by acids or alkalis. To dye silk with it, the alcoholic solution of the dye is mixed with about eight times its bulk of hot water acidulated with tartaric acid, and then poured into the dye-bath, which consists of cold water slightly acidulated: when it is well mixed, the silk is to be worked in till it is of the required shade. If a bluer shade is required, a little sulphindigotic acid may be added to the dye-bath, or the silk may previously be dyed blue with prussian blue or otherwise, and then worked in the dye-bath above mentioned. The same method serves for dyeing silk with violine or roseine.

To dye wool with aniline-purple, the dye-bath is composed of nothing but a dilute aqueous solution of the colouring matter kept at 50° or 60° C. (122° or 140° F.). Acids should be avoided, or only a very small quantity used, as they injure the colour. The same method is applicable to the dyeing of wool with fuchsine, violine, roseine, and chinoline colours.

To dye cotton with aniline purple, so as to resist the action of soap and of light, the process has to be modified, so as to form on the cotton fibre an insoluble compound of the colouring matter with tannin and a metallic base.

To effect this, the cotton has to be soaked in a decoction of sumach, galls, or any other substance rich in tannin, for an hour or two, and then passed into a weak solution of stannate of sodium, and worked in it for about an hour; it is then wrung out, turned in a dilute acid liquor, and then rinsed in water. Cotton thus prepared is of a pale yellow colour, and has a remarkable power of combining with aniline purple. The above process may be modified, as for example, the stannate of sodium may be applied to the cotton before the tannin, and alum may also be used in the place of stannate of sodium. To dye this prepared cotton with aniline-purple, it is only necessary to work it in an acidulated solution of the colouring matter; when thus prepared, the cotton will absorb all the colouring matter of the dye-bath, leaving the water perfectly colourless. It has been found that cotton thus prepared can be dyed with any colouring matter that forms an insoluble compound with tannin. It is therefore used for dyeing with roseine, violine, fuchsine, and chinoline colours.

Cotton may also be dyed a very good and fast colour by mordanting it with a basic lead-salt, and then working it in a hot solution of soap to which aniline-purple has been added.

Oiled cotton, such as is used for dyeing with madder, is also used in dyeing these colours. Cotton simply oiled, and before mordanted with alum and galls, absorbs coal-tar colouring matters with great avidity, producing very fine shades. Oiled

cotton mordanted with alum and galls also combines rapidly with these colouring matters: but as the colour of the prepared cotton is generally rather yellow, it interferes sometimes with the beauty of the result.

Cotton is sometimes washed with albumin, which is coagulated by the action of steam, and the albumin, which covers the cotton, dyed in the usual manner.

Violine, roseine, fuchsine, and also the chinoline colours, combine with unmordanted vegetable fibres as well as aniline-purple.

Printing of Calico with Aniline-purple and other Coal-tar Colours.—The process generally employed for printing with these colouring matters is simply to mix them with albumin or lactarin, print this mixture on the fabric, and then to coagulate the albumin or lactarin by the agency of steam.

Another method is to print tannin upon the fabric previously prepared with stannate of sodium, and then dye it in a hot dilute acid solution of the colouring matter; by this means the parts of the fabric which are covered with tannin are dyed a deep colour, but the other parts are only slightly coloured. These are cleared by well-known processes. This method of applying these colouring matters is also modified by printing a compound of the colouring matter required and tannin on the prepared cloth, instead of the tannin only, and then steaming the goods.

Violine.—This dye-stuff, the solutions of which have a colour resembling that of the field violet, was first obtained by Dr. D. Price. It is produced by oxidising aniline with sulphuric acid and peroxide of lead. It is even less soluble in water than aniline-purple, very soluble in alcohol. Its colour is destroyed by reducing agents, but restored on exposure to the air. The methods of dyeing with it are the same as for aniline-purple.

Colours intermediate between Blue and Yellow: GREENS.

Green dyes are, for the most part, produced by the combination of yellow and blue applied either together or separately. For the production of a good green tint, it is essential that both of the primary colours be quite pure, any admixture of red in either of them causing the green to appear dull. For dyeing green with a single bath, the stuff or fibre is sometimes mordanted with alum and then dipped into a bath of *fustic* mixed with *indigo-carmin*. When two baths are used, the stuff is first dyed blue, then well washed and boiled for three hours in a bath of fustic mordanted with alum and cream of tartar, mixed with a small quantity of Saxony blue (a solution of 1 pt. indigo in 6 pts. sulphuric acid). If it be then dipped into a logwood-bath, it acquires the tint called by the French, *vert-dragon*. *Saxony green*, which is brighter, is produced by dipping the piece into a second bath of fustic of greater concentration.

A very beautiful green colour called *Vert-Venus*, *Vert-Azof*, or *Vert-Lumière*, is produced on silk by a dye imported from China, called *Chinese green* or *Lo-Kao*; silks thus dyed are especially admired for the beautiful green shades they assume in artificial light. Very large quantities of this dye were imported in 1853 by Messrs. Guinon of Lyons. More recently, however, M. Charvin, of Lyons, has obtained the same dye from the common buckthorn (*Rhamnus catharticus*). It is remarkable for being capable of producing with proper reagents all the colours of the spectrum. Its use is, however, greatly restricted by its want of stability. Moreover, Messrs. Guinon, Marnas, and Bonnet, have found that very fine greens, which likewise maintain their colour in artificial light, may be produced at less cost by first dyeing the silk in prussian blue, and then in an acidulated bath of picric acid.

Chrome-greens consisting of hydrated oxide of chromium are now much used as pigments in calico-printing: for their preparation see vol. i. p. 950. They likewise maintain their colour in artificial light.

Aniline-green, or *Emeraldine*.—Aniline treated with hydrochloric acid and chlorate of potassium, or a salt of aniline treated with sesquichloride of iron, yields a green compound, the existence of which has long been known to chemists. All attempts to dye silk or wool with it have hitherto failed; but it may be produced on cotton fabrics by printing with acid hydrochlorate of aniline on a fabric prepared with chlorate of potassium. A beautiful bright green then gradually appears, and only requires to be washed. If the green fabric is passed through a solution of acid chromate of potassium, this colour is transformed into a dark indigo-blue, called *azurine*. (Calvert.)

Colours composed of Red, Blue, and Yellow: BROWNS, GREYS, and BLACKS.

Bronze is produced on wool by immersion in a bath of weld, fustic, alum, and tartar, in which it is boiled for three hours; it is then left in a cellar for six days, washed, dipped in a bath of weld and madder, again washed and dipped in a blue bath.

For *olive*, the wool is first dyed blue, then boiled for four hours in a bath of alum, sumach, fustic, soot, and logwood, then taken out and redipped after addition of a small quantity of copperas. Similar processes yield *myrtle-green*, *reseda*, and other shades in which yellow is the predominating colour.

Maroon, in which red predominates, is obtained by boiling the stuff for three hours in a bath of weld and fustic mordanted with alum and tartar, then leaving it in the cellar for a week, washing, boiling it for a short time in a madder-bath, and lastly dipping it in a blue-bath. To obtain a darker colour, the stuff, after leaving the madder-bath, is boiled for two hours with logwood, sumach, and copperas. Similar processes are adopted for *cinnamon* and other *browns*.

Brown Maroon is produced by dipping the stuff for three hours in a bath of gall-nuts, sandal-wood, Brazil-wood, and madder, then adding logwood and copperas.

Black is produced by a mixture of indigo, various yellow dyes, and the tannin of gall-nuts or sumach, sulphates and acetates of iron and copper, cream of tartar, &c.

The black called in France *noir de sedan*, which is one of the finest and most durable, is given to wool by first dyeing it blue with indigo, then, after careful washing, dipping it for three hours in a bath of sumach and logwood, at 80° or 90° C.; then taking it out, adding to the bath 335 grammes of protosulphate of iron for each metre of stuff, redipping for an hour at 38° C., and repeating this process three times. A very fine black is likewise obtained by dyeing the wool with logwood and iron, and then dipping it in a weak solution of bichromate of potash at 40° or 50° C.

Silk is dyed black with protosalts of iron and the tannin of gall-nuts, or, more cheaply, of chestnuts. The silk is first dipped in the tannin-bath, whence it issues with a colour of nankeen yellow, then washed, and dipped in a bath of protosulphate of iron at 90° C. Pyrolignite of iron is likewise used, and iron filings and sulphate of copper are added to the bath, together with a small quantity of basic acetate of lead, to take up the sulphuric acid set free by the decomposition of the ferrous and cupric sulphates. Gum and dextrin are likewise added to give the liquid the requisite consistence. The silk, as it issues from the bath, has a rusty colour, which, however, soon turns black on exposure to the air.

Cotton and linen may be dyed black in the same manner as wool. A very black dye is also produced by dipping them first in a bath of galls and logwood, then in pyrolignite of iron at 90° C.

Greys of various shades are obtained in like manner by, reducing the proportions of gall-nuts, logwood, pyrolignite, &c. An alumina mordant is generally added to give a violet tint.

A variety of *brown* and *grey* tints are also produced by the fixation on the stuff of metallic oxides, such as the oxides of iron and manganese.

Catechu-black on silk. The silks are passed into a solution of ferric salt, then into a hot soap-solution containing an excess of soap, whence they are passed into a slightly acid bath of yellow prussiate. When thus dyed prussian blue, they are dipped into a solution of ferric salt of specific gravity 1.15, the object of which is to give an iron mordant to the silk. They are then thoroughly washed and passed into a bath of catechu, for organzine at 203° , for tram at 172° F., the silks being worked in this bath until it is cold, so as thoroughly to saturate the iron mordant with the colouring principle of catechu, and thus produce a black. They are then wrung on the peg, and exposed to the air for 24 hours, after which they are passed into a soap solution at 50° washed thoroughly; and the organzine is then dipped into a bath of weak acetic acid, the tram into a solution of weak hydrochloric acid. Finally, the silks are passed through an emulsion of oil, well worked on the peg, and left to dry. These last operations are intended to remove, by means of the fatty matters, the harshness which the silk would otherwise possess.

Catechu is capable of yielding a great variety of colours. It contains two distinct principles, *catechu-tannic acid*, and *catechin*, the former of which yields various shades of drab, while the latter yields, with metallic salts, salmon, red, and wood colours.

For further details, see the articles **DYEING** and **CALICO-PRINTING** in *Ure's Dictionary of Arts, Manufactures, and Mines*, and in *Muspratt's Chemistry*. DYHENYLES. Löwig's name for the organic radicles C^oH^{2n-2} .

DYOTRIYLES. Löwig's name for the radicles C^oH^{2n+2} .

DYOXYLITE. Syn. with LANARKITE.

DYSCLAZITE. Syn. with OKENITE.

DYSKOLITE. Syn. with SAUSSURITE.

DYSLUITE. (Zn;Fe;Mn) ($\text{Al}^2\text{,Fe}^2$) O^2 .—A variety of spinel, occurring imbedded in the limestone of New Jersey. It forms octahedral crystals of a yellowish and greyish brown colour, glassy lustre, opaque. Hardness = 4·5; specific gravity = 4·55. With borax before the blowpipe, it melts to a dark garnet-red glass. (Thomson, Rammelsberg.) See SPINEL.

DYSLYSIN. $\text{C}^{24}\text{H}^{36}\text{O}^3$. (Berzelius, Ann. Ch. Pharm. xxxiii. 139; xliii. 1.—Theyer and Schlosser, *ibid.* l. 235.—Strecker, *ibid.* lvii. 22.)—A product of the decomposition of choloïdic or cholalic acid, produced when either of these acids is heated to 300° C., or treated for some time with hydrochloric or dilute sulphuric acid

The best mode of preparing it is to boil ox-bile freed from fats and colouring matters with hydrochloric acid for 12 to 24 hours; wash the hard, friable, resinous mass which separates, with water; then boil it repeatedly with alcohol to remove admixed choloïdic acid; dissolve the residue in ether; and either evaporate the ether, which then leaves the dyslysin as a yellowish or brownish mass, or, better, precipitate the ethereal solution with alcohol, which throws it down with less colour.

Dyslysin is an amorphous substance, doubtless colourless when quite pure, but generally yellowish; melts when heated above 140° C. It is insoluble in water, acids, potash-ley, and alcohol (hence the name), but soluble in ether. Alcoholic potash converts it into choloïdic acid.

DYSLYTE. See EULYTE.

DYSLYTITE. A brown-black powder, obtained as a residue from many masses of meteoric iron when they are dissolved in hydrochloric acid. It amounts to between 0·25 and 2·25 per cent. of the entire mass, and is supposed to be a phosphide of iron, nickel, and magnesium. (Shepard, Sill. Am. J. [2] ii. 380.)

DYSNITE, or DYSSNITE. Syn. with RHODONITE.

DYSODIL. *Houille papyracée, Terre bitumineuse feuilletée, Terre folieuse bitumineuse de Melilli. Stinkkohle, blätterige Stinkerde.* A soft, finely laminated substance, occurring at Melilli in Sicily, of greenish and yellowish grey colour, and specific gravity 1·14 to 1·25. It burns with flame and an unpleasant odour, leaving a friable skeleton (Handw. d. Chem. 2^{te}. Aufl. ii. [3] 535).

DYSTOMITE. Syn. with DATHOLITE.

DYSINTRIBITE. (Shepard, Sill. Am. J. [2] xii. 209.—Smith and Brush, *ibid.* xvi. 50.)—A rock occurring at Diana and other places in St. Lawrence County, New York. It is massive, slaty, and tough, and has the aspect of serpentine. Hardness = 3 to 3·5; specific gravity 2·76 to 2·81. Colour, green, yellow, and grey, sometimes mottled with red. Its composition varies widely, but it consists mainly of silica and alumina, with water and several protoxides in variable proportions; so that it must be regarded as a mixture. The following analyses are by Smith and Brush:—

SiO^2	Al^1O^3	Fe^4O^3	Ca^2O	Mg^2O	K^2O	Na^2O	H^2O	Mn^2O	
44·80	34·	3·01	0·66	0·42	6·87	3·60	5·38	0·30	= 99·94
46·70	31·01	3·69	trace	0·50	11·68	trace	5·30	.	= 98·88
44·94	25·05	3·33	8·44	6·86	5·80	trace	6·15	.	= 100·57

Before the blowpipe it splits into thin splinters, and melts to a white mass, having the aspect of porcelain.

E

EARTHS. This name is applied to the oxides of the metals, barium, strontium, calcium, magnesium, glucinum, aluminium, zirconium, yttrium, and thorium. The earlier chemists distinguished lime and magnesia, by the appellation of *Terræ absorbentes*, from the *earths* in a more limited sense; to these *absorbent* or *alkaline* earths, baryta, discovered in 1774 by Scheele, and strontia, discovered later, were afterwards added. Baryta, strontia, and lime, being soluble in water, and possessing strong alkaline and caustic properties, are sometimes designated *carthy alkalis*, e.g. by Gmelin in his Handbook; but the term *alkaline earths* is more generally adopted. Magnesia is usually classed among the earths proper. Silica was formerly numbered among the earths; but it is now regarded as an acid (or rather anhydride).

EARTHY COBALT. }
EARTHY MANGANESE. } See WAD.

EAU DE COLOGNE. *Kölnisches Wasser.*—A perfume consisting of a solution of various essential oils in alcohol. Numerous recipes have been given for its preparation. One of the best, according to Förster, is to dissolve in 6 quarts of spirit of 82 per cent. Tralles, the following mixture of oils: *Oil of orange, bergamot, lemon, linette* (*Citrus Lumia*), *essence de petits grains*, each 1 oz.; *oleum de Cedro, de Cedrat, essence de Portugal, de Neroli*, each $\frac{1}{2}$ oz.; oil of rosemary, $\frac{1}{4}$ oz.; oil of thyme, $\frac{1}{8}$ oz. (Handw. d. Chem. iv. 428; see also *Ure's Dictionary of Arts, Manufactures, and Mines*, art. PERFUMERY, iii. 428.)

EAU DE JAVELLE. A solution of hypochlorite of sodium. (See HYPOCHLORITES.)

EAU DE LUCE. *Aqua Lucæ.*—A milky mixture of rectified oil of amber with alcohol and ammonia.

EBLANIN. Syn. with PYROXANTHIN.

EBONITE. Caoutchouc hardened by kneading or rolling with half its weight of sulphur. (See CAOUTCHOUC, i. 740.)

EBONY. The black heart-wood of *Diospyros Ebenum*, a tree of the styraceous order, indigenous in Ceylon, Madagascar, the Mauritius, and many other tropical countries. It is very hard, heavier than water, and takes a fine polish. It has a biting taste, and gives off an aromatic odour when burnt. According to Petersen and Schödler, it contains, when dried at 100° C., 49·8 per cent. carbon, 5·3 hydrogen, and 44·9 oxygen.

EBULLIOSCOPE. *Ebullition Alcoholometer.*—An instrument for determining the strength of hydrated alcohol by its boiling point. (See ALCOHOL, i. 95; also *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 72.)

EBULLITION. See HEAT.

EGGONINE. *Ekgonine* (from *ἐκγονος*, offshoot). $C^9H^{16}NO^3$.—A base obtained by the decomposition of cocain under the influence of hydrochloric acid:

It is most readily obtained by heating cocain with hydrochloric acid to 100° C. in a sealed tube. It is soluble in water. Its platinum-salt crystallises in orange-yellow prisms. (Wöhler, *Ann. Ch. Pharm.* cxxi. 372.)

ECHINITES. Fossil radiate animals found in the chalk.

ECLOGITE. *Smaragdite-rock, Onphazite-rock.*—A crystallo-granular rock consisting essentially of red garnet and green smaragdite, sometimes also containing kyanite and white mica.

EDDOES. (*Arum esculentum*.)—A plant cultivated for food in most tropical climates. According to T. J. Herapath (*Chem. Soc. Qu. J.* iii. 196), the fresh roots yield 1·647 per cent. ash, containing in 100 pts.:

Matter soluble in water:

K ² O	NaCl	SO ³	CO ²	P ² O ⁵	Total.				
38·9	7·0	3·3	10·4	4·1	63·7

Matter insoluble in water:

Ca ² O	Mg ² O	Al ⁴ O ³	Fe ⁴ O ³	SO ³	SiO ²	CO ²	P ² O ⁵		
15·7	trace	trace	1·0	1·1	5·2	3·5	9·8	.	36·3
									100·0

From these results Herapath concludes that eddoes exhausts the soil of phosphoric acid and alkalis more than the Spanish potato or batatas (i. 520), but less than the common potato.

EDELFORSITE. *Aedelforsite.*—A silicate of calcium, $2Ca^2O \cdot 3SiO^2$, or $Ca^4Si^3O^8$, found at Aedelfors in Småland, Sweden, Cziklowa in the Bannat, and Gjelleback in Norway. It is massive, fibrous or feathery, white or greyish, with vitreous lustre and transparent. Specific gravity = 2·58. Hardness = 5·5. Melts to a clear glass before the blowpipe. (Hisinger, *Kongl. Vetensk. Acad. Handl.* 1823, p. 177; 1838, p. 191.)

The same name is given by Retzius (*Dissert. de Trem. Norweg. et zeolo rubro*, Aedelfors, Lund, 1818) to the red zeolite of Aedelfors, which occurs there in fibrous aggregations, white, light grey, or reddish, translucent on the edges, and with a vitreous lustre. Specific gravity = 2.6. Hardness = 6. According to Retzius, it contains 60.28 per cent. SiO_2 , 15.42 Al^3O_3 , 8.18 Ca^2O , 4.16 Fe^4O_3 , 0.42 Mg^2O and Mn^4O_3 , and 11.07 water. A similar mineral from Fahlun in Sweden was found by Hisinger to contain 60.0 SiO_2 , 15.6 Al^3O_3 , 1.8 Fe^4O_3 , 8.0 Ca^2O , and 11.6 water (= 97.0), while he obtained from the Aedelfors zeolite 53.76 SiO_2 , 18.17 Al^3O_3 , 4.02 Fe^4O_3 , 10.90 Ca^2O , and 11.23 H_2O (= 98.38). (Dana, ii. 307.)

EDELITE. Prehnite from Aedelfors in Sweden.

EDENITE. Grammatite from Edenville, Orange County, New York.

EDINGTONITE. A mineral occurring on the Kilpatrick Hills, near Glasgow, in small crystals belonging to the dimetric or quadratic system. The crystals are square prisms, acuminate with the faces of a quadratic octahedron. Colour greyish white. Hardness = 4.0 to 4.5. Specific gravity 2.694. According to Heddle's analysis (Phil. Mag. [4] ix. 179), it contains 36.98 SiO_2 , 22.63 Al^3O_3 , 26.84 Ba^2O , 12.46 water, with traces of soda and lime (total 98.91), whence may be deduced the formula $3\text{Ba}^2\text{O} \cdot 2\text{SiO}_2 + 4(\text{Al}^3\text{O}_3 \cdot 2\text{SiO}_2) + 12\text{H}_2\text{O}$, which is equivalent to $(\text{Ba}^{\text{al}}\text{H}^{10})\text{Si}^{10}\text{O}^{40} + 7 \text{ aq.}$, and reducible to $\text{R}^4\text{SiO}_4 + 7 \text{ aq.}$, the formula of an orthosilicate.

EDUCT. This term is applied to a body separated by the decomposition of another in which it previously existed as such, in contradistinction to product, which denotes a compound not previously existing, but formed during the decomposition. The volatile oil of lemon-peel is an educt, because it pre-exists in the peel; but bitter almond oil is a product, because it does not exist ready formed in bitter almonds, but is produced by the action of emulsin and water on amygdalin. In many cases, however, the same substance may be regarded as an educt or as a product, according to the view which is taken of the constitution of the body from which it is derived. Thus the lime and carbonic anhydride obtained by heating chalk to redness, are educts, if the chalk be regarded as $\text{Ca}^2\text{O} \cdot \text{CO}_2$, products if it be regarded as $\text{Ca}^2 \cdot \text{CO}_3$, or $(\text{CO})^{\text{al}} \cdot \text{Ca}^2 \cdot \text{O}$, &c. Similarly the ammonia evolved by heating sal-ammoniac with lime is an educt, if that salt is composed of $\text{NH}_3 \cdot \text{HCl}$, but a product if its composition is that expressed by the formula $\text{NH}_4 \cdot \text{Cl}$. Even the elementary bodies, as evolved from their compounds, may be regarded as products, if, as explained in the article CHEMICAL AFFINITY (i. 858), we suppose a molecule of a free element to be formed by the union of two elementary atoms in opposite polar states; as for example, when hydrogen is evolved by the action of hydrochloric acid on hydride of copper: $\text{Cu}^+\text{H}^- + \text{H}^+\text{Cl}^- = \text{Cu}^+\text{Cl}^- + \text{H}^+\text{H}^-$, or when sulphur is precipitated by the mutual action of sulphurous anhydride and sulphydric acid: $2\text{H}^+\text{S}^- + \text{S}^{2-} = 2\text{H}^+\text{O}^- + \text{S}^{2-}$.

EDULCORATION. A term applied to washing, or lixiviation, in cases when the soluble matter is rejected as worthless, and the insoluble residue is the material required.

EDWARDSITE. See MONAZITE.

EFFERVESCENCE is the commotion produced in liquids by some part of the mass suddenly taking the gaseous form and escaping in numerous bubbles.

EFFLORESCENCE. This term is applied to two or three different phenomena, characterised by the formation of a loose pulverulent deposit on the surface of a solid body.

1. Crystallised salts are said to effloresce when they lose their water of crystallisation and fall to powder: *e. g.* neutral carbonate of sodium, $\text{Na}^2\text{CO}_3 + 5 \text{ aq.}$

2. The formation of a pulverulent crystalline deposit on the surface of a porous body, in consequence of the crystallisation of a salt existing in solution within its pores, or formed from materials existing therein, is also called efflorescence: *e. g.* the crystallisation of nitrate of potassium on the surface of the earth or in caves, as in India, or on saltpetre plantations,—of sulphate and carbonate of sodium on walls,—of alum on alum-slate,—of ferrous sulphate on iron pyrites, &c. In all these cases, the solution of the salt is drawn by capillary action to the surface of the solid body, and there crystallises in consequence of the evaporation of the water.

3. The term efflorescence is likewise applied to the effect which sometimes takes place when a saline solution is left to evaporate slowly in an open vessel. The solid salt separates in dendritic crystals just where the surface of the liquid touches the side of the vessel, and the solution, rising by capillarity between these crystals, forms a

fresh crystallisation just above the first layer; and this process is continually repeated till the crystallisation thus formed extends over the edge of the vessel, and sometimes down to the table on which it stands. Sal-ammoniac and other ammonia-salts often effloresce in this manner. The effect may be prevented to a certain extent by greasing the edge of the vessel, or, better, by quickly boiling the solution, or evaporating it by heat from above.

EGERAN. Syn. with IDOCRASE.

EGG. (Prout, Phil. Trans. 1822, p. 377.—Prévost and Dumas, Ann. d.Sc. nat. iv. 47.—Prévost and Morin, *Lehmann's Zoochemie*, Heidelberg, 1858, p. 693.—Baudrimont and St. Ange, Compt. rend. xvii. 1343.—Gobley, Compt. rend. xxi. 766.—J. Phys. Chim. [3] xi. 409; xii. 513.—Valenciennes and Frémy, J. Pharm. [3] xxvi. 5, 321, 415; *Traité de Chimie générale par Pelouze et Frémy*, 2^{me} Ed. 1857, vi. 227.—Lehmann, *Lehrbuch d. physiol. Chemie*, translated by Dr. Day, ii. 353; iii. 439; also in *Gmelin's Handbuch*, viii. 282, 546, 557, 658, and 693.—Handw. d. Chem. 2^{te} Aufl. ii. [3] 342, 554, 652.)

The eggs of *birds* consist of four parts, viz. 1. The shell, which is a hard calcareous envelope; 2. A thin membrane, called the *membrana putaminis*, which lines the shell; 3. The white, or albumen, which is a colourless liquid enclosed in large cells formed of a thin membrane; and 4. The yolk or vitellum surrounded by the albumen, and likewise enclosed in a membrane, which is connected with that which forms the cells of the albumen by two knotted ligaments called *chalazæ*.

The shell consists mainly of carbonate of calcium, with smaller quantities of phosphate of calcium and animal matter. In the egg-shells of the domestic fowl, Vauquelin and Proust found,

	Vauquelin.	Proust.
Carbonate of calcium	89.6	91
Phosphate of calcium, with a little phosphate of magnesium	5.7	7
Animal matter containing sulphur	4.7	2
	<hr/> 100.0	<hr/> 100

The egg-shell of the ostrich contains, according to Wicke, 3.28 p. c. organic matter and 97.41 carbonate of calcium.

The lining membrane of the shell of poultry eggs contains, according to Scherer, 50.7 p. c. carbon, 6.6 hydrogen, 16.8 nitrogen, and 26.0 oxygen and sulphur. When incinerated, it leaves a small quantity of ash consisting chiefly of phosphate of calcium.

The white or albumen of the egg is not a mere solution of albumin or albuminate of sodium in water. When examined by the microscope, it exhibits, besides the chalazæ and the amorphous cellular membranes, a number of small bodies with three projecting points, or aggregates of small needles, consisting of fat. The cellular membrane is that which gives the gelatinous consistence to white of egg. When the white is beaten up with water, and the intimate mixture thus formed is diluted with a large quantity of water, the chalazæ and membranes separate as a flocculent sediment.

Lehmann found in white of egg, in addition to albumin, a small quantity of fat, glucose, extractive matter, mineral salts, and free gases. Nicklès found a trace of fluorine. In the fresh white of poultry eggs, Lehmann found carbonates in variable quantity, depending perhaps on the time for which the eggs had been exposed to the air. The quantity of water in the albumen varies from 82 to 88 p. c.; the quantity of albumin, mostly in combination with soda, is about 12.5 p. c. of the fresh albumen; that of the extractive matters is 3.14 p. c. of the solid residue. The proportion of inorganic salts is 0.64 to 0.68 (Lehmann), 0.65 (Poleck). The dried residue of the albumen yields 3.042 p. c. fusible ash (Lehmann). In the dried albumen of poultry eggs, Lehmann found, as an average of numerous determinations, 0.5 p. c. fermentable sugar. G. Meissner found a much larger quantity, viz. 8 p. c. of the dried residue. In 100 pts. of the ash of the albumen of poultry eggs, Poleck found 25.67 KCl, 8.57 NaCl, 5.43 K₂O, 12.49 Na₂O, 6.25 Ca₂O, 7.03 Mg₂O, 2.09 Fe₂O₃, 15.28 P₂O₅, 0.84 SO₃, 9.01 CO₂, and 7.05 SiO₂. The chlorides and other soluble salts form the larger portion of this ash, whereas in the ash of the yolk, the insoluble salts predominate.

The yolk of birds' eggs forms a thick, viscid, slightly translucent, yellow liquid, destitute of odour, but having a faint peculiar taste: when mixed with water, it forms a white emulsion. It blues reddened litmus paper, solidifies to a friable mass when boiled, is coagulated by cold alcohol, and gives up to ether a reddish-yellow fat. When examined by the microscope, it is found to consist of a semifluid mass of very fine *granules*, amongst which there swim variously sized *yolk-corpuscles* and *fat globules*.

The yolk-corpuscles consist mainly of fat and pigment; the fine granules, according

to Lehmann, of casein containing but a small quantity of alkali; the fluid of the yolk consists of albumin poor in alkali, in a state of actual solution. The substance formerly called vitellin is now known to be a mixture of casein and albumin.

The fat of the yolk appears to consist chiefly of olein and palmitin; it also contains cholesterin or a very similar body, and according to Gobley, cerebrin and lecithin (*q. v.*) The colouring matters of the yolk have not been accurately investigated: it is merely known that they consist of a red and a yellow pigment, one or the other of which is albuminous.

In 1000 pts. of the yolk of the egg of the domestic fowl, Gobley found 514.90 water, 157.60 vitellin, 304.70 fat (consisting of 213.00 palmitin and olein, 4.40 cholesterin, 84.30 lecithin and 3.00 cerebrin), 4.00 alcoholic extract, 5.50 colouring matter, 0.30 chloride of ammonium, 2.80 alkaline chlorides and sulphates, 10.20 earthy phosphates, with a trace of oxide of iron.

Among the constituents of the ash, the potassium-salts and phosphates occupy the chief place, the chlorides and the sodium-salts being present in small quantity only. Polek found in 100 pts. of the ash of the yolk of hens' eggs, 5.94 potash, 4.82 soda, 15.79 lime, 2.36 magnesia, 1.85 ferric oxide, 68.26 phosphoric anhydride, and 0.92 silica (= 99.94).

Changes of the egg during incubation.—From observations on the eggs of the domestic fowl, Prout deduced the following conclusions:

1. The relative weights of the several parts of the egg vary considerably. Ten eggs gave on the average, in 1000 pts.; shell and lining membrane 106.9 pts., white 604.2, yolk 288.9. The membrane weighs about $2\frac{1}{2}$ pts. per thousand of the entire egg. —2. The egg loses during incubation about $\frac{1}{6}$ of its weight, which is about eight times as much as it would lose in the same time if left to itself. —3. At the commencement of incubation, the yolk gives up oil to the white, whereby the white is altered and becomes like the casein of milk, the yolk at the same time taking up water and salts. —4. At a later stage, the water and salts leave the yolk, which gradually resumes its original volume. In the last week of incubation, it diminishes still further in bulk, and gives up the greater part of its phosphorus, which is used in the formation of bone, uniting as phosphoric acid with lime, which is not originally contained in the fluids of the egg, but appears to be derived from the shell.

The results obtained by Prévost and Dumas are as follows: The contents of the unincubated egg were found to consist of 10.72 per cent. fat, 16.58 substance free from fat (8.19 in the white and 8.36 in the yolk) and 72.55 per cent. water. After seven days' incubation, the inner part of the egg consisted of 9.32 per cent. ether-extract, 13.94 substance free from fat (with 8 per cent. albumin), and 76.74 water. Of substance free from fat the white contained 34.9 per cent., the thick yolk 16.5, the fluid yolk 4.4, the membranes of the white 7.7, the amniotic liquid 1.3 per cent. The fat and solid substance had therefore diminished during incubation, but the amount of water was relatively increased after fourteen days' incubation, the lining membrane of the shell, the interior of the fœtus, and in one instance also, the amniotic liquid exhibited an acid reaction. 100 pts. of the interior of the egg consisted of 9.46 ether-extract, 16.09 dry matter with 7.7 albumin, and 74.43 water. The white contained 3.3 per cent. dry matter free from fat; the yolk 19.3; the membranes 9.1; the fœtus 7.2; the amnios 1.4 per cent. After twenty-one days' incubation, the interior of the egg consisted of 5.68 per cent. fat, 15.44 dry substance free from fat ($\frac{1}{6}$ of which was yolk, $\frac{1}{6}$ yolk-membrane and $\frac{2}{3}$ fœtus), and 78.88 per cent. water. The yolk then contained 29.0 per cent. the yolk membrane 20.6, the fœtus 14.6 per cent. dry matter free from fat.

The weight of the shell remained nearly constant. The fat of the egg before incubation had a uniform yellow colour; on the seventh day the thick yolk yielded to ether a yellow oil; the liquid yolk a yellow, later a colourless fat. The membranes and amnios yielded a thick white fat, the fœtus a white fat like hog's lard. On the fourteenth day, the yolk-oil was yellow and thick; that of the fœtus reddish and solid. On the twenty-first day, the yolk-fat was thick and pale yellow; that of the membranes dark yellow and partially solid: the fœtus yielded at first a solid yellow, afterwards a soft, white fat.

Respecting the mineral constituents of eggs, Prévost and Morin have obtained the following results:

Eggs before incubation contained;

	Dry substance free from fat.	Ash.	Insoluble phosphates.	Soluble salts.
In the white . . .	15.090	0.85	0.13	0.68
In the yolk . . .	15.166	0.90	0.90	
	<hr/> 30.256	<hr/> 1.75	<hr/> 1.03	<hr/> 0.68

After twenty-one days incubation :

	Dry substance free from fat.	Ash.	Insoluble phosphates.	Soluble salts.
In the yolk	5·51	0·150	0·145	0·005
„ yolk-membrane . .	4·80	0·205	0·205	
„ putamen, chorion and amnios. }	0·42	0·040	0·015	0·025
„ foetus	16·87	1·825	1·059	0·730
	<u>27·60</u>	<u>2·220</u>	<u>1·424</u>	<u>0·760</u>

The loss of weight of the egg during incubation was found by Prévost and Morin (contrary to the observations of Prout, p. 364) to be the same in a given time as that of the egg when left to itself, so that it appears to arise from simple drying. Unimpregnated eggs do not putrefy during incubation, their contents retain their original consistence, but the yolk becomes darker.

It has long been known that non-incubated eggs respire, giving off water and carbonic acid and absorbing oxygen, so that the air confined at the broad end of the egg is richer in oxygen than the external air. From the investigations of Baudrimont and St. Ange, as well as from those of Viborg and Schwann, it appears that this process of respiration, in other words, the interchange of gas through the shell, is accelerated during incubation, and is moreover necessary to the process of development, inasmuch as eggs enclosed in an atmosphere of hydrogen or carbonic anhydride quickly die.

Eggs of Fishes.—The eggs of fishes, and likewise those of reptiles, insects, mollusca, &c., do not contain an albuminous investment like that of birds' eggs, but consist merely of a fluid corresponding to the yolk, and enclosed in a membrane, which is itself enclosed in a shell.

The yolk, or vitellum, of the eggs of cartilaginous fishes consists of an albuminous liquid, holding in solution certain mineral salts, chiefly chlorides and phosphates, and in suspension, white grains or plates, consisting of ichthin, the form of which is regular and constant in each species, but differs in different species. According to Radlkofer, they are crystalline and double-refracting. These grains are mixed with a small quantity of phosphoretted fat, which is soluble in ether and alcohol, forms a kind of mucilage with water, and exhibits some analogy to the oleophosphoric acid of the brain. (Valenciennes and Frémy.)

The roe of the sturgeon is salted and sold as *caviare*. John found in 100 pts. of it, 6·2 fluid albumin, 4·3 butyraceous fat, 6·7 common salt, 0·5 phosphate of calcium with a little iron, 24·3 coagulated albumin, and 58 water.

The eggs of bony fishes also contain grains or plates similar to those in the yolk of cartilaginous fishes, but consisting of three substances insoluble in water, viz. ichthin, ichthidin, and ichthulin. The albumin of fishes' eggs appears to differ from that of birds' eggs; in fact, that of certain fishes dissolves in hydrochloric acid without coloration, and begins to coagulate at 45° C., whereas the albumin of birds' eggs dissolves in hydrochloric acid with deep violet-blue colour, and does not coagulate below 60° C.

The fluids of the eggs of bony fishes undergo a change of composition during their sojourn in the oviduct. While still attached to the ovary, they contain only traces of albumin, but those in the oviduct contain a considerable quantity of it. The eggs of the *carp* in an early stage of development contain ichthidin and ichthulin; when fully developed, they no longer contain ichthidin, the ichthulin gradually disappears, and when they have become quite transparent, they contain nothing but a strongly albuminous liquid, holding phosphoretted fat in suspension. (Valenciennes and Frémy.)

According to Goble (J. Phys. Chim. [3] xi. 409; xii. 513), carps' eggs exhibit in their composition a certain degree of similarity to hens' eggs. They appear to be deficient in the alkaline albumin which surrounds the yolk of the fowl's egg, but they contain an albuminous substance, paravitellin, agreeing in composition and properties with vitellin, and a fat, which, like that of the yolk of poultry eggs, is composed of a fixed oil and a tenacious infusible substance. The oil, which is present in small quantity only, consists of olein and palmitin; the tenacious substance is a mixture of several compounds, including cholesterin, lecithin, and cerebrin, the second of which contains phosphorus. Carps' eggs boiled with water yield, according to Goble, an acid liquid, which becomes more acid on addition of alcohol. The colouring matter of carps' eggs appears to be of two kinds, like that of poultry eggs, a red ferruginous substance, like the colouring matter of blood, and a yellow substance. Goble gives the mean percentage composition of the eggs, as follows:—64·08 water, 14·06 paravitellin, 2·57 olein and palmitin, 0·26 cholesterin, 3·04 lecithin, 0·20 cerebrin, 0·04 chloride of ammonium, 0·15 chlorides of potassium and sodium, 0·04 sulphate and phosphate of

potassium, 0.29 phosphates of magnesium and calcium, 0.39 extract of flesh, 14.53 membrane, and 0.03 colouring matter, with traces of iron, and loss.

Eggs of Reptiles.—The eggs of the *tortoise* are composed of a gelatinous white, small in quantity, containing but little albumin, and enclosed in the cells of the large transparent membranes. The yolk is very rich in albumin, and contains a considerable quantity of phosphoretted oil together with grains of emydin (*q. v.*).

In the egg-shell of *Emys amazonica*, L. Gmelin found 26.6 per cent. animal matter insoluble in hydrochloric acid, 10.7 animal matter soluble in that acid, 55.4 carbonate of calcium, 7.3 phosphate of calcium, and traces of magnesia.

In the egg-shell of *Alligator sclerops*, not quite freed from membrane, Brummerstadt found 1.36 per cent. water, 5.99 organic matter, 91.10 carbonate of calcium, 2.33 carbonate of magnesium, and 0.54 earthy phosphates.

The eggs of the *lizard* resemble those of the *tortoise* to a certain extent; they do not contain ichthin or emydin. (Valenciennes and Frémy.)

The eggs of the common *viper* contain an albumin, like that of the ray, gelatinous, and made up of transparent elastic films containing a slightly albuminated water. The yolk contains a liquid very rich in albumin, and having a large quantity of fat floating in it, but on bringing it in contact with water, the liquid thickens more and more; and at last becomes quite gelatinous. This change of state is due to the presence of a body resembling vitellin, which is rendered insoluble by the slow action of water. (Valenciennes and Frémy.)

The gelatinous matter of the eggs of *frogs* is composed of a tissue of hyaloid membranes, containing water, absorbed after the eggs have been laid. It is modified by boiling, becoming slightly opaline, while the yolk hardens, showing that it contains albumin. The yolk is blackened by a peculiar pigment, which also colours the extremely thin vitelline membrane; the liquid of the yolk contains a very small quantity of fatty matter united in transparent drops: another substance which, under the microscope, presents the appearance of an extremely thin membrane, covered with black dots, and a large quantity of extremely small vitelline granules, insoluble in water, but soluble in acetic acid. The eggs of *tritons* exhibit the same composition; the white exterior matter is similar to that of frogs' eggs.

The eggs of *Crustaceans* do not contain ichthulin; their albumin appears to differ in some respects from that of other eggs, not coagulating below 74° C. The eggs of *crabs* and *lobsters* contain the substance which exists in the shell of the animal, and is the cause of the red colour which it assumes when boiled. In the eggs, this substance appears to be in a state of solution, and to be precipitated, on diluting the crushed eggs with water, as a green resinous substance, which is reddened even by drying in vacuo, also by the action of salts which absorb water, by the action of alcohol or ether, and lastly when rubbed with a solid body. In the reddened state, the colouring matter may easily be obtained by heating the albuminous liquid which holds it in solution, and dissolving out the colouring matter from the coagulated albumin which encloses it, by means of alcohol. (Valenciennes and Frémy.)

Eggs of Arachnida and Insects.—The eggs of *spiders* contain albumin, fatty matters and a large quantity of matter precipitable by water. The eggs of *ants* exhibit similar composition. (Valenciennes and Frémy.)

Reinsch found in the eggs of *Papilio Crategi*, 2.36 per cent. shell (containing 2.14 animal matter, and 0.22 carbonate of calcium), 8.32 albumin, 8.22 fat, with traces of volatile oil, 0.88 unsaponifiable fat, 0.57 phosphate of calcium, with traces of ferric oxide, 4.65 animal substances with salts, and 75.00 water.

Eggs of Mollusca.—These eggs appear to differ altogether in composition from those of other animals. Thus the eggs of the snail do not contain a trace of fat, but are formed entirely of hyaloid membranes, enclosing a viscid, colourless liquid, which holds in solution an azotised body different from albumin, inasmuch as it does not coagulate by heat, is precipitated by acetic acid, and dissolves in hydrochloric acid, without producing a violet colour. (Valenciennes and Frémy.)

F. W. Burdach examined the eggs of *Limnæus stagnalis*, in different stages of development, with the view of ascertaining whether the quantity of fat in them increases during their development at the expense of the albuminoids. The eggs in an early stage of development were found to contain in the dry state, 4.05 per cent. mineral salts, 0.65 fat, and therefore, 95.26 albuminates; in a second experiment, 3.55 salts, 0.64 fat, and 95.81 albuminates. The fully developed eggs yielded 6.00 and 6.62 per cent. salts, 2.18 and 1.55 fat, and 91.82 albuminates. These experiments seem to show that the albuminates are partly converted into fat in the process of development. (Burdach, *De commutat. subst. protein. in adipem*, *Dissertatio*. Regiomontii Frussor. 1853.)

The following general conclusions are deduced by Valenciennes and Frémy from their researches on the eggs of different classes and orders of animals.

1. Among vertebrate animals, the eggs of birds, reptiles, and fishes exhibit differences which may be demonstrated by the most simple analysis; nevertheless, the eggs of saurians and ophidians present considerable analogy to those of birds, whereas the eggs of batrachians approach more to those of cartilaginous fishes.

2. The eggs of arachnida and insects differ altogether in composition from those of other animals.

3. The eggs of crustaceans, which are organised so as to be hatched in water, exhibit no resemblance to those of fishes or amphibious vertebrata.

4. Similar observations apply to the eggs of molluscs.

5. These differences correspond not only with classes and orders, but likewise extend to natural families, and do not stop even there; inasmuch as the eggs of cartilaginous fishes have not the same composition as those of bony fishes: moreover, a carp's egg is very different from that of a salmon, and the egg of an ophidian, an adder, for example, does not contain the same principles as that of a chelonian.

6. Eggs contain several distinct proximate principles, viz. vitellin, ichthin, ichthulin, ichthidin, and emydin, designated by the generic name of *vitelline substances*.

7. Though the composition of the proximate principles is the same in closely allied species, the form and size of the vitelline substances varies sufficiently to be recognised and assigned for each species.

8. The albuminous substances derived from the eggs of birds, reptiles, fishes and crustaceans exhibit in their chemical properties and in their point of congelation, differences sufficient to justify the conclusion that they constitute different proximate principles.

9. An egg undergoes changes attended with considerable modifications of its liquid constituents, at the different epochs of its formation, at the moment of its separation from the ovary, and during its sojourn in the oviduct before it is laid.

EHLITE. A basic phosphate (or phosphovanadate) of copper found at Ehl, near Linz on the Rhine, at Nischnei-Tagilsk in the Ural, and at Libethen in Hungary (the so-called *crude libethenite*), usually in botryoidal and kidney-shaped aggregates, or massive and imbedded, rarely crystallised. It cleaves in one direction, produces a verdigris-green to emerald-green streak, is translucent on the edges, has a nacreous lustre on the cleavage faces. Hardness = 1·5 to 4·0. Specific gravity = 3·8 to 4·3. Before the blowpipe it decrepitates violently, and melts easily to a black bead, which solidifies in the crystalline state. On charcoal it yields copper. Dissolves easily in hydrochloric acid and in ammonia.

According to an older analysis by Bergemann (Schw. J. liv. 305), it contains 24·93 per cent. P_2O_5 , 65·99 Cu_2O , and 9·06 water, agreeing approximately with the formula $5Cu_2O.P_2O_5 + \frac{3}{2}H_2O$, or $2(Cu^3PO_4.2CuHO) + H_2O$ (calc. 23·94 P_2O_5 , 66·97 Cu_2O , and 9·09 water). Analyses by R. Hermann (J. pr. Chem. xxxvii. 183), Rhodius (*ibid.* xlii. 457), and Nordenskiöld (*ibid.* lxxii. 457), lead to similar results. According to a later analysis by Bergemann (Jahresber. v. Leonhard f. Min. 1858, p. 191), the mineral likewise contains vanadium, viz. 7·34 V_2O_5 , 17·89 P_2O_5 , 64·09 Cu_2O , and 8·90, which may be represented by the formula $3Cu_2O.V_2O_5 + 6(3Cu_2O.P_2O_5 + aq.) + 3(Cu_2O.H_2O)$, or $Cu^3VO_3.3(2Cu^3PO_4.aq.).3CuHO$. But it is probably a mixture, as indeed might be inferred from the great variations in its hardness and density.

EHRENBERGITE. An amorphous mineral occurring as a deposit in trachyte in the Siebengebirg. In the recent state it is nearly gelatinous, easily compressible, and when dried becomes lighter in colour, fissured, fine-grained, and opaque. In the dry state it adheres but little to the tongue. In water it disintegrates and resumes its original character. According to Ehrenberg, it becomes white by gentle ignition, but recovers its former colour by immersion in water. Analyses by Bischof (I.) and Schnabel (II.) show that its composition is very variable:

	SiO_2	Al_2O_3	Fe_2O_3	Mn_2O	Cu_2O	Mg_2O	H_2O	K_2O, Na_2O	Total.
I.	64·54	6·04	4·56	4·61	3·96	0·41	7·77	8·11	100
II.	56·77	15·77	1·65	0·86	2·76	1·30	17·11	3·78	100

According to Schnabel, water extracts from it chlorine, sulphuric acid, and magnesia; hydrochloric acid extracts iron and manganese. (Jahresber. d. Chem. 1852, p. 867.)

EKBERGITE. A massive fibrous variety of Scapolite (*q. v.*)

ELAENE. C^9H^{18} .—Syn. with NONYLENE (*q. v.*)

ELÆOLITE. A variety of nephelin, having a waxy or fatty lustre, slight translucence, and a grey, dingy blue, green, red, or brown colour. In crystalline form and composition it does not differ essentially from nephelin, but is distinguished by the greater ease with which it melts to a tumid glass. (See NEPHELIN.)

ELÆOMETER. A kind of hydrometer for detecting adulterations in fixed oils,

such as palm-oil, linseed-oil, &c., by their specific gravity, and partly also by their different rates of expansion by heat. The indications are not very exact.

ELÆOPTENE. A term applied to the more volatile portion of a natural essential oil, the other portion, which solidifies more readily, being called a stearoptene or camphor.

ELÆOSACCHARUM. *Oelzucker.*—A finely triturated mixture of sugar with a volatile oil (*e. g.* oil of anise, lemon, &c. *Elæosaccharum anisi, citri*, &c.). Such mixtures may be prepared by rubbing the rind of lemons, oranges, &c., or the fruits themselves, on loaf sugar, or by directly mixing the aromatic substance with the sugar, as in the preparation of vanilla.

ELAËRIN. The name given by Chevreul to the more fusible constituent of the grease of sheep's wool, in which it is associated with stearin. It is said to saponify with difficulty, yielding a peculiar acid, elæric acid. Neither the fat nor the acid has been sufficiently examined to establish its separate identity.

ELAÏC ACID. Syn. with OLEIC ACID.

ELAÏDIC ACID. $C^{18}H^{34}O^2$. (Boudet, *Ann. Ch. Phys.* l. 391.—Laurent, *ibid.* lxx. 149.—Meyer, *Ann. Ch. Pharm.* xxxv. 174.—Gottlieb, *ibid.* lvii. 54.)—A solid isomeric modification of oleic acid, produced by the action of nitrous acid. It may be obtained by solidifying olive oil with vapour of nitrous acid, or with mercurous nitrate, saponifying the solid glyceride thus obtained (elaïdin), and decomposing it with a mineral acid. The elaïdic acid thus obtained is, however, always more or less contaminated with margaric acid. A better process is to treat pure oleic acid with nitrous acid. Elaïdic acid may also be prepared by decomposing oleate of barium with a quantity of fuming nitric acid, exactly sufficient to unite with the baryta. On leaving the liquid at rest, the elaïdic acid rises to the surface, and may be freed from unaltered oleic acid by pressure between bibulous paper and crystallisation from alcohol.

Elaïdic acid melts between 44° and 45° C. It dissolves readily in *alcohol*, and is deposited from the concentrated solution in laminæ resembling benzoic acid; it likewise dissolves in *ether*, but not so freely. The solutions have an acid reaction. When kept for a long time at 65° C. it absorbs oxygen, acquires a disagreeable odour, liquefies, and is then no longer solidified by nitrous acid. Elaïdic acid distils for the most part without alteration. Treated with melting *potash* it is converted, like oleic acid, into acetate and palmitate of potassium, with evolution of hydrogen:

The ELAÏDATES, $C^{18}H^{33}MO^2$, are isomeric with the oleates. All the neutral elaïdates are insoluble in water, only the alkaline salts containing excess of alkali being soluble. An excess of water decomposes them, precipitating acid salts.

Elaïdate of ammonium crystallises in scales; it is sparingly soluble in ether. The *potassium-salt* also crystallises in scales; the *sodium-salt* in large shining leaflets. The *barium-* and *lead-salts* are white precipitates. The *silver-salt*, $C^{18}H^{33}AgO^2$, is a white precipitate, sparingly soluble in water, alcohol, and ether, when once dried, easily soluble when recently precipitated. It dissolves easily in warm aqueous ammonia, and is deposited in great part on cooling in small prismatic crystals.

ELAÏDIC ETHERS. (Laurent, *Ann. Ch. Phys.* xxxv. 296.—Meyer, *Ann. Ch. Pharm.* xxxv. 186.)—*Elaïdate of Ethyl*, $C^{18}H^{33}O^2.C^2H^3$, is obtained by boiling 2 pts. of elaïdic acid with 1 pt. of sulphuric acid and 4 pts. of alcohol, boiling the mixture, with cohobation, for several hours; also by saturating an alcoholic solution of elaïdic acid with hydrochloric acid. It is a colourless oil, odourless in the cold, of specific gravity 0.869 at 18° C.; insoluble in water. Alcohol dissolves about $\frac{1}{5}$ of its volume of it; ether dissolves it in all proportions. It boils a little above 310° C., and distils without alteration, according to Laurent; according to Meyer, it is decomposed by distillation. Alkalis in alcoholic solution convert it into an alkaline elaïdate.

Elaïdate of Methyl, $C^{18}H^{33}O^2.CH^3$.—Prepared like the preceding compound. It is an oily liquid of specific gravity 0.872 at 18° C.

ELAÏDIN. A solid isomeric modification of olein, produced by the action of nitrous acid (or of nitric acid in contact with mercury) on olein; fuming nitric acid also solidifies olein after some time, but an excess of the acid hinders the solidification. Elaïdin, like olein, has never been obtained sufficiently pure for analysis, being always contaminated with margarin, and an oily substance which is reddened by potash. It may be purified to a certain extent by dissolving it in ether, cooling the solution to 0° C., and washing the deposit with ether. Elaïdin thus prepared bears considerable resemblance to stearin, and according to Meyer's analysis (*Ann. Ch. Pharm.* xxxv. 178), which gave 77.3 per cent. carbon and 12.0 hydrogen, may be regarded as tri-elaïdin, $C^{57}H^{104}O^6 = C^3H^8O^3$ (glycerin) + $3C^{18}H^{34}O^2$ (elaïdic acid) - $3H^2O$ (calc.

7.73 carbon, and 11.7 hydrogen). It melts at 32° C., is nearly insoluble in alcohol, but dissolves readily in ether. By dry distillation it yields acrolein, elaidic acid, and hydrocarbons.

Elaidin is saponified by alkalis, yielding glycerin and a salt of elaidic acid. The *Unguentum oxygenatum* and *U. citrinum* of the pharmacopœias, prepared from hog's lard with nitric acid, contain impure elaidin.

ELAIN. Syn. with OLEIN.

ELAIN-PHOSPHORIC ACID. Syn. with OLEOPHOSPHORIC ACID.

ELAIN-SULPHURIC ACID. Syn. with OLEOSULPHURIC or SULPHOLEIC ACID.

ELAIDIC ACID. Syn. with RICINOLEIC ACID.

ELAIDOMETER. Berjot's name for a percolating apparatus, in which he exhausts oil seeds with sulphide of carbon, in order to determine the quantity of oil contained in them, by evaporating the sulphide of carbon and weighing the oil which remains. (Rép. Chim. app. ii. 160.)

ELALDEHYDE. A solid isomeric modification of aldehyde (i. 109). Lieben (Ann. Ch. Pharm. Suppl. Bd. i. 114) has shown that a similar modification may be obtained by treating aldehyde with iodide of ethyl.

ELAONE. Syn. with OLEONE.

ELASMOSE. Syn. with FOLIATED TELLURIUM. (See TELLURIUM.)

ELASTIC BITUMEN. Syn. with ELATERITE.

ELASTIC TISSUE. (Lehmann, *Physiological Chemistry*, iii. 49; also *Gmelin's Handbuch*, viii. 459. Handw. d. Chem. 2^e Aufl. ii. [3] 667.)—The elementary fibres of this tissue are somewhat extensively distributed in the animal organism, though they never occur independently of other histological elements. They are most commonly found intermixed with the fibres of the connective tissue, very frequently also with smooth muscular fibres. They occur in the yellow elastic ligaments, as in the *Ligamenta flava* of the vertebral column, the inferior vocal chords, the *Ligamentum nuchæ* or neck-band of mammals, the elastic ligaments of the claws of the felidæ, and the hinge-ligament of bivalves. Large groups of elastic fibres connected into membranous sheaths are met with in the *fascia lata* and in the middle coats of the arteries and veins. Smaller accumulations of these fibres occur in many other parts, as, for instance, in the corium, and under the mucous membrane, more especially in the pharynx, the pylorus, cæcum, &c. The diameter of the elastic fibres varies considerably in different parts; thus, in the serous membranes, they are so fine as not to admit of exact measurement, whereas in the neck-band of some animals, they have a diameter of 0.004", and in the coatings of the arteries they are still broader.

The chemical basis of the elastic tissue, the so-called elastin, as obtained by boiling the tissue with alcohol, ether, water, strong acetic acid and dilute potash-ley, then with water, moderately strong hydrochloric acid, and again with water,—is a brittle, yellowish, distinctly fibrous mass, which when immersed in water, dilute ammonia or acetic acid, swells up and recovers its elasticity completely. It is quite insoluble in water, even after several days' boiling, thereby differing essentially from the true connective tissue, which is converted into gelatin by boiling with water. Elastin is likewise insoluble in alcohol, ether, and acetic acid. Strong potash-ley dissolves it with brownish colour: the solution, neutralised with sulphuric acid, does not gelatinise on evaporation, and is not precipitated by any acid excepting tannic acid. Elastin prepared as above burns without residue on platinum foil, and is free from sulphur. When boiled for some time with sulphuric acid, it yields leucine.

Purified elastic tissue from the neck-band of the horse has been analysed by Tilanus and W. Müller, with the following results:

	Tilanus.		W. Müller.			
Carbon . . .	54.90	55.65	55.47	55.72	55.55	55.09
Hydrogen . . .	7.25	7.41	7.54	7.67	7.11	7.33
Nitrogen . . .	17.52	17.74	16.09	15.71	16.52	16.43
Oxygen . . .	20.33	19.20	20.90	20.90	20.82	21.15
	100.00	100.00	100.00	100.00	100.00	100.00

ELASTICITY is the power possessed by many bodies of recovering their original shape and size, as soon as the external forces which altered them have ceased to act. There is perhaps no substance in which this power is altogether absent, but in some

bodies, moist clay for example, it exists in so slight a degree that for all practical purposes, they may be regarded as inelastic. The elasticity of a body is perfect or imperfect, according as it recovers its original shape and size wholly or partially on the removal of the disturbing force.

Elasticity of Gases.—Gases not only yield to pressure and expand to their original bulk on the removal of that pressure, but their particles exhibit a constant tendency to fly asunder, so that a gas exerts a constant pressure against the sides of the vessel in which it is enclosed.

The elastic force of a gas is measured by the pressure which it is capable of sustaining, or by the pressure required to keep it within a given volume. Observation shows that the elastic force of the air at the earth's surface is capable of sustaining a column of mercury of the average height of thirty inches, which is equivalent to a weight of about fourteen pounds on the square inch; more exactly, when the height of the barometric column reduced to 0° C. is 760 millimetres, the pressure on a square metre is $0.760 \times 1000 \times 13.596 = 10333$ kilogrammes, or 1.0333 kilogrammes on a square centimetre.

To measure the elastic force of a quantity of air in an enclosed space, the open end of a barometer-tube is connected with this space, as in the barometer-gauge of the air-pump. If the gas is confined by a liquid, as in a jar standing over water or mercury, the difference of level of the liquid without and within the tube must be taken into account. This difference of level must be reduced to its equivalent in mercury

by multiplying by $\frac{d}{13.596}$ (d being the specific gravity of the liquid, and 13.596 that of mercury), and the product added to or subtracted from the height of the barometer, according as the level of the liquid within the gas-jar is below or above that without. If the gas stands over mercury, the preceding factor is reduced to 1; if over water, it is $\frac{1}{13.596} = 0.073551$.

The elastic force of a gas at a given temperature varies inversely as its volume. This law, called Boyle's or Mariotte's law, has been demonstrated experimentally up to pressures equal to twenty-seven times the ordinary pressure of the atmosphere, for gases capable of bearing that pressure without liquefaction. At pressures near those at which liquefaction takes place, the elasticity does not vary in the exact inverse ratio of the volume.

Elasticity of Liquids.—Liquids when subjected to pressure undergo a certain diminution of volume, and return to their original volume when the pressure is removed. The contraction produced even by very great pressures, is, however, very small, and consequently liquids were for a long time supposed to be absolutely incompressible; this conclusion was, moreover, supposed to be directly established by certain experiments made by the Florentine Academicians in the seventeenth century, in which closed metallic vessels completely filled with liquids were subjected to strong pressure or hammering; the vessels became cracked and the liquid oozed out, and this was regarded as a proof of its incompressibility. Canton in 1761 first attacked the problem in the right way, by subjecting liquids in thermometer-shaped vessels to strong pressure under the receiver of a condensing pump. These experiments established the fact of the compressibility of liquids, and subsequent researches by Perkins (Gilb. Ann. lxxii. 173; Pogg. Ann. ix. 547), by Oersted (Ann. Ch. Phys. [2] xxii. 190), and by Colladon and Sturm (Pogg. Ann. xii. 39), made with somewhat similar apparatus, afforded further proof of the compression, and determined its amount for several liquids. Subsequently experiments were made by Aimé (Ann. Ch. Phys. [3] viii. 257) on the coast of Algeria, by sinking thermometer-shaped vessels, attached to cords, in the sea, by which they were subjected to a pressure of 200 atmospheres.

Regnault has also made experiments on the compressibility of liquids by means of an instrument called a *piezometer*, consisting of a vessel like a thermometer with a cylindrical bulb and a graduated stem to hold the liquid; this vessel was enclosed in a strong vessel filled with water, and having a piston working water-tight in its neck, to communicate the pressure, and the whole was enclosed in a larger vessel of water to keep the temperature constant. In these experiments, the compression of the glass-vessel was directly determined, whereas former observers had determined this point from other observations, and not always with the same kind of glass. Lastly, Grassi (Ann. Ch. Phys. [3] xxxi. 437) has continued these experiments with the same apparatus, but using a more exact method of determining the compression of the glass vessel.

The following table gives the compressibility of several liquids, as determined by Grassi; the number for mercury is calculated from Regnault's experiments. The column headed "compressibility" shows the diminution in volume of a unit-volume

of the liquid when the pressure upon it is increased by 1 atmosphere. The column headed "pressure in atmospheres" shows the pressure to which the liquid was actually subjected; where blanks are left in this column, the superadded pressure was equal to 1 atmosphere.

Compressibility of Liquids (Grassi).

The compressibility of mercury, according to the older mode of calculation, is 0·000003517; the compressibility of de-aerated water at a given temperature is proportional to the pressure; the same is true for saline solutions and dilute sulphuric acid. In ether, alcohol, wood-spirit, and chloroform, the amount of compression increases more rapidly than the pressure. In different solutions of the same salt, the compressibility is smaller as the quantity of salt dissolved is greater. The compressibility of water decreases with rise of temperature; that of ether and of alcohol increases with the temperature. Water appears to exhibit a maximum of compressibility between 0° and 4·1 C.

The following table contains the results obtained by Colladon and Sturm and by Aimé; they agree very nearly with the preceding, excepting in the case of mercury. According to Colladon and Sturm, however, the compressibility of alcohol and ether decreases as the temperature rises.

Compressibility of Liquids (Colladon and Sturm; Aimé).

Elasticity of Solids.—The phenomena of elasticity in solid bodies are much more complicated than in liquids or in gases. Solids can be extended as well as compressed, or they may be compressed in one direction and at the same time stretched in another, as when a rod or plate is bent; and lastly they may be twisted, which effect may take place with or without compression or extension. When the alteration in size or form of a solid body is not carried beyond a certain limit, different for each body, the particles return exactly into their former relative positions on the removal of the disturbing force; in other words, within this limit of elasticity, the body is perfectly elastic. Beyond this limit, the alteration of form or size is more or less permanent, the molecules of the body no longer returning exactly to their former relative positions, as in malleable and ductile bodies, which retain whatever form is given them by strong pressure or hammering.

For some kinds of iron, the limit of elasticity corresponds to a tension of about 14 kilogrammes for each square millimetre of the transverse section; for other kinds, about 20 kilogrammes. If a bar or wire of iron be stretched by a force less than this, the extension is found to be proportional to the stretching force applied; beyond this limit, the extension increases more rapidly than in the direct ratio of the force, the wire becoming permanently stretched; and when the tension is increased to about 40 kilogrammes per square millimetre, the wire breaks. Other metals exhibit similar relations.

The coefficient of elasticity is the extension produced on the unit of length, by the unit of tension exerted upon the unit of transverse section; the reciprocal of this number is called the modulus of elasticity. Suppose a prismatic rod whose

length is l and transverse section c , to receive the elongation l' by a force P , within the limit of elasticity, pulling in the direction of its length; then $\frac{P}{c}$ is the tension exerted on the transverse section 1, and $\frac{l'}{l}$ the elongation produced by this force in the length 1. Consequently $\frac{l'}{l} : \frac{P}{c} = \frac{l'c}{lP}$ is the coefficient of elasticity, and $\frac{lP}{l'c}$ the modulus of elasticity of the rod. If the modulus be denoted by E , the elongation a produced by the stretching force S on the transverse section 1 will be $a = \frac{S}{E}$, or if ϵ be the coefficient of elasticity, $a = S\epsilon$. The length of the rod being l , the elongation of the rod by the tension S (or $\frac{P}{c}$) is la ; consequently $l' = la = \epsilon \frac{Pl}{c} = \frac{Pl}{cE}$.

Similar formulæ apply to the case of compression; E and F have then the same values as for tension, but the modulus of elasticity will perhaps have a different value. The equation $Ea = S$ shows that the modulus of elasticity is the tension which would produce the unit of elongation, that is to say, would stretch the rod to twice its primitive length, supposing that it would conform to the laws of elasticity up to that limit, instead of breaking, as most bodies would do, long before. The only substance that will bear such an amount of tension without disruption is vulcanised caoutchouc.

The following table gives the moduli of elasticity, expressed in kilogrammes, for a transverse section of 1 square millimetre, of certain metals and alloys. The numbers in the last two columns were not obtained with the same wires as those in the first three.

Name of metal.	Specific gravity.	Modulus of Elasticity.				
		Of the annealed metal.			Of the unannealed metal.

Brass	8.247	9005	9782

The modulus of elasticity of an alloy is nearly the mean between those of the component metals. The passage of an electric current somewhat diminishes the modulus of elasticity of a metal (independently of the diminution consequent on the rise of temperature, produced at the same time), the effect ceasing, however, with the passage of the current. (Wertheim.)

Crystallised bodies not belonging to the regular system exhibit different degrees of elasticity in different directions.

ELATERIN. A substance contained in the fruit of the spirting cucumber (*Momordica Elaterium*), whence it may be extracted by boiling alcohol, and purified by precipitation with water, washing with ether, and recrystallisation from hot alcohol. It forms colourless hexagonal tables, fusible, decomposable by heat, insoluble in water, sparingly soluble in ether, very soluble in alcohol. It dissolves in sulphuric acid, forming a red liquid, which, when diluted with water, deposits a brown substance. Nitric acid dissolves elaterin without alteration. Elaterin is precipitated from its alcoholic solution by acetate of lead and nitrate of silver. Taken internally, it acts as an emetic and as a purgative. It gives by analysis 69.23 to 69.49 p. c. carbon, and

8.23 to 8.21 hydrogen, agreeing nearly with the empirical formula $C^{20}H^{14}O^4$. (Zwenger, Ann. Ch. Pharm. xliii. 359.)

ELATERITE. *Elastic bitumen. Mineral caoutchouc.* A fossil resin resembling asphalt, occurring in soft, flexible, somewhat elastic masses, at Castleton in Derbyshire, in a coal mine at Montrelais near Nantes at the depth of 230 feet, also at Neufchatel, and on the island of Zante. Specific gravity of the Derbyshire variety = 0.9053 to 1.233. Lustre, resinous. Colour, blackish-brown of various shades. Subtranslucent, sometimes exhibiting a dark orange-red colour by transmitted light. It takes fire readily, and burns with a lively yellow flame, emitting a bituminous odour. According to Johnston (Phil. Mag. 1838, July 23), it is a hydrocarbon containing 83.7—85.5 carbon, and 12.5—13.28 hydrogen. Henry (Ann. Phil. 1826, p. 70), on the other hand, found from 36.75 to 40.10 oxygen, whence Rammelsberg (*Mineral-chemie*, p. 966) concludes that it consists mainly of a hydrocarbon C^nH^{2n} , but mixed with an oxygenated compound.

ELATERIUM. The extract obtained by evaporating the juice of the fresh fruit of the spirting cucumber (*Momordica Elaterium*). It has a greenish or green-brown colour, a sharp bitter taste, and acts as a drastic purgative and an emetic. It contains elaterin, together with starch, resin, &c.

ELATHIN. An oily body produced by the action of ammonia and sulphur on acetone, and passing over on distillation between 120° and 200° C. (Zeise, Ann. Ch. Pharm. xlvii. 43.)

ELATIN. Syn. with ELATERIN.

ELAYL. Syn. with ETHYLENE.

ELECAMPIN. Syn. with INULIN.

ELECTRICITY. (Robison's *Mechanical Philosophy*, edited by Brewster, London, 1822, iv. 1. — Roget, *Library of Useful Knowledge; Natural Philosophy*, vol. ii. London, 1828. — Becquerel, *Traité expérimental de l'Électricité et du Magnétisme*, 7 tomes, Paris, 1834–1840. — Faraday, *Experimental Researches in Electricity*, 3 vol., London, 1839–1855. — J. Müller, *Lehrbuch der Physik und Meteorologie*, 2 Bände. Braunschweig, 1853. Bd. ii. S. 61. — P. T. Riess, *Die Lehre der Reibungs-electricität*, 2 Bände. Berlin, 1853. — De la Rive, *Traité d'Électricité théorique et appliquée*. 3 tomes, Paris, 1854–1858.

The phenomena displayed by rubbing a piece of amber, constitute one of the earliest physical facts recorded in the history of science. Thales, of Miletus, ascribed its mysterious power of attracting and repelling light bodies to an inherent soul or essence, which, awakened by friction, went forth and brought back the small particles floating around. In times near to our own, the same hypothesis was resorted to by Robert Boyle. From *ἤλεκτρον*, the Greek name of amber, the name “electricity” has been applied to the science which investigates the attractions and repulsions, the emission of light, explosions, and a variety of physical and chemical phenomena, which are produced, not only by the friction of vitreous, resinous, and metallic surfaces, but by various other modes of mechanical disturbance, by heat, by chemical action, and by magnetism.

If we rub a glass tube with a dry hand or a silk handkerchief, and then approach it to bits of paper or cotton, feathers, gold leaf, it will first attract these bodies, and then repel them. If the tube be held parallel to a table on which they have been laid, an electrical dance will be performed.

In a dark room, flashes of bluish light will be seen to play about the surface of the tube, while it is being rubbed, and on approaching the knuckle to it, a spark will pass between the two, accompanied by a snapping noise.

If to the farther end of the tube we hang a brass ball, by a thread of linen, hemp, or a metallic wire, the ball will participate with the rubbed tube in its attractive powers. But if the ball be suspended by a cord of silk, worsted, or hair, or by a rod of glass, wax, or pitch, the attractive and repulsive virtue will not pass into it.

This last experiment shows that the electric power, when developed, passes easily through some bodies and not through others. The former are called conductors of electricity; the latter non-conductors, or insulators. These last terms must not, however, be taken in their absolute sense; there is no known body which is absolutely destitute of the power of conducting electricity: in fact, there is a regular gradation of power from the best conductors to the worst.

1. The following is a list of conductors of electricity—that is to say, of bodies through which that power passes without much resistance—arranged in the order of their conducting power, the best conductors standing at the head of the list.

The metals
Charcoal
Plumbago
Strong acids
Soot and lamp-black
Metallic ores
Metallic oxides
Dilute acids
Saline solutions
Animal fluids
Sea-water

Rain-water
Ice and snow above 0° F.
Living vegetables
Living animals
Flame
Smoke
Vapour
Salts
Rarefied air
Dry earths
Massive minerals.

The metals differ greatly among themselves in conducting power: the methods of estimating their relative conducting powers will be described hereafter.

2. The following is a list of electrical non-conductors, in the inverse order of their insulating power:—

Dry metallic oxides, including fused alkaline and earthy hydrates
Oils, of which the densest are best
Ice below 0° of Fahr.
Phosphorus
Dry chalk and lime
Lycopodium
Caoutchouc
Camphor
Massive minerals, non-metallic
Marble
Porcelain
Baked wood, and dried vegetables
Dry paper, parchment, and leather

Dry gases
Wool, hair, and feathers
Dyed silk
Bleached silk
Raw silk
Glass, and all vitrified bodies, comprehending diamond and crystallised transparent minerals
Asphaltum
Wax
Sulphur
Resins, including gutta percha
Amber
Shellac.

Gutta percha possesses very great insulating power, but its place in the list has not been determined with certainty; indeed its insulating power varies considerably with its quality. Gun-cotton and collodion are likewise excellent insulators.

All bodies are capable of becoming electric by friction; but to enable a conducting body to exhibit this power when excited, it must be *insulated*, that is to say, cut off from electric communication with the ground: thus, if we hold a brass rod in the hand and rub it, no signs of electricity will be apparent, because the electricity, as fast as it is developed, passes along the rod into the hand which holds it, thence through the body, which is made of conducting materials, into the ground, where it is lost by diffusion; but if a metal cylinder be supported on a stem of glass, gutta-percha, or shellac, or suspended by silk cords, and then rubbed with flannel or beaten with a cat-skin, it will acquire the property of attracting light bodies.

It was formerly supposed that conducting bodies could not be excited by friction: hence they were called non-electrics, non-conducting bodies being called electrics; the latter term is still often applied to bodies, like glass and shellac, which are the most easily excited by friction.

When an excited electric is brought in contact with another non-conducting body, the part of the latter touched by the excited body becomes electrical, but the power does not spread over its surface: but when one point of an insulated metal rod or ball is touched by an excited electric, the power is immediately communicated to every part of it; and if the conductor thus electrified be touched by another insulated conductor, the whole surface of that conductor immediately becomes electrified, acquiring the power of giving sparks and attracting light bodies, and at the same time the electric power of the first conductor is diminished in intensity. In fact, the electric power originally possessed by the one is now distributed between the conductors in the proportion of their surfaces.

The facility with which electricity is communicated from one conducting body to another, renders the complete insulation of conductors of great importance in all electrical experiments. Light bodies, such as balls of elder-pith, feathers, &c., used to exhibit attraction and repulsion, are suspended by silk cords: metallic conductors are supported on rods of glass, gutta-percha, shell-lac, or sealing-wax. The air when dry is an insulator: indeed, if this were not the case, it would be scarcely possible to obtain any manifestation of electric power, as it would be dissipated into the atmosphere as fast as it was developed; and, in fact, in a damp atmosphere it is very difficult to retain the electric power on the surface of any excited body, as the aqueous vapour

possesses considerable conducting power. Moreover, the atmospheric moisture quickly condenses on the insulating supports, especially on glass and silk, and completely destroys their insulating power; hence it is of great importance, when working in a damp atmosphere, to keep the insulating supports as warm as possible, and to rub them frequently with a dry cloth. The insulating power of glass is greatly increased by covering it with copal varnish.

The insulating power of air is likewise diminished by heat; indeed very hot air conducts with great facility. The best way of depriving an excited non-conductor of its electric charge is to move it about for a while a few inches above the flame of a spirit-lamp.

OF THE TWO ELECTRICITIES.

The phenomena above mentioned, that is to say, the attraction and subsequent repulsion of light bodies, and the production of the electric light, are manifested by all bodies whatever, when in a state of electric excitement, whether brought into that state by friction, or by communication with a previously excited body. In certain respects, however, the electric powers excited in different bodies are opposed to, and capable of neutralising, one another.

Rub a glass tube with silk, and bring it near a feather suspended by a silken cord; the feather will approach the glass, remain in contact with it for a short time, then fly off, and will afterwards be persistently repelled by the glass. Now rub a piece of sealing-wax with flannel, and bring it near another feather suspended on silk: the same phenomena will take place; but, on the other hand, the feather which is repelled by the excited glass is attracted by the excited wax, and that which is repelled by the wax is attracted by the glass. Moreover, the two feathers thus electrified attract each other, whereas two feathers electrified by contact, either with the glass or with the wax, repel each other.

There are, then, two kinds of electric force, exactly similar in certain of their manifestations, but directly opposed in others. One of these powers, which is developed most frequently, though not invariably, on glass, is sometimes called *vitreous electricity*; and the other, which is most frequently manifested by resinous and waxy bodies, is called, *resinous electricity*. The phenomena above described may be summed up as follows:—*Bodies similarly electrified* (both vitreously or both resinously) *repel each other*, and *bodies dissimilarly electrified* (one vitreously and the other resinously) *attract each other*.

Neither of these electric powers is ever manifested without the other, though from the manner in which the excitement is produced, it frequently happens that only one becomes apparent. Experiment shows, that in all cases whatever, when two bodies are rubbed together, one becomes vitreously, the other resinously electrified. Thus, if a stick of sealing-wax be rubbed with a piece of flannel attached to the end of a glass rod or a stick of baked wood, the wax will acquire resinous, the flannel vitreous electricity, the one attracting a feather or pith-ball which has been in contact with and is repelled by the other. In like manner it may be shown, that when glass is rubbed with silk, the glass becomes vitreously, the silk resinously electrified. If the rubber in either case, instead of being fixed on an insulating support, be held in the hand, the electricity which it acquires cannot show itself, because it passes through the body into the ground.

The kind of electricity which any given substance acquires by friction is not always the same, but varies according to the nature of the substance against which it is rubbed. Thus, woollen cloth becomes vitreously electrified when rubbed against wax or resin, resinously when rubbed against glass; glass itself becomes resinous when rubbed with a cat-skin, vitreous when rubbed with cloth. The following table, taken from De la Rive, gives a list of substances, each of which becomes vitreously electrified when rubbed with either of those which follow it; resinously, when rubbed with either of those which precede it:—

The skin of a cat
Diamond
Flannel
Ivory
Rock-crystal
Wool
Glass
Cotton
Linen cloth
White silk
The dry hand

Wood
Sealing wax
Colophony
Amber
Sulphur
Caoutchouc
Gutta percha
Prepared paper
Collodion
Gun-cotton.

No visible relation can be pointed out between the nature or constitution of the substances, and the species of electricity which is developed by their mutual friction. The only general law among the phenomena is, that the rubbing and the rubbed body always acquire opposite electricities. Sulphur is vitreously electrified when rubbed with every metal except lead, and resinously with lead and every other kind of rubber. Resinous bodies rubbed against each other acquire alternately the vitreous and resinous electricity; but, rubbed against all other bodies, they become resinously electrical. White silk acquires vitreous electricity with black silk, metals, and black cloth; and resinous with paper, the human hand, hair, and weasel's skin. Black silk becomes vitreously electrical with sealing-wax, but resinously with hares', weasels', and ferrets' skins; also with brass, silver, iron, the human hand, and white silk. Woollen cloth is strongly vitreous with zine and bismuth; moderately so with silver, copper, lead, and specular iron. It is resinous with platinum, gold, tin, antimony, grey copper, protosulphide and hemisulphide of copper, and the sulphides of silver, antimony, and iron. When two ribands of equal surface are excited by drawing one lengthwise over a part of the other, that which has suffered friction in its whole length becomes vitreously, and the other resinously, electrical. Silk stuffs agitated in the atmosphere with a rapid motion, always take the resinous electricity, while the air becomes vitreously electrified. The general result which was deduced by Coulomb, from his very numerous and exact experiments on this subject, is the following:—

When the surfaces of two bodies are rubbed together, that whose component parts recede least from each other, or are least disturbed from their natural position of repose, appear, in consequence, more disposed to assume the vitreous electricity: this tendency augments if the surface experiences a transient compression. Reciprocally, that surface whose particles deviate most from their ordinary position, by the violence of the other, or by any cause whatever, is, for that reason, more disposed to take the resinous condition. This tendency increases if the surface undergoes a real dilatation. The stronger this opposition of circumstances, the more energetic is the development of electricity on the two surfaces. It grows feebler in proportion as their state becomes more similar. Perfect equality would nullify the phenomena, provided it could exist. Thus, when a dry animal or vegetable substance is rubbed against a rough metallic surface, it exhibits signs of resinous electricity: in this case, its parts are forcibly separated. When, on the other hand, it is rubbed on a polished metal, which scarcely affects its surface, or merely compresses the particles, it either affords no evidence of electricity, or it exhibits the vitreous kind. Heat, by dilating the pores, acts on the surfaces of bodies as a coarser rubber would do. It disposes them to take the resinous electricity. Thus, also, new black silk, strongly dyed, being rubbed against a riband of white, takes always the resinous electricity. But when the black stuff is worn, and the colour faded, if we open the pores of the white riband by heat, this acquires in its turn a greater tendency to the resinous electricity than the black silk, and consequently makes it vitreous. This disposition vanishes, as might be expected, with the accidental cause that produced it; and the white riband, on becoming cold, reacquires the vitreous electricity. The black dye produces on wool the same effect as on silk. A white riband, rubbed against white woollen stuff, always gives signs of resinous electricity; but, against wool dyed black, it affords signs of vitreous electricity.

There are several other ways, besides friction, of developing electricity, viz., by heat, by magnetism, by chemical action, and by the change of state of bodies from the solid to the liquid and gaseous, and *vice versâ*; but it is better to defer their consideration till we have considered the principal properties and effects of electricity developed by friction.

Theory of Electricity.—The facility with which electricity is communicated from one body to another, and makes its way to all parts of a conducting body, or chain of conductors, however complex in form, gave rise, at an early stage of the science, to the idea that it is a fluid; and the discovery of the opposite characters of vitreously and resinously electrified bodies further led to the hypothesis that there exist two such fluids or at least two modifications of the same fluid, which, when they exist together, neutralise each other's effect, but when separated manifest themselves in the several ways already noticed.

Reserving for a future part of this article the discussion as to the comparative merits of this theory and others which have been proposed for explaining the phenomena of electricity, we shall for the present regard it merely as a convenient mode of linking together, and generalising those phenomena,—presenting it for this purpose in the form of the following propositions:

1. All bodies contain two very mobile, elastic, imponderable fluids, called the electric fluids.
2. The particles of each of these fluids repel each other, and attract those of the

other fluid, with forces which are equal at equal distances, but diminish with increase of distance.

3. These fluids are capable of passing from one body to another, and travelling over or through different bodies with different degrees of facility.

It is easy to see that the theory thus stated accords with all the phenomena hitherto described. When the two fluids are contained in a body in equal quantities, their attractive and repulsive forces, exerted on any particle of either fluid situated externally to that body, are equal, and neutralise each other, so that no electrical phenomena are apparent, but the body appears in its ordinary state. But when, by friction or otherwise, a separation of the fluids takes place, and one of them becomes accumulated on a body, or a particular part of a body, in greater quantity than the other, the excess will show itself by attractive and repulsive forces exerted upon the fluids contained in neighbouring bodies.

When two movable bodies, pith-balls for instance, are charged with the same kind of electricity (say vitreous), the excess of vitreous fluid in each is driven to the outer side, where its further progress is prevented by the air, through which it cannot readily pass; it there exerts a pressure on the two balls in opposite directions, causing them to recede from one another. If the two bodies are oppositely charged, the excess of vitreous electricity of the one, and the resinous electricity of the other, attract each other and accumulate on their contiguous surfaces, where they exert a pressure impelling the balls towards each other. If the balls actually come in contact, an interchange of the two electric fluids takes place between them, and if they were charged with equal quantities of the two fluids, their charges neutralise each other exactly, and both bodies return to their natural state, no longer appearing electrified. If the quantity of vitreous electricity on the one was larger than that of resinous electricity on the other, both appear vitreous after contact, and *vice versâ*.

The neutralisation or union of the opposite electricities may also take place without actual contact. Suppose two brass balls supported on insulating stands to be oppositely electrified and gradually brought nearer to each other. As they approach, the opposite electric fluids will be drawn more and more to the nearest points of their surfaces, and at length the attraction between them will become strong enough to overcome the resistance of the intervening air. The union of the opposite electricities then takes place through the air in the form of an electric spark, longer and brighter, as the quantities of the opposite fluids present on the balls are greater. If the balls cannot be brought near enough, the union of their opposite electricities may be effected by connecting them by means of an insulated metal rod or other conductor. In either case, the balls after being connected, appear neutral or similarly charged, according as their opposite charges were equal or unequal.

The union of the opposite electricities in either of the ways above mentioned is called the electric discharge. In the case just considered, it is instantaneous; but suppose the two brass balls or other conducting bodies, to be connected, one with a constant source of vitreous, the other with a constant source of resinous electricity, and a communication made between them by a rod or wire of metal: in that case, an uninterrupted series of charges and discharges of the opposite electricities will take place along the conducting chain. This is called the electric current; we may suppose indeed that a stream of vitreous electricity is flowing through the conductors in one direction, and a stream of resinous electricity in the other, during the whole time that the action is kept up.

Electricity in the state of discharge, whether sudden or continuous, is called dynamic electricity, that is, electricity in motion; in the charged state it is called static electricity, or electricity of tension.

The opposite electricities are now most frequently distinguished by the terms positive and negative, the former being used synonymously with vitreous, the latter with resinous electricity. It must be distinctly understood, however, that there is nothing in the first mentioned kind of electricity (that commonly developed on glass) to entitle it to be considered more positive than the other. The terms positive and negative as applied to the two electricities, are intended merely to indicate opposition of properties and the power of mutual neutralisation. It is often convenient to abbreviate them into $+E$ and $-E$.

ELECTRICAL MACHINES.

For the study of electrical phenomena, it is necessary to have means of liberating the electric fluids in larger quantity than is possible by the simple apparatus hitherto mentioned. Machines for this purpose consist of a cylinder or circular plate of glass turning on a horizontal axis and rubbing against a cushion of silk or leather. The

glass thus acquires a charge of positive or vitreous electricity, which is transferred to an insulated metallic conductor.

Fig. 370 represents a cylinder machine. The cylinder rubs against the cushion, which is attached to a hollow brass cylinder supported on glass legs. To the upper edge of the cushion is attached a silk flap which lies over the upper part of the glass cylinder. On the other side of the glass cylinder is another brass conductor, called the *prime conductor*, also supported on glass legs, and having on the side next to the glass cylinder a row of pointed wires, fixed to it on a level with the axis of the cylinder; these are for the purpose of facilitating the passage of the electricity from the glass cylinder to the conductor, as will be presently explained.

The cushion is covered with an amalgam of mercury, tin, and zinc, mixed up to a pasty consistence with tallow-grease or lard. This amalgam is found to be the best of all exciters for glass. A good proportion of the ingredients is 65 pts. mercury, 24 tin, and 11 zinc. They should be melted together and constantly stirred. Bisulphide of tin is also a good material for covering the rubber; but it is troublesome to prepare.

On turning the cylinder, the glass acquires positive electricity, the cushion and the brass conductor attached to it negative electricity, and the positive charge of the glass is transferred to the prime conductor. If both conductors are insulated, the charge on each of them soon reaches its maximum; that is to say, the transfer of $+E$ to the glass, and of $-E$ to the cushion, soon becomes as great as the machine is capable of effecting; but if the negative conductor is connected with the ground by a brass chain or wire, the $-E$ developed on the cushion is at once carried away, and an equal quantity of $+E$ is transferred to the glass cylinder, and thence to the prime conductor, which will then give off its positive charge in long bright sparks to any conducting body brought near it. If, on the other hand, the positive conductor be connected with the ground, and the negative conductor insulated, the $+E$ is continuously carried away into the earth, and an equal quantity of $-E$ is transferred from the prime conductor to the glass cylinder, and thence to the negative conductor, which then acquires a high negative charge, and will also give bright sparks to any conductor presented to it. If both conductors are insulated, and jointed brass rods terminated by knobs inserted into them and brought within a short distance of each other, the $+E$ and $-E$ recombine in a continuous series of sparks as long as the machine is worked. If the terminal knobs are brought very close to each other, the sparks are small but more continuous than when the interval between the knobs is greater; and if the two knobs are brought into actual contact, no sparks pass, and, indeed, neither conductor shows any signs of charge, either by giving sparks or by attracting light bodies; nevertheless, as long as the machine is worked, the separation of the two electricities is going on at the surface of contact of the glass and cushion; the $+E$ is being transferred to the one conductor, the $-E$ to the other, and the two are continually re-uniting along the connecting brass rods; in short, an electric current is established through the machine, and though it does not show itself in any of the ways just mentioned, may be made to produce a variety of effects which will be described hereafter.

The *plate-machine* represented in *fig. 371* will be understood without special description. Various forms are given to it. In that shown in the figure, which is the ordinary form, the rubber is uninsulated, so that there is no means of obtaining negative electricity, and to insulate the cushions of a plate machine introduces considerable complication. For this reason cylinder machines are the more convenient for the purpose of illustrating

Fig. 370.

Fig. 371.

the principles of the science. When, on the other hand, it is merely required to obtain one kind of electricity, as for investigating the effects of the electric discharge or current on bodies through which it passes, plate machines are usually preferred, as they are more compact, and yield a greater quantity of electricity from a given surface of glass.

Recently, ebonite (hardened caoutchouc) has come much into use instead of glass for plate electrical machines; it produces powerful electric excitement, and does not condense moisture on its surface so readily as glass does; hence, while new, it is better adapted for use in damp weather; but the friction of the rubber destroys the polish of its surface, whereby its efficiency as a source of electricity is greatly diminished. The electricity obtained from the prime conductor of a machine with an ebonite plate is resinous or negative electricity.

ELECTROSCOPES AND ELECTROMETERS.

An *electroscope* is an instrument for indicating the presence of electricity in a state of charge or tension, by means of the attraction and repulsion of light bodies. In this sense any light body, such as a feather or a pith-ball, suspended by a silk line, may be regarded as an electroscope. Two pith-balls connected by a linen or cotton thread, which is a conductor, and hung over an insulated metal rod to which a charge is communicated, will indicate its presence by their divergence. For detecting small charges of electricity, the gold-leaf electroscope (*fig. 372*,) is a very convenient and indeed indispensable instrument. It consists of a glass jar open at both ends, and supported on a wooden stand covered with tin foil. The neck is closed with a cap, through which there passes a brass rod *c*, to the lower extremity of which are attached two strips of gold-leaf or Dutch metal; to the upper end of the rod *c* is attached a brass cap *b*. A charge of electricity communicated to this cap is immediately transferred to the leaves, and causes them to diverge. As a strong charge sometimes causes the leaves to strike against the sides of the glass, thereby giving it a charge of electricity, which, if retained, would disturb the indications of the instrument, two strips of tin foil, *e f*, are pasted on the inside of the jar, so that when the leaves strike against them, the charge may be immediately carried down into the stand, and thus got rid of. Where very great delicacy is not required, it is best to use leaves of Dutch metal, as they are easily replaced when injured; but for greater delicacy gold leaves must be used. The sensitiveness of the instrument is greatly increased by certain additions, to be afterwards described.

Fig. 372.

Fig. 373.

To test the kind and degree of charge of an electrified body by means of this instrument, the body is touched with a small brass ball suspended by a silk line, or with an instrument called a *proof plane*, consisting of a small disc of gilt paper attached to a thin stick of shellac, and the ball or plane is then brought in contact with the cap of the electroscope. The degree of divergence of the leaves gives an approximate indication of the strength of the charge; and its nature, whether positive or negative, may be known by holding above the cap an excited glass rod, which increases or diminishes the divergence of the leaves, according to the kind of electricity with which they are charged. For a description of Peltier's electroscope, see Peltier, (*Ann. Ch. Phys.* [2] lxii. 422), also Riess (*Reibungs-Electricität*, i. 64).

An *electrometer* is an instrument for measuring quantitatively the charge of an electrified body. The one most used is the torsion balance or torsion

electrometer of Coulomb, represented in *fig. 373*. It consists of a glass case *A* (*fig. 373*),

of cylindrical or cubical form, surmounted by a vertical glass tube about 2 feet high; through the axis of the tube there passes a silver wire or a glass thread, carrying at its lower extremity a brass weight, which stretches it, and through which there passes a needle of shell-lac, terminated by gilt pith-balls, *e, f*. The wire or glass thread is fastened at its upper extremity to a button, *b*, which moves stiffly in the cap, and carries an index, *i*, moving over a graduated circle, to measure the angle through which the thread is twisted. In the cover of the glass case there is a lateral aperture, *m*, for introducing a gilt pith ball attached to a shellac stem, this ball having the same diameter as those at the end of the needle (sometimes proof planes are substituted for the balls). This ball, after having been brought in contact with the body whose electric charge is to be measured, is introduced into the glass case, as shown in the figure, where it first attracts the ball *e*, and then having charged it, repels it to a certain distance, which may be measured in degrees on the divided circle. Now when a thread or wire is twisted, the force with which it tends to untwist increases in direct proportion to the angle of torsion. Thus, if one electric charge drives the movable ball to 10° from the fixed ball and another drives it 20° , the repulsive force in the second case is twice as great as in the first. But the usual mode of working with the torsion balance is, after having communicated the charge to the movable ball, and driven it off, to twist the thread the contrary way, till the movable ball is brought within a certain distance of the fixed ball. Suppose that this distance is 10° , and the thread has been twisted through 20° ; then the total force of torsion is 30° , for the thread is twisted through 10° at the bottom and 20° at the top. The use of the instrument will be illustrated by describing its application to the investigation of the

LAWS OF ELECTRIC ATTRACTION AND REPULSION.

1. *With regard to distance.*—Let the fixed ball be charged from the conductor of an electrical machine, and its charge communicated to the movable ball as above described. Suppose the movable ball to become stationary at 36° from the fixed ball, the thread or wire having been previously quite untwisted. Now let the wire be twisted till the movable ball is brought to 18° distance from the fixed ball; for this it will be found necessary to twist the wire through 126° , making the entire torsion equal to $126^\circ + 18^\circ = 144^\circ$. Next let the wire be further twisted till the distance between the two balls is reduced to 9° ; this will require the wire to be twisted through 567° , making the entire torsion $= 567^\circ + 9^\circ = 576^\circ$. The forces required to keep the balls at 36° , 18° , and 9° apart are therefore as the numbers 36, 144, 576, that is to say, when the distances are as $1 : \frac{1}{2} : \frac{1}{4}$, the repulsive forces are as $1 : 4 : 16$; hence the repulsive force exerted between two bodies similarly electrified varies inversely as the square of the distance.

In like manner by charging the fixed and movable balls with opposite electricities, it may be shown that the attractive force follows the same law.

2. *With regard to quantity.*—Coulomb's method of determining the manner in which the attractive or repulsive force between two electrified bodies varies with the quantities of free electricity contained in them, is based upon the obvious assumption that if two equal and similar insulated conductors, two equal metallic spheres, for example, be electrified and placed in contact, the electric charge will be divided equally between them. This being granted, the law in question may be investigated as follows:—Observe the force of torsion which at a certain distance equilibrates the attractive or repulsive force exerted between the fixed and movable ball of the torsion balance, which, as already observed, are of equal diameter. Now take a third gilt ball, likewise of the same size, and insulated, but not electrified, and touch with it the fixed ball of the balance. This contact deprives the fixed ball of half its electricity, the charge of the movable ball remaining unaltered. It will then be found that the force of torsion required to keep the balls at the same distance is only half what it was before. If the electricity of the movable ball be then reduced to one-half in the same manner, the force required to keep it at the same distance will be reduced to one-fourth of its original amount, and by again reducing the charge of either ball one-half, the force required will be reduced to one-eighth of the original amount. Hence: *At a given distance the attractive and repulsive forces exerted between two electrified bodies are as the product of the quantities of free electricity contained in them.*

If then *E, E'* are the quantities of free electricity in two bodies, and *D* the distance between them, the attractive or repulsive force between them is represented by the equation:

$$F = m \frac{EE'}{D^2}$$

m being a constant.

This law is, however, subject to modification, depending on the form of the body and on the mode of distribution of the electric charge upon it. Like the law of gravitation, it is strictly true only for material points, or for spheres, which act upon one another like material points situated at their respective centres, or for other bodies whose dimensions are insignificant as compared with the distances between them. Moreover, when two charged bodies are in presence of one another, the distribution of the charge on each is not the same as if the other were removed; and this also materially affects the magnitude of the resultant attractive or repulsive force exerted between them. Coulomb's experiments, which were made with spheres, may, however, be regarded as proving that the attraction and repulsion between the ultimate particles of the electric fluids follow the law of the inverse squares.

DISTRIBUTION OF ELECTRICITY.

In consequence of the mutual repulsion of the particles of each of the electric fluids, and the facility with which they can traverse conducting bodies, it follows, that any charge of electricity communicated to an insulated conductor will be confined to its surface, the interior remaining in the neutral state; for even if a charge of either electricity be communicated to the interior of a solid conductor, the mutual repulsion of its particles will drive it to the surface, where it will be retained by the insulating power of the air, or other surrounding non-conductor. The experimental proof of this proposition is easy. Charge an insulated metallic vessel of any shape whatever with electricity from the conductor of a machine; touch different parts of its surface with a proof-plane or carrier-ball, (p. 380), and then bring the plane or ball in contact with a gold-leaf electroscope; the external surface will be found strongly charged, while the inner surface exhibits no charge whatever, and this will be the case even though the external surface is charged sufficiently to give strong sparks.

It follows from this, that a charge of electricity is distributed between two conductors in contact in proportion to their surfaces, not to their masses. Coulomb gave experimental proof of this by observing the repulsive force between the two balls of the torsion balance, before and after the fixed ball had been touched with a third ball of exactly the same size, likewise insulated but unelectrified. Whether this third ball was solid or hollow, made of copper, lead, or any other metal, of wood, cork, or elder-pith, or, in short, of any conducting substance whatever, it always took away from the fixed ball of the torsion balance half the electricity which it possessed. If the un-electrified ball had a double surface, the electric charge of the fixed ball of the torsion balance was reduced to a third of its original amount; and in all cases, the charge was found to be distributed between the two in the proportion of their surfaces.

Distribution of electricity on surfaces of different forms.—When an insulated metallic sphere placed at a considerable distance from all other conducting bodies is charged with electricity of either kind, all the points of its surface are found to be charged in the same degree: this may be shown by means of the proof-plane and torsion balance, as already described. This uniformity of charge implies that the electric fluid is distributed over the surface of the sphere in a stratum of uniform thickness; for if there were more at one point than at another, the proof-plane would then receive a higher charge. This mode of distribution is a direct consequence of the law of variation of force according to the inverse squares of the distances. To show this, let the circle *b g d* (fig. 374) represent a section through the centre of a conducting sphere charged—say

Fig. 374.

with $+E$. It is clear that when the whole is in a state of equilibrium, any particle of positive electricity *a*, within the sphere must be equally repelled by the portions of electric fluid situated on opposite parts of the surface, and any particle of negative electricity equally attracted by such opposite portions. Draw through *a* two straight lines *daf*, *gah*, making a small angle with each other, and suppose them to revolve round the line *bac* bisecting the angle *dag*. They will then trace out two small conical spaces, the bases of which are portions of the spherical surface. The condition of equilibrium of the particle *a* is that the action exerted upon it by the fluid on the portions of surfaces *dg* and *fh*, must be equal. Now the action of any particle in the surface *dg* on *a*, is to that of a particle in *fh* as $(ac)^2$ to $(ab)^2$; therefore, to ensure equilibrium, the quantity of electricity on the surface *dg* must be to that on *fh* as $(ab)^2$ to $(ac)^2$; but these

surfaces themselves are to one another in the same ratio; hence it follows, that the thickness of the stratum of electric fluid on dg must be the same as that on fh . If, for example, $ab = 2ac$, then the quantity of electricity on dg must be four times as great as that on fh ; but the surface $dg = 4fh$; and it is evident that a fourfold quantity spread over a fourfold surface must form a stratum of the same thickness.

But in an oval-shaped body, such as that represented in section in *fig. 375*, a similar construction will show that the electric fluid must be accumulated in a thicker stratum towards the narrow ends. For in this case the surface dg bears to fh a ratio greater than that of $(ab)^2$ to $(ac)^2$, greater therefore than the ratio of the quantity of electricity on dg to that on fh ; consequently, the thickness of the stratum of fluid in dg must be less than that on fh . In the case of an ellipsoid of revolution, mathematical analysis shows that the thicknesses of the electrical stratum at the ends of the axes are directly as the lengths of those axes; and this conclusion is confirmed by experiments with the torsion balance.

Fig. 375.

In general, all elongated conductors exhibit an excess of electrical charge towards their extremities. A cylinder 5 centimetres in diameter and 85 centimetres long, with hemispherical ends, was found by Coulomb to exhibit at the extremities an electric charge 2.3 times as great as in the middle; at 25 centimetres from the extremities, the charge was 1.25 times as great as in the middle. In a prismatic conductor, the distribution is similar; in a thin plate, the thickness of the electric stratum increases rapidly from the middle towards the edges. Now the tendency of electricity to escape from any part of a charged conductor, increases rapidly with the thickness of the stratum of electric fluid at that point, in consequence of the crowding together of a greater number of mutually repulsive particles within a given space. Hence it follows that elongated conductors, such as pointed rods, will discharge electricity much more rapidly than rounded ones; indeed, when a pointed rod or wire is inserted into the conductor of an electrical machine, it is impossible to obtain large sparks from it, however quickly the machine may be worked, the charge being rapidly dissipated from the point. Hence, to retain the charge on the surface of a conductor, that surface must be well polished, and free from all sharp projections.

The discharge of electricity from a pointed conductor gives rise to a rapid charging of the surrounding particles of air, and these particles becoming electrified, similarly to the conductor, are quickly repelled from it, and produce a wind, blowing as it were from the extremity of the conductor. Moreover, since the repulsion is mutual, if the pointed conductor be movable, it will be impelled in the opposite direction to the stream of air. Thus, if a cross formed of brass wires, having their ends bent in one direction, as in *fig. 376*, be supported by a cap on a pointed rod inserted into the conductor of an electrical machine in action, it will rotate in a direction opposite to that in which the points are turned.

Fig. 376.

Quantity and Intensity of Charge.—The same quantity of electricity exhibits very different degrees of repulsive force, according to the way in which it is distributed. Thus a quantity of electricity which, when communicated to an insulated metallic ball, exerts a repulsive force equivalent to a torsion of 10° , will exert only half that force, or 5° , when distributed over two such spheres of the same diameter (p. 381). This is frequently expressed by saying that the *intensity* of the charge in the first case is double that in the second. Intensity, in fact, denotes the tendency of electricity to escape from any space in which it is confined, and its power of overcoming obstacles to its passage. The term is applied with reference to electricity much in the same way as *temperature* with respect to heat. Just as a pint of water at 100° C. can produce many effects which a gallon of water at 50° cannot, *e.g.* causing alcohol to boil, fat to melt, &c., although the quantity of heat in the latter (as measured by the quantity of ice that it will melt on cooling to 0°) is greater than in the former; so likewise a small quantity of electricity confined in a small space exerts a much greater repulsive force than a larger quantity distributed over a comparatively larger space. The intensity of an electric charge is, in fact, proportional to the square of the thickness of the stratum of electric fluid on the surface of the charged body. For the repulsive force exerted between any two portions of the same electric fluid at a given distance varies

as the product of those quantities (p. 381), and if they are both increased n times, the repulsive force between them increases n^2 times. Now the tendency of electricity to escape from a charged body arises from the repulsion exerted on the electricity at any one point of its surface by the total quantity of electricity of the same kind diffused over the rest of the surface. If now the quantity of free electricity contained in the body be doubled, the thickness of the superficial stratum will be doubled at all points; consequently the repulsive force between the portions of electricity at any two points will be quadrupled. And, in general, if the quantity is increased n times, the intensity or tendency to escape increases n^2 times.

DEVELOPMENT OF ELECTRICITY BY INDUCTION OR INFLUENCE.

A body charged with electricity and brought into the neighbourhood of an insulated conductor in its natural state, produces an immediate separation of the electric fluids in that body, repelling that of the same kind with its own charge, and attracting that of the opposite kind. Thus, let an insulated metallic cylinder B C (*fig. 377*), having a number of pith-ball electroscopes suspended from it, be brought near a body A, charged

Fig. 377.

with $+E$, but not near enough to allow a spark to pass between them. The electroscopes near the extremities of the cylinder will immediately diverge, while those near the middle keep their natural position. On the removal of the charged ball, they all fall down again, and resume their divergent position when it again approaches the cylinder. Further, if a pith-ball suspended on silk and charged with $+E$, be held near different parts of the cylinder while the ball A is in position, it will be attracted at the end nearest to A, repelled at the farther end, and neither attracted nor repelled near the middle, showing that the near end exhibits electricity opposite to that of A, and the farther end the same electricity as A. The same may be further shown by touching the different parts of the cylinder with a proof-plane, and transferring the charges to an electroscope; this mode of testing also shows that there is, somewhere between the extremities of the cylinder, a neutral line, where neither kind of electricity predominates. The exact position of this line and the distribution of the opposite electricities on either side of it varies with the dimensions of the cylinder, its distance from the charged body A, and the strength of the charge of A. When the charged body A is removed, the two electricities in B C reunite, and this body no longer exhibits any electric excitement, provided always that the two bodies have never been brought near enough to allow of an interchange of their opposite electricities in the form of a spark, and that B C has remained insulated all the time.

Suppose now that while B C is under the influence of A, a second insulated conducting cylinder is joined on to the end C. The $+E$ will then be driven into this second cylinder, and the first will exhibit $-E$ over the greater part of its surface. Now separate the two cylinders, and then remove the body A. The first cylinder then remains permanently negative and the second positive. Suppose, in the next place, that the cylinder B C, while under the influence of A, is touched with the finger. The $+E$ will then be driven into the ground, the cylinder will remain negative, and if it be again insulated before A is removed, it will remain permanently negative. This effect may easily be shown by the gold-leaf electroscope. On holding over the cap an excited stick of sealing wax, the $+E$ of the electroscope is drawn up into the cap, and the $-E$ driven into the leaves, which then diverge; on removing the sealing wax, the two electricities recombine, and the leaves collapse; but if, while the excited wax is held over the electroscope, the cap be touched with the finger, the leaves collapse, because the $-E$, which made them diverge, is driven into the ground; if the finger be then removed, the sealing-wax remaining in position, the leaves will still hang vertically; but on then removing the wax, they instantly diverge with a positive charge, because the positive electricity previously retained in the cap by the attraction of the $-E$ of the excited wax, now distributes itself uniformly through the cap, wire, and leaves, which

thus acquire a permanent positive charge. On again approaching the excited wax or other negatively electrified body, they collapse; but the approach of an excited glass tube makes them diverge more widely. This is the most convenient way of using the gold-leaf electroscope to see whether the charge of a given body is positive or negative.

The separation of the electric fluids in a neutral body under the influence of an electrified body is called *electrisation by induction* or *influence*. It is evident that a body charged with either kind of electricity must exert this influence on all the bodies in its neighbourhood, separating their electric fluids with more or less facility, according to their conducting powers. When a light body, such as a feather, is brought near an electrified body, the opposite electricity is developed on the nearer side of the feather, and the mutual attraction of the opposite electricities causes the feather to approach the excited body. The attraction of neutral by charged bodies is, therefore, merely a particular case of the mutual attraction between the opposite electricities.

It is evident that the influence of a charged body on the electric fluids of neighbouring bodies will be exerted equally whether they are previously in their natural state or not. When two bodies similarly charged, say both with $+E$, are brought near each other, the mutual repulsion of the similar electricities causes them to accumulate on those points of the surfaces which are farthest from each other. On the other hand, if they are oppositely charged, the mutual attraction of the $+E$ and $-E$ causes them to accumulate in greatest quantity on the contiguous portions of the surfaces. When a body containing excess of $+E$ is brought near a neutral body, as BC (*fig. 377*), the $-E$ drawn to the nearer end of that body acts upon the $+E$ of A , causing it to accumulate on the part of A nearest to B ; and this again causes a further flow of $-E$ to B , and thus the action goes on till, if the bodies are not too far apart, the mutual attraction of the opposite electricities is strong enough to overcome the resistance of the air or other intervening insulator, and an interchange of the two takes place in the form of a spark, the result being that the previously electrified body has its charge diminished, and the previously neutral body, if insulated, becomes permanently charged with the same kind of electricity as A .

We proceed to apply the preceding principles to the construction of several useful electrical instruments.

The Electrophorus.—This instrument consists of a cake or plate A (*fig. 378*), of some material easily excited by friction, as glass, ebonite, gutta percha, or resinous mixtures of various kinds, resting on a metallic plate B , called the sole, and provided with a metallic cover C , which simply rests upon it, and can be removed by an insulating handle H . A good material for the cake, according to Böttger, is 5 pts. shellac, 5 mastic, 2 Venice turpentine, and 1 marine glue, (a mixture of shellac, coal-tar, and caoutchouc, i. 739). This mixture must be carefully heated over a fire, so that when poured out, it may have no air bubbles on its surface. Pfaff recommends a mixture of 8 pts. colophony, 1 shellac, and 1 Venice turpentine. Shellac mixed only with 10 per cent. Venice turpentine is still better, but dearer. Either of these resinous mixtures is better than glass or ebonite, because it does not condense moisture so easily on its surface.

The resinous cake, when beaten with a cat-skin, becomes negatively electrified. When the cover is laid upon it, no communication of electricity takes place from one to the other, but the $-E$ on the surface of the cake acts inductively on the electric fluids of the cover, attracting the $+E$ to the lower surface and repelling the $-E$ to the upper. If the cover be lifted up by its insulating handle, the electric fluids reunite, and the cover appears perfectly neutral. But if, while it rests on the cake, it be touched with the finger, the $-E$ on its upper surface is driven away, and more $+E$ enters it; so that, on removing the finger and then raising the cover by its insulating handle, it appears strongly positive and gives bright sparks. On discharging the cover, replacing it, again touching it with the finger, insulating, and raising it by the handle, it will again be found charged with $+E$ as strongly as before; and this charging of the cover may be repeated any number of times, as long as the surface of the cake retains its negative charge, which in a dry atmosphere it will do for a long time. Indeed, if the cover be laid on the cake and the apparatus set aside in a dry place, it will retain its charge for months.

If glass, or any other material which becomes positive by friction, be used as the electric, the cover will of course acquire a negative charge.

The electrophorus is a very convenient instrument to the chemist, as it supplies a ready means of obtaining a spark for the explosion of gaseous mixtures.

The Condenser.—This is a contrivance for increasing the delicacy of electroscopes. On the cover of a gold-leaf electroscope (*fig. 379*) is laid a circular brass plate, well

Fig. 378.

polished; and on this is laid another brass plate of the same diameter, provided with an insulating handle, and covered on its lower surface with copal varnish, to prevent metallic contact between the plates. Let the lower plate *a*, be connected with a feeble source of electricity (say $+E$) not strong enough to produce a sensible deflection of the gold-leaves. Now touch the upper plate *b* with the finger. The $+E$ in *a* will then decompose the electric fluid in *b*, driving the $+E$ away, and causing a

Fig. 379.

Fig. 380.

flow of $-E$ to the lower surface of *b*; this $-E$ will then draw more $+E$ into *a*, and this again will draw more $-E$ to the lower surface of *b*, and thus the action will go on till a quantity of $+E$ is accumulated on *a*, much larger than it would otherwise have acquired. Now disconnect *a* with the source of electricity, and lift up the plate *b*. The $+E$ accumulated on *a* will then diffuse itself through the electroscope, and cause the leaves to diverge. In this way, decided indications of electric action may often be obtained from sources too feeble to produce a deflection of the electroscope by direct communication. Instead of using the instrument in the way just described, the upper plate may be connected with the source of electricity and the lower plate with the ground; in this case, the action will take place in a similar manner, but the electricity with which the leaves diverge will be of the opposite kind to that of the source.

The Coated Plate and Leyden Jar.—Let a glass plate *C* (fig. 380) coated on both sides with tin-foil to within about 2 inches of its edges, and having a pith-ball suspended by a thin silver wire attached to each coating, be placed near the conductor of an electrical machine, so that $+E$ may be communicated to one of its coatings *p*, while the other *n*, remains insulated. Both the pith-balls immediately stand out, and the approach of an excited glass rod shows that *b* as well as *a* has received a positive charge. The cause of this is obvious. The $+E$ communicated to the coating *p* from the machine draws the $-E$ of the opposite coating *n* towards the surface of the glass, and repels the $+E$ to the outer surface of *n*, and into the ball *b*. While the coating *n* remains insulated, $+E$ continues to flow into the coating *p*, till a particle of it is repelled as strongly in one direction by the action of the $+E$ on the two coatings *p*, *n*, as it is urged in the contrary direction by the $+E$ in the conductor of the machine. When this point is attained, the electricity begins to start out from the edges of the coating *p* in sparks and streams in all directions. Now connect *n* with the ground. Immediately the state of tension of the electricity on *p* appears relieved, and the escape of electricity from its edges ceases; in fact the $+E$ on the outer surface of *n* has been driven away into the ground, and $-E$ has entered in its place; this $-E$ draws the $+E$ on *p* more towards the surface of the

glass, and enables more $+E$ to enter it from the machine; and this action will go on till a particle of $+E$ about to enter *p* is as much repelled by the $+E$ which has already entered *p*, as it is attracted by the $-E$ on the opposite coating *n*, and repelled by the $+E$ in the conductor of the machine. During all this time, the coating *p* remains active towards external bodies, giving sparks when touched, and causing the ball *a* to stand out, while *n* remains neutral to external bodies, although it contains a large excess of $-E$. This must indeed be the case; for so long as *n* remains uninsulated, $+E$ will flow out of it, till a particle on the outer surface is as much attracted by the $-E$ on the rest of the coating *n*, as it is repelled by the $+E$ on *p*. Further, it is evident that to produce this equilibrium on *n*, the quantity of $+E$ on *p* must be absolutely greater than that of the $-E$ on *n*, because the former acts at a greater distance on any particle of electricity in *n*. But from this it also follows that the coating *p* must contain free $+E$; because the $-E$ on *n*, being smaller in quantity than the $+E$ on *p*, and likewise acting at a greater distance, cannot

neutralise the whole of it. Hence on removing the apparatus from the machine, and disconnecting n with the earth, p appears active, giving sparks and repelling the ball a , while n is neutral and the ball b hangs vertically. Now touch p with the finger or any other uninsulated conductor; immediately p becomes neutral, for the same reason that n was neutral before, that is to say, $+E$ is driven out of it, till the action of the $+E$ still remaining on it is neutralised by the $-E$ on n . Then, as before, it follows that the quantity of this $-E$ must now be greater than that of the $+E$ on p ; consequently, a portion of the $-E$ on n will be free, the pith-ball b will stand out, and the coating n will give a spark to any conductor which approaches it. In this way, each coating may be alternately rendered neutral and active, a certain portion of $+E$ being each time taken from the one, and $-E$ from the other, till both are restored to their natural state.

The accumulating power of the coated plate may be approximately estimated as follows:

Let the quantity of $+E$ which the coating p can take up, when n is insulated, be denoted by 1; and suppose the thickness of the plate to be such that this quantity 1 on p can neutralise on n a quantity of $-E$ denoted by μ , a fraction less than 1. Then μ on n will neutralise μ^2 on p ; this will neutralise μ^3 on n , and so on. Consequently, the total quantity of $+E$ accumulated on p when n is uninsulated and the plate is fully charged, will be:

$$1 + \mu^2 + \mu^4 + \mu^6 + \&c. = \frac{1}{1 - \mu^2};$$

and the quantity of $-E$ accumulated at the same time on n will be:

$$\mu + \mu^3 + \mu^5 + \mu^7 + \&c. = \frac{\mu}{1 - \mu^2}.$$

If, for example, $\mu = \frac{9}{10}$, the quantity of $+E$ accumulated on p will be $\frac{100}{19} = 5\frac{5}{19}$

and that of $-E$ on n will be $\frac{90}{19} = 4\frac{14}{19}$; that is to say, the plate with one coating un-

insulated can take up rather more than 5 times as much electricity as when both sides are uninsulated.

The quantities of $+E$ removed by alternately touching the two coatings are, from the positive coating, $1, \mu^2, \mu^4, \mu^6, \&c.$, and from the negative coating, $\mu, \mu^3, \mu^5, \&c.$

If, instead of touching the coatings alternately, a direct communication be made between them by touching the neutral coating with a wire and bending it round till it comes within a short distance of the active coating, a sudden discharge takes place, accompanied by a bright flash and a loud snap, the large quantities of the opposite electricities accumulated on the two coatings recombining at once through the conducting wire. The discharge thus effected is not, however, quite complete; a small quantity of electricity always remains, and may be discharged by again connecting the coatings after a short time. This residual charge is due, partly to the penetration of the opposite electricities within the substance of the glass, partly to their extension beyond the edge of the coatings.

When the communication is made by touching the two coatings with the hands, the peculiar convulsive sensation called the electric shock, is experienced in the arms and chest.

The quantity of electricity which may be accumulated on a coated plate of glass or other insulator increases directly with the extent of coated surface. With a given extent of surface, it is also greater as the glass is thinner: for, as the accumulation depends upon the mutual attraction of the opposite electricities on the two surfaces, it will be greater as the distance between them is less. The thickness cannot however be diminished beyond a certain limit, as the two electricities would then recombine through the substance of the glass and cause a fracture.

The charging of a coated insulator takes place in the same way, whatever may be its shape. The most convenient form is that of a glass jar (*fig. 381*) coated with tin-foil inside and out to within a few inches of its lip, and fitted with a wooden lid, through which there passes a brass rod, terminated above by a knob and below by a chain reaching to the bottom. The jar is charged by holding

Fig. 381.

its knob to the conductor of the machine. If it be insulated, sparks may be taken from the outer coating all the time that the charging is going on. In this way two jars may be charged at once; but, from the preceding explanation, it is evident that the charge of the second jar will not be so strong as that of the first.

When a very large extent of coated surface is required, a number of jars are connected together by placing them in a tray lined with tin-foil and joining their knobs by brass rods; they then act as one jar. The arrangement is called an *Electrical Battery*.

Unit-jar.—This is a very useful contrivance, invented by Mr. Harris, of Plymouth, for measuring the quantity of electricity communicated to a large jar or battery. It consists of a small Leyden jar, A (*fig. 382*), supported in an inverted position on the insulating stem, *e f*. The inner coating of this jar is connected by the wire *a d* with the positive conductor of an electrical machine, and its outer coating is connected by

Fig. 382.

the wire *b* with the inside coating of the jar or battery to be charged. To the outer coating of A there is also attached a wire *g c*, terminating in the brass knob *c*, at a short distance from *a*. On working the machine, $+E$ is communicated to the inside of the unit-jar A, and a certain quantity of $+E$ is thereby driven from the outer coating through the wire *b* into the jar or battery to be charged. As soon, however, as the charge of the unit-jar, has reached a certain degree of intensity, a discharge takes place by a spark, between the knobs *a, c*, this discharge merely neutralising the charge of the unit-jar, without affecting that of the large jar or battery; on continuing to work the machine, more $+E$ is driven from the outside of A into the large jar, and, after a while, the small jar is again discharged by a spark at *a c*. Now, as the distance of the knobs *a, c* remains constant, it is clear that each discharge indicates an equal charge of the unit-jar, and consequently the transference of an equal quantity of $+E$ from the outside of this jar to the inside of the larger jar or battery. Hence the number of sparks passing between the knobs *a, c* serves as a measure of the quantity of electricity accumulated in the large jar or battery.

THE ELECTRIC DISCHARGE.

The recombination of the opposite electricities which constitutes discharge, may, as already observed, be either continuous or sudden,—continuous, or in the form of a current, when two sources of the opposite electricities are connected by a good conducting chain,—as when the two conductors of a cylinder machine (p. 379) are joined by a metallic chain or wire;—sudden, when the opposite electricities are allowed to accumulate on the surfaces of two contiguous conductors till their mutual attraction becomes strong enough to overcome the intervening resistances, whatever they may be. It is scarcely necessary to observe that the difference here mentioned is one, not of kind, but of degree; there is no such thing as an absolute non-conductor, and the very best conductors, viz. the metals, offer an appreciable and measurable resistance to the passage of the electric fluid; still the difference at the two extremes of the scale is sufficiently great to give rise to a wide range of phenomena.

Discharge through Air and other Gases: the Electric Light.

When two oppositely charged conductors are brought within a certain distance of one another in a gaseous medium, discharge takes place between them in the well-known form of the electric spark. The form, dimensions, brightness, and colour of the spark, vary considerably according to the size and shape of the conductors, and the nature and physical state of the surrounding medium. When the surfaces are well rounded, as those of spheres, or the ends of cylinders of considerable diameter, and the distance between them not very great, the sparks are nearly continuous, straight, and attended with a loud snapping noise; on increasing the distance, they pass at longer intervals, and with a louder noise, because the opposite electricities have to be brought to a higher state of tension before they can overcome the resistance of the intervening air, and consequently a greater quantity of electricity passes in a single spark. At a still longer interval, if the machine is in good action, the sparks become forked, as if the electricity were seeking out the easiest passage through the air, and taking advantage of any conducting matter, such as particles of dust, that may be floating in it; at the same time the spark becomes less bright, and is attended with a duller snap and more or less of a sputtering noise. Between smaller balls, or when a small ball is presented towards the conductor of the machine, the sparks at a given distance are more con-

tinuous, because a smaller quantity of electricity suffices to produce the requisite tension.

When a brass rod terminating in a ball is inserted into the positive conductor of a machine in good action, and no other good conductor is near, the electricity is often discharged from it in the form of a brush (*fig. 383*), consisting of a short straight stem and numerous diverging ramifications, the effect being greatly assisted by any slight roughness on the surface of the ball, or by holding a large conducting surface, such as the hand, at the distance of a few inches from it. It is caused by the discharge of comparatively small quantities of electricity at very short intervals, the tension at one point of the electrified ball being brought up to the discharging point, while there is no good conductor near enough to receive a larger quantity of the accumulated electricity at once. The electricity then escapes into the air in visible streams, the light becoming fainter and fainter as it is diffused over a wider space, and at a certain distance ceasing altogether. A large conducting surface held within a certain distance of the ball facilitates the brush discharge, by itself assuming the negative state of charge, and thus intensifying the positive charge on the ball (*p. 385*).

Fig. 383.

By using a smaller ball or a thick wire with a rounded end, the brush becomes more continuous, but smaller and less luminous, and when the conductor terminates in a sharp point, the brush disappears altogether, and is replaced by a quiet and continuous glow, surrounding the point, and accompanied by a stream of air flowing outwards from it. In this case, in consequence of the intensity of the charge near the end of the wire, the surrounding particles of air are quickly brought into a similar electrical state, and are repelled, and thus carry away the electricity of the pointed conductor so rapidly, that only a small quantity of it escapes in visible form. The glow may be changed into a brush by anything which impedes the current of air, as by the approach of the hand or other large conducting surface. The glow is of a more continuous character than the brush, a smaller quantity of electricity sufficing to keep the end of a pointed wire at the discharging tension than when the conductor has a rounded termination. Hence glow may be changed to brush by charging the conductor at intervals instead of continuously; thus a pointed wire inserted into an insulated conductor placed in contact with the conductor of an electrical machine, will exhibit glow discharge; but by separating the two conductors, so that sparks may pass from the machine, the glow is changed into a succession of brushes.

The character of the brush in air varies greatly according as the body from which it proceeds is electrified positively or negatively. The negative brush (*fig. 384*) is in all cases much smaller and more compressed than the positive brush, never exhibiting the same beautiful ramifications as the latter. This is the case whether the negative brush proceeds from a small knob or a blunt-pointed rod inserted into the negative conductor of the machine, or from a similar knob or wire held within a certain distance of the positive conductor, so that it may acquire a negative charge by induction. When the two brushes are produced simultaneously, by holding an uninsulated knob or wire near another wire inserted into the positive conductor of the machine, the difference in their appearance is very conspicuous (*fig. 385*).

Fig. 384.

Fig. 385.

The cause of this remarkable difference has been the subject of much discussion, and is perhaps not quite satisfactorily made out; but it is most probably related to the fact, which Faraday has demonstrated by numerous experiments (*Experimental Researches*, series xii. xiii.), that negative electricity discharges into air at a somewhat lower tension than positive electricity, so that a negatively electrified knob or wire projecting into the air is sooner brought up to the state of tension at which discharge commences, than one which is positively electrified, and therefore discharges the electricity at shorter intervals and in smaller quantities at once. Faraday has ascertained that a rounded metal rod projecting into the air and electrified negatively, discharges at intervals seven or eight times shorter than when it is charged positively. In

accordance with this, it is found that the approach of the hand, or other large conductor, does not alter the character of the negative as it does that of the positive brush, until it is brought near enough to produce a spark.

When the end of the electrified conductor is reduced to a point, very little difference can be perceived between the positive and negative discharge from it.

Dark Discharge.—The glow discharge, especially on a negative surface, is generally accompanied by a dark interval through which the electricity appears to travel without being visible. Faraday describes an experiment in which two brass rods 0·3 of an inch in diameter, entering a glass globe on opposite sides, had their ends brought in contact, and the air about them very much rarefied. A discharge of electricity was then made through them, and whilst that was continued, the ends were separated one from the other. At the moment of separation, a continuous glow came over the negative rod, the positive termination remaining quite dark. As the distance was increased, a purple stream or haze appeared on the end of the positive rod, and proceeded directly outwards to the negative rod, elongating as the interval was enlarged, but never joining the negative glow, there being always an interval of $\frac{1}{16}$ to $\frac{1}{20}$ of an inch between them. The appearance is shown in fig. 386.

Fig. 386.

It appears then that air can discharge electricity, like a conductor, without luminosity. In many cases, the effect is doubtless to be attributed to the current of air which, as already observed, invariably accompanies glow; in other cases, however, this explanation will scarcely suffice: for dark intervals are often seen in sparks, especially in coal-gas, in which case the discharge is too rapid to admit of the formation of a current of air. In such cases, the dark intervals probably consist of portions of air possessed of greater conducting power than the rest, perhaps from the presence of particles of dust—or in coal-gas, in which they are peculiarly conspicuous, from the presence of minute particles of solid hydrocarbons floating in the gas. The phenomenon may be compared to that which is seen in the ignition of a wire composed of alternations of silver and platinum by the voltaic current, the silver, which conducts better than the platinum, appearing less luminous.

Discharge in Rarefied Air.—When the air between two oppositely charged bodies is rarefied, the number of particles which oppose the union of the opposite electricities is diminished, and consequently a lower intensity of charge will be sufficient to induce their combination. Hence with a given charging power, the spark will strike through longer distances. The most convenient apparatus for showing this effect is an ordinary cylindrical receiver standing on the plate of an air pump, and closed at the top with a brass cap and stuffing box, through which there passes a brass rod, terminating, within the receiver, in a ball, or point, or any other desired form. By connecting this rod with the conductor of the machine, and working the pump, the increased facility of discharge as the rarefaction proceeds is strikingly exhibited. When the exhaustion has been carried to a considerable extent, the whole of the receiver appears filled with beautiful streams of violet or rose-coloured light, which pass with little or no noise.

The conditions which determine the occurrence of brush and glow in highly rarefied air are much the same as in air of ordinary density. When the sliding wire is placed in complete metallic communication with the conductor of the machine, so that the supply of electricity is very regular, the ball at the lower end of the wire generally becomes covered with a quiet glow, the greater part of the receiver remaining dark, and only a few slight coruscations appearing here and there on the plate of the air pump; but by allowing sparks to pass from the machine, the discharge in the receiver immediately takes the forms of splendid streams and brushes. Rarefaction of the air seems to develop the negative brush in a greater degree comparatively, than the positive brush. According to Faraday, extensive ramifications are easily obtained from a ball or rounded termination electrified negatively, to the plate of the air pump. The glow is also very easily produced on a negative ball in rarefied air.

It is of course impossible to say what would take place in a perfect vacuum, whether in fact the discharge would take the form of a continued stream, or be stopped altogether; the former supposition is perhaps the more probable; but in an atmosphere of extreme tenuity, such as the Torricellian vacuum, in which, however, vapour of mercury is present, or the vacuum produced by filling a tube with carbonic acid gas, exhausting as much as possible with the air-pump, and absorbing the remainder by solid potash, very remarkable effects are observed. The discharge, whether from the conductor of an electrical machine, or from a Leyden jar discharged through a wet string, or from a voltaic battery, or from an induction coil, generally exhibits remark-

able stratifications, that is, alternations of light and dark bands, extending from one terminal conductor to the other. These stratifications, which have probably some analogy to the light and dark bands observed by Faraday in the spark, and other forms of discharge, are seen only when the rarefaction is carried to a very high degree—but, on the other hand, they disappear when the vacuum is nearly perfect, the discharge then appearing continuous throughout the tube. In the Torricellian vacuum, when not very complete, the discharge is sometimes intensely white, filling the entire tube, without stratification. These curious and brilliant phenomena have been studied in great detail by M. Gassiot, and are described in a series of papers published in the Transactions and Proceedings of the Royal Society (Phil. Trans. 1858, 1859; Proc. Roy. Soc. x. 146, 601; xi. 36, 269, 274, 393, 432). We shall return to them in speaking of the light produced by the voltaic battery and the induction coil.

Discharge in different Gases.—Different gases, at the same pressure and temperature, possess different powers of insulation. Faraday

Fig. 387.

has obtained approximate measures of these differences, by means of the apparatus represented in fig. 387. S, L are two brass balls, the distance between which can be varied at pleasure, and s, l two other balls of nearly the same diameters as S and L, but placed at the fixed distance of 0.62 inch, and enclosed in a receiver which can be exhausted and filled with any required gas. The balls s, S are connected by wires with the insulated conductor n, which can itself be connected at pleasure, either with the positive or with the negative conductor of an electrical machine, and the large balls l, L are connected with the earth. It is clear that, with air in the receiver, the discharge may be made to pass in sparks either at v or at u, by increasing or diminishing the distance between the balls S, L; and by filling the receiver with different gases, and regulating the distance between these balls, so as to cause all the sparks to pass at v, the relative insulating power of the gases may be measured. It was found, however, that the interval u might be altered within certain limits, and yet sparks pass either there or at v. The extremes were therefore noted, viz. the greatest distance short of that at which the discharge *always* took place at v in the gas, and the least distance short of that at which it *always* took place at u in the air. The intervals were also found to be different according as the small balls s and S were made positive or negative. The following table gives the *mean* results:

	s and S positive.	s and S negative.
Hydrochloric acid gas	1.105	0.720
Olefiant gas	0.750	0.730
Air	0.695	0.635
Carbonic anhydride	0.640	0.590
Nitrogen	0.615	0.645
Oxygen	0.505	0.510
Coal-gas	0.490	0.525
Hydrogen	0.370	0.275

These numbers show that, with a positive charge on the small balls, and with the same surfaces, and under the same circumstances of pressure and temperature, hydro-

chloric acid gas has three times the insulating or restraining power of hydrogen gas, and nearly twice that of oxygen, nitrogen, or common air. The differences are not due to specific gravity; for though hydrogen is the lowest of all, oxygen is much lower than nitrogen, and also lower than olefiant gas; and carbonic anhydride, though much heavier than olefiant gas or hydrochloric acid, is lower than either. The difference of insulating power in the gases appears, therefore, to be a specific electric quality, or relation (see page 400).

The negative numbers in the preceding table do not follow the same order as the positive numbers. In air, hydrogen, carbonic anhydride, olefiant gas, and hydrochloric acid, the tension rose higher when the smaller ball was made positive than when it was negative, whilst in oxygen, nitrogen, and coal-gas, the reverse was the case. When the conductor *n* was connected only with the receiver containing hydrochloric acid gas, the discharge was found to be easier when the small ball *s* was negative, than when it was positive; in the latter case, much of the electricity was given off as brush discharge from the connecting wire, whereas in the former it all passed through the hydrochloric acid gas.

The colour and appearance of the spark and brush vary considerably according to the nature of the gas.—In *air*, the sparks exhibit the well-known bright light and violet-blue colour, and often have faint or dark parts in their course, when the quantity of electricity passing is not great.—In *nitrogen*, the sparks are very beautiful, having the same general appearance as in air, but more colour of a bluish or purple character.—In *oxygen*, they are whiter than in air or nitrogen, and somewhat less brilliant.—In *hydrogen*, they have a very fine crimson colour, which, however, disappears as the atmosphere is rarefied; the spark in this gas produces very little sound.—In *carbonic anhydride* the colour of the spark is similar to that in air, but with a slight green tint: the sparks are, under similar circumstances, of strength of charge, form of conductors, &c., longer and more regular in form than in air; altogether this gas affords peculiar facility to the spark discharge.—In *hydrochloric acid gas*, the spark is white, and exhibits no dark spaces.—In *coal-gas*, the spark is sometimes green, sometimes red, sometimes partly green and partly red; black parts also occur suddenly in the line of the spark, that is to say, they are not connected by any dull part with bright portions, but the two seem to join directly one with the other.

The appearances of the brush in air have been already described.—*Nitrogen* gives brushes with great facility from positive surfaces; they are always fine in form, light, and colour, and in rarefied nitrogen are magnificent: they surpass the discharges in any other gas, as to the quantity of light evolved. The difference between the positive and negative brushes in nitrogen is greater even than in air.—In *oxygen*, the positive brush is compressed and poor, while the negative brush is not much less developed than in air; indeed, the two are so alike that it is often difficult to distinguish one from the other, and this similarity continues even when the oxygen is gradually rarefied.—In *hydrogen*, the positive brush is more developed than in oxygen, but not so fine as in nitrogen; in rarefied hydrogen, the ramifications are very fine in form, but pale in colour; in the rarest state of the gas they have a pale grey-green tint; the negative brush is much the same in hydrogen as in air.—In *carbonic anhydride*, at common pressures, the positive brush is very poor as to size, light, and colour; in the rarefied gas, it is better in form, but weak as to light, and has a dull greenish or purplish hue; altogether the positive brush in this gas is not much superior to the negative brush.—In *hydrochloric acid gas*, the brush is very difficult to produce at common pressures, even with the interrupted spark-current (p. 389). In the rarefied gas, the brush is more easily formed, but is generally of a low squat form, poor in light, and very similar on the positive and negative surfaces. In the highly rarefied gas, a few large ramifications are obtained from the positive surface, but of a pale bluish colour, utterly unlike those of nitrogen.—In *coal-gas*, the brushes are difficult to produce, as compared with nitrogen, and the positive not much superior to the negative in character, either at common or at low pressures. At common pressures, they are short and strong, generally of a greenish colour, and possessing much of the spark character.

On the whole then it appears that the character of the brush is essentially connected with the nature of the gas through which it passes; that the positive brush always shows a certain degree of superiority to the negative brush; but it is only in nitrogen, hydrogen, and common air that the difference is great, while in oxygen it almost vanishes.

Glow-discharge occurs in all the gases above mentioned under circumstances similar to those already described (p. 389); it is always accompanied by a wind proceeding either to or from the glowing part, and if the access of air is interfered with, the glow disappears.

Dark discharge has likewise been observed in all the gases examined, most easily in hydrochloric acid, and in coal gas (p. 390). In the latter, the discharge between balls

about an inch apart was accompanied by short brushes on the ends, and a dark interval of about half an inch between them, notwithstanding that the discharge had the quick sound of a dull spark, so that its dark portions could not have depended on convection, that is to say, on the formation of a stream of gaseous particles.

Luminous Discharge in Liquids and Solids.—Sparks may be obtained in insulating liquids and solids, as in oil of turpentine, olive oil, resin, glass, &c., their passage being generally attended with more or less disruption of the particles of the body; also in imperfect conductors, such as water, spermaceti, &c. Brushes may be obtained in oil of turpentine, by passing sparks from the machine to a wire going through a glass tube into the liquid contained in a metallic vessel; they are small, and so feebly luminous as to be visible only in a dark room, and exhibit simple, very divergent ramifications. The presence of a few solid particles, as of dust or silk in the liquid greatly facilitates the production of the brush. (Faraday.)

Duration of the Electric Light.—Wheatstone has examined the duration of the electric spark by means of a revolving mirror. The principle of the method is this: when a steady light, such as the flame of a candle, is viewed in a fixed mirror, its image appears in one constant direction; but if the plane of the mirror be moved through a certain angle, the image changes its position, and if the mirror be made to rotate very rapidly, the image will appear drawn out into a long line of light, because, in the successive positions through which it passes, it remains for a certain time on the retina, and consequently the luminous impression of the image in its former positions is seen at the same time that it has advanced to a new one. If then the electric spark has any perceptible duration, it must also appear elongated when viewed in a mirror rotating with a certain velocity. In Wheatstone's experiments, the mirror was rotated at a rate which would have produced an elongation of half a degree in the image of the spark, if its duration were equal to $\frac{1}{72000}$ of a second. No elongation or distortion was, however, perceived in the image of the spark from the conductor of an electrical machine, or from a Leyden jar discharged in the ordinary way, or of the stream of light in an exhausted tube 6 feet long; they all appeared in the rotating mirror just the same as when it was at rest. Under these circumstances, therefore, the duration of the electric spark is less than $\frac{1}{72000}$ of a second. When, however, the discharge is made through a very long wire, say half a mile long, or through a bad conductor, the image of the spark in the revolving mirror does appear elongated, showing that the discharge is then not momentary but gradual.

When a rapidly revolving wheel is viewed by ordinary light, its spokes can no longer be distinguished; but when it is viewed by the electric spark in a dark room, the spokes are distinctly seen; in fact, the wheel appears at rest. This likewise shows the momentary character of the ordinary spark. In like manner, a rapidly rotating disc painted with the colours of the spectrum, which appears white by daylight or candlelight, exhibits the separate colours when viewed by the electric spark.

Velocity of the Electric Discharge.

Wheatstone has applied his revolving mirror to determine the rate at which electricity travels through conductors. For this purpose, six copper balls are fixed on a circular board, called the *spark-board* (fig. 388), and connected in such a manner as to

give three sparks with one discharge of a Leyden jar. The wire 1, connects one of these balls with the inside of the jar; from this ball the discharge passes in the form of sparks to the one on the left, and thence through the wire 2, which is joined to 3 by a thin wire $\frac{1}{4}$ of a mile long, to the third ball; thence, by a spark, to the fourth ball, from which it is conveyed by the wires 4 and 5, also connected by a thin wire $\frac{1}{4}$ of a mile long, to the fifth ball, and thence by a spark to the sixth ball, which is connected by the wire 6, with the outside coating of the jar. The intervals through which the sparks pass are 0.1 inch wide.

Fig. 388.

The spark-board is fixed vertically, at a distance of 10 feet from the revolving mirror, and so that the six balls shall be in a horizontal line, parallel to the axis of rotation of the mirror, and at the same height as that axis. The observer places himself so that the axis of rotation is directed towards him, and looks vertically down upon the

mirror. The discharging apparatus is arranged so that the sparks may appear just as the mirror is inclined to the horizon at an angle of 45°. (For the details of the arrangement, see De la Rive, ii. 127.)

If, now, the mirror were fixed at this inclination, the three sparks would be seen projected on a horizontal plane, thus . . . ; but when the mirror is made to revolve very rapidly, they are all three drawn out into lines; and, moreover, the middle spark appears pushed aside from the others, the relative positions of the three sparks being ———— when the mirror revolves from right to left, and ———— when it revolves from left to right. From this result Wheatstone deduces the following conclusions:—

1. As the two external sparks retain their relative positions, while the middle one lags behind them, it follows that the discharge begins simultaneously at the two ends of the circuit and proceeds in a perceptible time to the middle.

2. By comparing the observed retardation of the middle spark with the velocity of rotation of the mirror, Wheatstone calculates that electricity travels through a metallic circuit at the rate of 288,000 miles in a second, a velocity greater than that of light (194,000 miles per second), and sufficient to make the circuit of the earth ten times in a second.

Other experimenters, however, by observing the time which the electric current takes to travel through great lengths of telegraph-wires, have obtained results differing widely from that of Wheatstone, and likewise from each other, as the following table will show:—

Velocity of Electric Discharge.

Observers.	Nature of Wire.	Miles per Second.
Wheatstone	Copper	288,000
Fizeau and Gonnelle	Copper (French telegraph)	112,680
Fizeau and Gonnelle	Iron do.	62,600
O'Mitchell	Iron (American telegraph)	28,524
Walker	Do. do.	18,780
Gould	Do. do.	15,907
Astronomers of Greenwich and Edinburgh	Copper (London and Edinburgh telegraph)	7,600
Astronomers of Greenwich and Brussels	Copper (London and Brussels telegraph)	2,700

The last result is more than a hundred times less than that obtained by Wheatstone. The cause of these large discrepancies has been pointed out by Faraday (*Experimental Researches*, vol. iii. p. 508), who has shown that when a telegraph wire encased in gutta percha, and buried in earth or immersed in water, is connected with one pole of a voltaic battery, the other pole communicating with the ground, the whole arrangement becomes charged like a Leyden jar, the wire forming the inner coating, the gutta percha the insulator, and the earth or water the outer coating. The inductive action thus exerted necessarily lowers the intensity of the charge in the wire (pp. 386, 387), and consequently the force with which the succession of charges and discharges constituting the current takes place along the wire. Hence the current is retarded, the amount of retardation varying according to the thickness of the gutta percha coating, the conducting power of the wire, and of the medium with which it is surrounded, the perfection of the insulation, &c. The very low velocity obtained with the London and Brussels wire is evidently due to the great conducting power of the water in which a considerable portion of the wire is immersed. A still greater retardation, due perhaps to imperfect insulation, was, however, observed by Faraday, in the subterraneous wire of the London and Manchester line, the current taking two seconds to travel 1500 miles, while, with the same length of wire in air, the time was almost inappreciable. But even with wires suspended in air, a certain amount of retardation is produced by induction towards neighbouring conductors, especially if the wire is stretched close to the ground, or to walls; it must, however, be very small as compared with that which takes place in a subterraneous or subaqueous wire separated from the surrounding conducting medium by an insulating coating only $\frac{1}{10}$ of an inch thick. In Wheatstone's experiment, the long connecting wires were bent into a number of parallel lengths at

some distance from each other and from the ground; in this case a certain amount of retardation may have arisen from the inductive action of the contiguous portions of the wire on each other; but on the whole, Wheatstone's mode of experimenting probably gives the nearest approximation to the rate at which electricity travels along a copper wire when unimpeded by disturbing causes; but the experiments with the telegraph wires clearly show that no absolute rate can be fixed, the actual velocity varying with the conducting power of the wire or other channel of communication, and the influence of neighbouring bodies.

Mechanical and Thermic Effects of the Electric Discharge.

The manner in which electricity travels through a solid body depends upon the relation between the dimensions and conducting power of that solid and the quantity and intensity of the charge. A thick mass of metal, or other good conductor, will convey any charge of electricity, even that of a thunder-cloud, without suffering any visible alteration; but when the charge is sent through thin wires, the result is different. The wire then becomes heated, showing that its particles are thrown into a state of agitation, the degree of heat developed depending upon the relation between the quantity and intensity of the charge and the conducting power of the wire; and when the charge of a powerful battery is transmitted through a very fine wire of silver, gold, copper, zinc, platinum, &c., the metal is melted and disintegrated, with a brilliant flash of light, and if stretched on paper, its particles are driven into the paper, forming an indelible stain.

The degree of heat developed in metallic wires under different circumstances by the discharge of an electrical battery has been investigated by Riess by means of an apparatus called an *electrical air thermometer*, originally invented by Harris. It consists of a glass globe (*fig. 389*) about 3 inches in diameter, having two lateral openings closed by brass caps, between which is stretched a thin spiral of platinum wire. A cylindrical glass tube about half a line in diameter, sealed to the globe, contains a column of coloured liquid, and serves as the stem of the thermometer, of which the globe is the bulb. When an electric charge is sent through the platinum wire, it becomes heated, and expands the air in the globe; the column of liquid is then pushed outwards, and the expansion indicated by a scale attached to the stem, serves as a measure of the rise of temperature produced in the wire by the discharge.

Fig. 389.

The charge of electricity communicated to the battery is measured by a unit jar. By this mode of observation, Riess has established the following laws:—

1. *The heating of the wire is directly proportional to the square of the quantity of electricity, and inversely proportional to the coated surface over which it is diffused (or directly proportional to the intensity); or if h be the rise of temperature measured by the expansion of the air in the thermometer, q the quantity of electricity, and s the extent of coated surface,*

$$h = n \frac{q^2}{s},$$

n being a constant depending on the thickness and length of the platinum wire and the rest of the conducting circuit. This law may be illustrated by the numbers in the following table, which contains the results of some of Riess's experiments. The

numbers in the uppermost horizontal line denote the number of jars of the same size composing the battery : —

s	2	4	6
q	h	h	h
2	1.5		
4	6.7	3.2	2.6
6	13.4	7.3	5.5
8	.	14.1	9.3

2. *The rise of temperature produced by a given discharge in wires of the same metal of equal length, but different diameter, is inversely as the fourth powers of their diameters, and the quantities of heat evolved are inversely as the transverse sections of the wires.* Thus, in wires whose diameters are as 1, 2, 3, &c., the same discharge produces rises of temperature which are as $1, \frac{1}{16}, \frac{1}{81},$ &c. ; but, as the masses of the wires are as 1, 4, 9, it is clear that the quantities of heat evolved in them must be as $1, \frac{1}{4}, \frac{1}{9},$ &c., that is, inversely as the transverse sections.

3. *With the same wire in the thermometer-bulb, the rise of the temperature produced in it by discharge of a given quantity of electricity, is less, the longer the circuit through which the discharge has to pass, and the thinner the wires that are inserted into it ; in other words, the rise of temperature produced by the discharge of a given quantity of electricity diminishes as the conducting power of the circuit is less.*

Wires of different metals of the same length and thickness inserted into the circuit, produce different degrees of diminution of the heat evolved in the thin wire : thus a platinum wire produces 6.44 times as much diminution as a copper wire of the same length and thickness : hence it is inferred that platinum offers 6.44 times as much resistance as copper to the passage of electricity.

The melting of very thin wires by the electric discharge is not a consequence of the heat evolved, but a specific electrical effect. For, by calculations founded on the observed rise of temperature produced in thicker wires, Riess has shown that the rise of temperature produced in a platinum wire, by a discharge strong enough to melt it, does not exceed 211° C.,—a heat not sufficient even to raise it to redness, much less to fuse it. And in fact, on sending through such a wire charges not quite sufficient to ignite it, appearances are observed which indicate a violent mechanical disturbance of its particles. The wire is sensibly agitated ; small sparks appear at its extremities ; particles are thrown off from its surface, in the form of a dense vapour ; and the wire, if not tightly stretched, becomes bent in several parts, the number and sharpness of the flexures increasing with the strength of the charge ; finally, with a certain strength of charge, the wire becomes red or white hot, and its particles are completely scattered. Easily oxidable metals, like iron, burn at the same time in the air, and are partly melted by the heat of the combustion.

Bodies of small conducting power are variously affected by the electric discharge. Electricity of low intensity cannot force its way suddenly through an imperfect conductor, even though the quantity accumulated, in a large battery, for example, may be very considerable. When a jar or battery is discharged through an imperfect conductor, such as wood, the discharge occupies a perceptible time, as may be known by the sound produced. When the resistance of the intervening solid body is very great, as that of glass or shellac, the accumulated electricity is dissipated in the air, sooner than it can pass through the non-conducting solid. But electricity of high intensity forces its way through bad conductors, often tearing them asunder and shattering whatever comes in its way. When two pointed wires are inserted into the ends of a piece of dry wood, and the charge of a large jar or battery sent through them, the wood is torn in pieces. In like manner, card-board, glass, thin cakes of resin, &c. may be perforated. Leyden jars are sometimes destroyed by the electricity of a strong charge forcing its way through the glass from the inner to the outer coating : a round hole is thereby produced, filled with finely powdered glass. When a powerful charge from a battery is sent through a piece of sugar placed between two wires, the sugar is broken into several pieces, which are thrown violently about, and appear phosphorescent in the dark for several minutes ; this last effect shows clearly the violent agitation to which the molecules of a body are subjected by the passage of electricity. The destructive effects of lightning, when it strikes a stone or wooden building, or the mast of a ship, not provided with a metallic conductor, belong to the same class of phenomena.

Chemical Effects of the Electric Discharge.

The highest charge of electricity, while remaining quiescent in a body, or in the statical condition, produces no perceptible change in its chemical constitution; but electricity in the state of discharge, or in the dynamic state, is capable of inducing both combination and decomposition.

Inflammable bodies are often set on fire by the electric discharge. The discharge of a moderate-sized jar instantly inflames a mass of tow filled with pounded resin. The spark from a very powerful electrical machine produces the same effect, and also sets fire to deal-shavings. A very small electric spark passed through a mixture of hydrogen, carbonic oxide, alcohol-vapour, ether-vapour, &c., with air or oxygen, or a mixture of chlorine and hydrogen, causes instant combination, attended with violent explosion if the gases are mixed in the combining proportions. Whether this effect is due to the heat developed by the spark, or to a direct exaltation of the chemical affinities concerned, is not precisely known, but the latter supposition is perhaps the more probable of the two. (For the methods of inflaming gaseous mixtures by the electric spark in analysis, see ANALYSIS, VOLUMETRIC, OF GASES, i. 269.)

The passage of electric sparks through moist air is always attended with the production of nitric acid: hence this acid is always present in the air after a thunder-storm. (See NITRIC ACID.)

Another very remarkable chemical effect of the electric discharge through air or oxygen is the formation of ozone. The air in the neighbourhood of an electrical machine in action always acquires a peculiar pungent odour, somewhat like that of phosphorus slowly oxidising; at the same time it acquires increased oxidising power, decomposing iodide of potassium, decolorising tincture of guaiacum, &c. These effects, first observed by Van Marum in the latter part of the last century, and since more particularly studied by Schönbein and others, are attributed by some to the production of an allotropic modification of oxygen, by others to the formation of a higher oxide of hydrogen (H^2O^2). That the effect is due, in great part at least, to a peculiar modification of oxygen, is completely proved by the fact that perfectly pure and dry oxygen acquires this exalted power when electric sparks are passed through it, or along the outside of a sealed tube containing it. Whether, when water is present, a higher oxide of hydrogen is likewise formed, is a question still under discussion. (See OZONE.)

Gunpowder laid on a plate of glass between the ends of two wires, may be fired by the discharge of a jar retarded by passing through a wet string or other imperfect conductor; without such retardation, the discharge merely scatters the powder, without firing it.

When a considerable quantity of electricity is passed gradually, and without formation of sparks, through a compound liquid, that liquid is in many instances resolved into its elements, which separate in opposite directions, the one taking the direction of the positive, the other that of the negative electricity. This effect is called ELECTROLYSIS, that is, decomposition by electricity. We shall consider it more fully hereafter, merely describing at present the methods devised by Faraday for showing that chemical decomposition can be produced by friction electricity. A glass plate (*fig. 390*) has two strips of tin-foil, *a*, *b* pasted on it; one of these is connected by a wire *c*, or wire and wet string, with the positive conductor of an electrical machine, the other by a wire *g* with the earth or the negative conductor. A small piece of filtering paper moistened with the liquid to be decomposed is laid on the plate midway between the two strips of tin-foil, and connected therewith by bent platinum-wires, as shown in the figure. Positive electricity then enters the solution at the point *p*,

Fig. 390.

and negative electricity at *n*. Now let the paper be moistened with a solution of iodide of potassium, and the machine worked. In a short time a brown spot of iodine will be produced at *p*, while no apparent change takes place at *n*; but if the

current be reversed by connecting *c* with the positive, and *g* with the negative conductor, a spot of iodine will soon appear at *n*, while that at *p* will disappear. If a piece of paper moistened with hydrochloric acid and coloured with indigo, be placed between *p* and *n*, the paper will be bleached at *p*, indicating the evolution of chlorine. When a piece of litmus paper is placed under *p*, and turmeric paper under *n*, both being moistened with sulphate or chloride of sodium, and the two made to touch each other, a red spot appears under each terminal, showing that an acid has been evolved at *p*, and an alkali at *n*. In a similar manner many other decompositions may be effected.

By the arrangement shown in *fig. 391*, several portions of the same solution or of

Fig. 391

different solutions may be decomposed at once, the acid or chlorous elements being always evolved at the positive terminals *p*, and the basic elements at the negative terminals *n*.

Instead of using the continuous current of the machine, the charge of a jar may be passed through the arrangement, a piece of wet string about four feet long being interposed in the circuit, to retard the discharge; the same decompositions are then produced. Without the interposition of the wet string, however, no decomposition takes place: it seems therefore to require a certain time. The greater the quantity of electricity passed, the greater also is the amount of decomposition produced.

The mode of passing the electricity through the solutions may also be varied in other ways, the only necessary condition being that a continuous current shall pass. Thus, if two triangular pieces of litmus and turmeric paper (*fig. 392*) moistened with

Fig. 392.

Fig. 393.

sulphate of sodium be placed between two metallic points *p*, *n*, connected with the conductors of an electrical machine in action, the turmeric paper being towards the negative, and the litmus *b* towards the positive terminal, the extremities of both papers will be reddened. This effect may also be repeated through several alternations, as in *fig. 393*, the pointed pieces of moistened paper serving to discharge the electricity like pointed wires.

In all these experiments, especial care must be taken that no sparks pass through the air over the moistened papers; for the passage of a spark through the air always gives rise to the formation of nitric acid, and this would of itself redden litmus, prevent the reddening of turmeric by an alkali, and separate iodine from iodide of potassium.

Magnetic Effects of the Electric Discharge.

When a piece of unmagnetised steel wire is placed at right angles to a wire of any metal, or to any conductor whatever, through which the charge of a large battery is

passed, the steel wire is rendered permanently magnetic, the direction of its poles being determined by a law which will be hereafter explained. If the steel needle be placed in the axis of a glass tube round which a helix of copper wire is coiled, and the charge, even of a small jar, be sent through the helix, the steel will also be permanently magnetised. The helix serves to intensify the action, by enabling the current to act upon all parts of the steel wire at once. This development of magnetism in steel is produced by the sudden discharge of electricity through good conductors in the neighbourhood of the steel.

The sudden discharge does not, however, produce any *deflection* of a magnetic needle; this requires time, or the action of a continuous current. That friction electricity is capable of deflecting the magnetic needle in the same manner as voltaic electricity, was first shown by Colladon of Geneva, whose results have been fully confirmed by Faraday. When the charge of a powerful battery is made to pass through the coil of a galvanometer consisting of copper wire covered with silk, the velocity of the discharge being diminished by interposing a wet string in the circuit, the needle is immediately deflected, its direction being determined by that of the current, in exactly the same manner as by the current of the voltaic battery. The deflection may also be produced by the direct current of the machine. For this purpose, one extremity of the galvanometer coil is connected with the negative conductor, and the other with a discharging rod, either by a wire or by a wet string. The machine is then worked, and the knob of the discharging rod brought in contact with the positive conductor of the machine. The needle immediately moves a little; as it begins to swing back, the contact with the machine is to be broken; then, when the needle has completed its backward swing, and is about to return, the circuit is again to be completed. In this manner, a fresh impulse is given to the needle, which, added to the first, makes it swing through a larger arc, and by repeating this mode of proceeding several times, the needle may be deflected 30° or 40° .

Molecular Theory of Electric Action.

We have hitherto regarded the phenomena of electricity as resulting from the mutual action of two fluids (or two modifications of the same fluid), which are capable of passing through ponderable bodies and from one body to another, and whose particles attract and repel one another with forces varying inversely as the squares of the distances between them. The preceding expositions are perhaps sufficient to show that this theory affords a connected view of all the leading phenomena of electricity as developed by friction.

Faraday, however, has proposed a totally different theory, which he has developed in the eleventh, twelfth, and thirteenth series of his "Experimental Researches." According to this theory, electric action is supposed to take place, not at finite distances, but solely between contiguous particles of matter. A body charged with electricity, say with $+E$, exerts a polarising action on those particles of the air, or other insulating medium, with which it is immediately in contact, inducing the opposite polarity ($-E$) on their nearer ends, and the polarity similar to its own ($+E$) on their farther ends; these particles thus polarised act in like manner on those immediately beyond them, those again on the next, and so on, the action continually extending outwards in all directions through the insulating medium, or dielectric, and the intensity of the charge becoming less, as it is communicated to a wider range of particles. If a conducting body is interposed in the sphere of action, its particles also become polarised, exactly in the same manner as those of the dielectric, the difference between insulators or dielectrics and conductors consisting in this, that the particles of a conductor are easily brought into the charged or polarised state by the influence of an electrified body, but immediately return to their ordinary unpolarised state as soon as that influence is removed,—whereas, those of an insulator offer considerable resistance to the polarising action of an electrified body, but when once polarised, return but slowly to their ordinary state, after the removal of the disturbing cause. This difference is, of course, one of degree only, not of kind, the best conductors offering some resistance to the polarising or inductive action, and the best insulators losing their polarised condition after a certain time.

Such, according to Faraday, is the process by which a body or medium becomes electrically charged by the inductive action or influence of a previously electrified body. Discharge is the return of the whole system of charged particles to their natural or uncharged state, and takes place when one particle, or a certain number of particles, in the system, is raised by the joint action of all the forces concerned, to a state of tension which it is unable to bear: in that case, this particle or set of particles first gives way, and all the rest follow; the system, in the charged state, is, in fact, in a condition of unstable equilibrium, and gives way at its weakest point, the return to

the state of stable equilibrium taking place with more or less violence, according to the nature of the particles concerned, and the intensity of their previous polarisation. The spark or other visible manifestation of electric action, marks the line of particles along which the greatest intensity of action takes place.

This molecular view of electric action is based upon the following facts and considerations : —

1. *The phenomena of electric discharge in gases and other insulating media vary according to the nature of the medium, which must therefore be directly concerned in their production.*

That the insulating medium intervening between charged conductors has something to do with the phenomena of charge and discharge, beyond acting as a mere obstacle to the union or neutralisation of the opposite electricities, is sufficiently proved by the different insulating powers of gases, at the same pressure and temperature; by the appearance and mode of formation of the spark and brush, and the very different characters of these forms of discharge in different gases; further by the effects produced by the electric discharge on solids and liquids (pp. 396, 397).

These phenomena, however, are not in themselves sufficient to show that the polarisation of the individual particles of a body or medium is the main thing in electric action, and that it is by the successive polarisation of such particles, and not by a direct action at a distance, that the influence of a charged body is conveyed to neighbouring conductors. The facts on which the molecular view is chiefly based are the following:

2. *Every dielectric medium exerts a certain influence, peculiar to itself, on the degree of electric induction which takes place through it; in other words, every such medium has a specific inductive capacity.*

To explain the meaning of this, suppose an electrified plate of metal, A, to be suspended midway between two similar plates, B, C, and exactly parallel to them. Then, if there is nothing but air between them, the plate A will induce equally towards B and C; but on interposing any other medium, say shellac, between A and C, the inductive actions exerted by A on B and C will no longer be equal. For the description of the apparatus and mode of experimenting, by which this question has been investigated, we must refer to Faraday's eleventh series of "Experimental Researches," or to the works of De la Rive and Riess; but the principle of the method may be explained as follows:

Suppose we have two Leyden jars with equal extent of coated surface, equal thickness of glass, and in short equal and similar in every respect. Charge one of them in the ordinary way to such a degree, that the charge, when communicated to an electrometer, shall exhibit a repulsive force, say of 40° ; then divide the charge between the two jars, by making a communication between the outer coatings, and bringing the knobs in contact. The charge will of course be equally divided between them, so that, if no loss of electricity has taken place by dispersion, each will exhibit a repulsive force of 20° . Now suppose one of the jars to be made of shellac of the same thickness as the glass, and otherwise similar in every respect. In that case, Faraday finds that the charge is not equally divided between the two; but that if the glass jar is charged first, it loses by communication a greater amount of repulsive force (or intensity) than the shellac jar gains; and on the contrary, if the shellac jar is charged first, it loses by communication a smaller amount of repulsive force than that which is gained by the glass. In short, the shellac acts just like glass of less thickness, a given thickness of it producing a more complete neutralisation of the opposite electricities, a result which is supposed to indicate a higher degree of susceptibility in its particles to inductive or polarising action. This is what is meant by saying that the shellac has greater specific inductive capacity than the glass. The division of an electric charge between two bodies of different specific inductive capacity may be compared with the communication of heat between two bodies of different specific heat, such as water and mercury, the temperature of the one always falling in greater proportion than that of the other rises.

By a method founded on the principle just explained, but not capable of yielding more than very rough numerical approximations, Faraday has obtained the following values of the specific inductive capacities of certain dielectrics:

Air and all other gases	1.00
Glass	1.76
Shellac	2.00
Sulphur	2.24

Certain non-conducting liquids, such as oil of turpentine and rectified naphtha, were also found to have inductive capacities greater than that of air.

Harris, by making use of discs of the different dielectrics of the same thickness, and coated on each side with tin-foil of less diameter than the dielectric, obtained the following results:

Air	1.00	Bees-wax	1.86
Resin	1.77	Glass	1.90
Pitch	1.80	Shellac	1.95

It appears then that solid dielectrics exhibit considerably greater inductive capacity than gases, but do not differ much in this respect among themselves. The results obtained with solid dielectrics are in fact just such as would follow if the metallic coatings were brought closer together, or, which comes to the same thing, if the charge were to penetrate to a certain extent within the substance of the dielectric. That such penetration takes place is well known; it is indeed the origin of the residual charge which is always found in a Leyden jar after it has been discharged (p. 387). Faraday has endeavoured to determine its amount in different dielectrics, so as to allow for it in calculating his results on specific inductive capacity. It is possible, however, that this disturbing cause has not been sufficiently allowed for, and that, if correctly estimated, it might be found fully adequate to account for the differences observed in the inductive powers of different insulators. Riess (*Reibungs-Electricität*, i. 356) attributes the entire effect to this cause. At all events, the experiments hitherto made are neither numerous enough, nor accurate enough, to establish a fact so important to the theory of electricity as that of specific inductive capacity.

3. *Induction through dielectrics takes place, not always in straight lines, as commonly supposed, but very often in curved lines.*

When a charged body is placed in the midst of a dielectric medium, such as the air, with no conductors near, the particles of the dielectric become polarised in the manner already described, the inductive action radiating outwards in all directions in straight lines; but when conductors come in the way, the lines of inductive force change their direction, curving to a certain extent round the conductor, this curvature resulting, partly from the action of the conductors, partly from the mutual action of the polarised molecules of the dielectric, whereby a force is produced transverse to the lines of inductive force, and giving them a tendency to bulge outwards. This same transverse force is probably concerned in the magnetic action of the electric current.

For proof of this curvature of the lines of inductive action, Faraday relies, partly on the visible forms of the electric discharge in gases, as seen in the spark and more especially in the brush discharge, partly on certain experiments specially directed to the point, of which, as the mode of action is the same in all, it will be sufficient to cite the following. A cylinder of shellac A (*fig.* 394) set in a vertical position is excited negatively by friction; and upon it is placed a brass hemisphere B. An insulated carrier-ball is placed in contact with the hemisphere, and above it, in the several positions *i, k, l, m, n, o, p*, then uninsulated by touching it with the finger, insulated again, and then brought in contact with an electroscope or electrometer. In all cases, it is found to have received a *positive* charge. This charge is evidently a charge by induction, and Faraday regards it as a proof that the induction takes place from the surface of the excited lac through the air in curved lines, bending, indeed, round the surface of the brass hemisphere. The effects are exactly similar when a globe or a plate of brass is laid on the top of the excited shellac.

It is, however, not difficult to show that these and all similar phenomena are perfectly in accordance with the theory of action at a distance in straight lines. In fact, the apparatus represented in figure 394, is merely a modified form of the electrophorus, and the explanation already given (p. 385) of the action of that instrument may be applied, almost word for word, to the results obtained with Faraday's apparatus. The shellac stem being excited negatively, acts inductively on the brass hemisphere, rendering the lower surface of it positive, and the upper surface, together with any other conductor in contact with it, negative. When, however, the brass hemisphere is uninsulated, as by touching it with the finger, the negative electricity is driven into the ground, and the whole surface of the hemisphere, and of the carrier-ball in contact with it, as at *i, k, l, or m*, becomes positive; consequently, when the hemisphere is again uninsulated, and the carrier-ball made to touch an electrometer, it exhibits a positive charge. When the carrier-ball is held above the hemisphere, the latter is insulated, and the $-E$ on its upper surface acts inductively on the carrier-ball at *n, o, or p*,

Fig. 394.

rendering it, while insulated, positive below and negative above, but when uninsulated, wholly positive, so that in this case also, the ball, when again insulated and carried to the electrometer, shows positive electricity.

Faraday says, however, in allusion perhaps to such a mode of explanation, "To suppose that induction acts in some way through or across the metal, is negatived by the simplest considerations; but a fact in proof will be better. If, instead of the ball [or hemisphere] B, a small disc of metal be used, the carrier may be charged at or above the middle of its upper surface; but if the plate be enlarged to $1\frac{1}{2}$ or 2 inches in diameter, then no charge will be given to the carrier when applied at the centre of its upper surface, though, when applied nearer to the edge, or even above the middle, a charge will be obtained; and this is true, though the plate may be a mere thin film of gold-leaf. Hence, it is clear that the induction is not *through* the metal, but through the surrounding air, or *dielectric*, and that in curved lines."

The non-charging of the carrier at the centre of the circular plate may, however, be explained in another way. When any conductor or chain of conductors whatever is placed under the influence of an electrified body, the two extremities of the conductor become oppositely electrified, and between the two there must be somewhere a neutral point or line. The exact position of this neutral point or line will depend upon a variety of circumstances, as on the form and size of the conductor, its distance from the charged body, and the strength of the original charge; but it must always be found somewhere, and there is no difficulty in supposing that, with the particular arrangement in question, it would be found at the centre of the plate. Indeed, with the hemisphere (*fig.* 394), the charge of the carrier-ball regularly diminished from the edges towards the middle, being 112° at *i*, 108° at *k*, 65° at *l*, and 35° at *m*; and with forms intermediate between the hemisphere and the flat disc, a regular gradation of charges at the middle point would doubtless be obtained.

But, as already observed, the action in this and all similar experiments, is merely that which takes place in the electrophorus, the condenser, the coated plate, and, indeed, in every conceivable arrangement in which a conductor is first placed under the influence of an electrified body, then uninsulated, and lastly insulated again. In all such cases, supposing the electrified body to be charged with $+E$, the $-E$ of the conductor is drawn to its nearer extremity, and on uninsulating it, the $+E$ is driven into the ground, so that, on again insulating the conductor, and removing it from the neighbourhood of the charged body, it appears *wholly negative*. The explanation of this effect on the commonly received theory of action at a distance, is clearer and more satisfactory than any explanation that has yet been suggested on the hypothesis of induction in curved lines.

The theory of induction in curved lines is further said to be supported by the fact that electric discharge, especially in the brush-form, frequently takes place in curves, as in *figs.* 395, 396, which represent the brush as formed between a charged con-

Fig. 395.

Fig. 396.

ductor and another on which it acts by induction. But in such cases, as well observed by De la Rive (*Traité*, i. 146), the curvature of the lines of discharge is not a primary, but a secondary effect, depending on the action of the conductors. The particles of air situated between the oppositely charged conductors become polarised, in the same manner as iron filings between two opposite magnetic poles, and arrange themselves in a similar manner. The curves of the electric discharge, as illustrated by the preceding figures, have, indeed, a strong general resemblance to the magnetic curves, as shown by iron filings. Now the form of the mag-

netic curves is determined by the joint action of the two magnetic poles, and depends upon the law of magnetic action with regard to distance: the curves are, in fact,

the graphic expression of the law of inverse squares (see Dela Rive, i. 592). Now it is not to be expected that the curves of the electric discharge between two conductors should exhibit the exact form of the magnetic curves; for they are disturbed by the influence of surrounding conductors, and by the continually shifting distribution of the charge on the surface of the conductors between which they are formed; nevertheless, the resemblance is sufficiently close to show that they are produced in a similar manner, and depend on the same law with regard to distance. Robison (*Mechanical Philosophy*, iv. 53) describes an experiment, in which a thin brass plate, coated with red sealing wax, was placed on two small insulated balls charged with opposite electricities, and a fine powder of black sealing wax was sprinkled on the plate from a considerable height; on tapping the plate gently with a glass rod, the fine particles of wax arranged themselves in curved lines, diverging from the point over each of the balls, just like iron-filings under the influence of a magnet.

The mutual action of conductors at a distance is then by no means inconsistent with the polarisation of the particles of the insulating medium; indeed, a number of non-conducting particles exposed to the action of two oppositely electrified bodies, or two centres of opposite electric force, *must* become polarised; but this is a very different thing from supposing that the charging of a conducting body by the influence of another cannot take place except through the intervention of those non-conducting particles. Whatever supposition we may make as to the manner in which a conductor becomes charged, whether (to use Faraday's expression) it polarises as a whole,—as if we suppose a quantity of electric fluid to be bodily transferred from one end of it to the other,—or whether the polarisation affects each individual particle, it is certain that conductors are more susceptible of electric influence than non-conductors (the terms are, of course, used relatively), taking a charge with facility, and returning with equal facility to their natural state when the disturbing force is removed. This being the case, we may expect that a conductor placed at a certain distance from a charged body will be electrified or polarised by its influence *before the intervening non-conducting particles*, just as if a number of very hard steel filings are strewn between a magnet and a bar of soft iron, the soft iron will be magnetised instantly, while the steel filings midway between the two will not become polarised, at least not to their full extent, for some considerable time. But further we may, while still retaining the hypothesis of action at a distance, suppose that a charged conductor is itself an aggregate of oppositely polarised particles. We know, from the phenomena of magnetism, that a heap of magnetised particles, with their similar poles all turned the same way, acts just as if one half of the mass possessed north, and the other half south polarity; thus a tube full of steel filings, magnetised by any of the ordinary methods, acts exactly like a magnet with a north pole at one end, a south at the other, and a medium line between them; in fact, in the middle of the mass, the opposite polarities neutralise each other, and show themselves only towards the ends. Just so must it be in a mass of particles, each of which has its two ends in opposite electrical states; the mass will act on external bodies, just as if one half of it were charged with $+E$ and the other with $-E$.

This view of the state of a charged conductor may perhaps afford the true explanation of the well-known fact that the charge of a conducting body appears to be confined to its external surface. The ordinary theory attributes this superficial distribution to the mutual repulsion between the particles of the electric fluid, an explanation, which is perfectly satisfactory when once the hypothesis is admitted. Faraday, on the other hand, maintains that the charge of a conductor is confined to its surface, because it is only there that the particles of the conductor are in contact with those of the surrounding dielectric, by which alone their charged or polarised state can be retained. But why, on his own hypothesis, should not these superficial particles polarise those next to them, and these the next, and so on throughout the mass? It may be true that the particles of a charged conductor return to their natural state the instant they are removed from the influence of a disturbing force; but while the superficial particles are polarised, the interior particles must be subject to their influence. The fact that a proof-plane applied to the interior of a charged conductor receives no charge, proves nothing more than that all the forces there acting upon it balance each other, and their resultant is nothing; indeed it is just the same when the proof-plane is applied to the inner surface of a hollow metallic conductor, although the metal there is in contact with the air, just as much as on the outer surface.

In illustrating the action of the electric forces by the analogous phenomena of magnetism, we must be careful not to push the comparison too far. Up to a certain point electric induction, in its effects at least, is similar in every respect to magnetic induction. A charged body disturbs the electric state of another body in its neighbourhood, just as a magnet induces polarity in a neighbouring piece of iron, and in the one case as in the other, the disturbed body returns to its ordinary unpolarised state on the removal of the disturbing cause, provided, in the case of electricity, the charge or

disturbance does not go beyond a certain degree of intensity. But if that limit is passed, discharge takes place between the two bodies in the form of a spark or otherwise, and after that, neither of them returns to its former state when they are separated; the original charge then appears divided between the two, the one losing what the other gains, just as when a liquid is poured from one vessel to another. Now there is nothing in magnetism analogous to this: a steel magnet may induce the most intense polarity on a piece of soft iron in contact with it, so that the two can only be separated by the exertion of great force; but the separation once effected, every thing is as before; the soft iron loses all its magnetism, and the steel magnet returns to its original state of polarity.

In the representation which it affords of the phenomena of electric discharge—in other words, of the division of a charge between two bodies—the ordinary fluid theory has certainly the advantage of clearness and precision. Moreover, the transference of an electric fluid from one body to another is by no means incompatible with the polarisation of contiguous molecules. A body may contain an excess of one or the other electric fluid, and at the same time that fluid may be accumulated on one side of each of its particles in larger quantity than on the other. Discharge may also be conceived to take place by transference of the electric fluids in opposite directions, from particle to particle, throughout the entire conducting chain. To explain this more fully, suppose a number of pieces of tin-foil to be pasted in a row on a plate of glass, and that one end of this row is presented to the conductor of an electrical machine, while the other is connected with the ground; a series of sparks will then be perceived at each interval between the pieces of tin-foil. Now suppose the number of these pieces to be increased, and the intervals between them diminished in width; the sparks will then be smaller, and the discharge more continuous; and if we imagine this diminution of the intervals to be continued indefinitely, they will at last become so small that the sparks will no longer be visible, but the discharge will take place with apparent continuity, as in a metallic rod; nevertheless, it will still be in reality a succession of discharges from one little piece of metal to the other. An electric current may, therefore, be regarded as a succession of charges and discharges, taking place between contiguous particles.

Theory of a single Electric Fluid.

Franklin attributed the phenomena of electricity to the action of a single electric fluid residing in all bodies, and capable of passing from one to another. The particles of this fluid are supposed to repel each other, and to be attracted by the particles of ponderable matter; and a body is in its natural or neutral electric state, when the quantity of electric fluid contained in it is such that the repulsion exerted by the whole of that fluid on a particle of electric fluid situated externally to the body, is equal to the attraction exerted on the same particle by the ponderable matter of the body. A body containing more than this natural quantity of electric fluid, is in the *positive* state, and exerts a repulsive action on the electric fluid of neighbouring bodies; and a body containing less than the natural quantity is in the *negative* state, and exerts an attractive action on the electric fluid in neighbouring bodies.

It is easy to see that this theory is capable of rendering an exact account of all the phenomena of induction and discharge. A body containing excess of electric fluid repels the fluid in a neighbouring conductor to the farther end, rendering that end positive, and the nearer end negative; and a body containing excess of ponderable matter attracts the fluid in a neighbouring conductor, rendering the nearer end of that conductor positive, and the farther end negative; and when the attraction between the electric fluid and the ponderable matter on the adjoining surfaces reaches a certain limit, a quantity of electric fluid passes from the positive to the negative surface, in the form of a spark, the redundant fluid of the positive body being then divided between the two. It is unnecessary to go into details; the explanation, in every case of charge and discharge, is the same as on the two-fluid theory, merely substituting the attraction between ponderable matter and electric fluid for that of the two electric fluids, one for the other.

The Franklinian theory has, however, been supposed to fail in accounting for the mutual repulsion of two negatively electrified bodies. When two bodies, pith-balls, for example, contain excess of electric fluid, the mutual repulsion of the particles of that fluid will cause it to be most concentrated at their farthest points, where, being prevented from going any farther, by the resistance of the air, it will cause the balls to fly asunder. But when the bodies contain less than their natural quantity of electric fluid, their mutual repulsion cannot be accounted for in a similar manner; hence Aepinus was induced to add to the Franklinian theory the assumption that *the particles of ponderable matter repel each other*. This assumption has usually been considered as opposed to the well-known fact of universal gravitation; but it is not

necessarily so: for, as pointed out by Roget, in his treatise on Electricity, in the "Library of Useful Knowledge," the tendency of any two bodies to move towards or away from one another, is the resultant of all the attractive and repulsive forces exerted between them; if, therefore, we suppose the sum of the repulsive forces (that is, of the particles of electric fluid for each other, and of the particles of ponderable matter for each other) to be slightly less, at the same distance, than the sum of the attractive forces (exerted between the particles of ponderable matter and electric fluid), there will remain a certain residual attractive force, which may constitute the force of gravitation.

On the other hand, we may observe that the assumption of a repulsive force between the particles of ponderable matter is not at all required to explain the phenomenon which gave rise to it. In fact, two negatively electrified bodies may be supposed to recede from each other, not because they actually repel each other, but because they attract one another less than either of them is attracted by the surrounding air,—just as a balloon rises in the air, not because it is actually repelled from the earth, but because it gravitates less than an equal bulk of air.

The Franklinian theory has been supposed to receive considerable support from the well-known appearance of the positive and negative brush (p. 389). The positive brush, with its divergent ramifications, does certainly suggest the idea of a fluid forcibly ejected through a narrow aperture, whereas the negative brush and glow have rather the appearance of streams of fluid converging towards an aperture; but the beautiful experiments of Faraday on the appearance of the electric discharge in different gases, show conclusively that the difference of character in the two brushes is much less absolute than was formerly supposed, and that it depends essentially on the nature of the medium. Gassiot, in one of his experiments on the electric discharge in vacuous tubes (Proc. Roy. Soc. ix. 605), speaks of "the appearance of a direction of a force emanating from the negative."

It would be difficult to single out any electrical phenomenon which affords a decisive argument in favour of the theory either of one or of two electric fluids. The two-fluid theory has, however, this advantage, that it represents the negative state of electric charge as the exact counterpart of the positive; whereas the one-fluid theory assumes a fundamental difference between the two, regarding one as arising from an excess, and the other from a deficiency, of electric fluid, without being able to say decidedly which is in excess and which in defect. The positive or vitreous state is indeed generally regarded as arising from excess of electric fluid; but, with the exception of certain appearances of the electric light just noticed, no difference has yet been pointed out between the phenomena of positively and negatively electrified bodies, capable of indicating in which of the two the excess is to be found.

Of late years, the study of the relations of electricity to heat, light, magnetism and mechanical force has led to the notion that its effects are due to peculiar arrangements and motions of the particles of ponderable matter, rather than to the movements of any peculiar fluid or fluids. And, however clear may be the view which the fluid theory affords of the phenomena of electric charge and discharge, it is not difficult to regard these phenomena, at least in their general features, from a different point of view. The opposite characters of the two electricities may be supposed to arise from two different kinds of motion among the particles of bodies, perhaps analogous to the vibrations of rays of light polarised in different planes; and the division of an electric charge between two bodies, may be compared to the division of velocity which takes place when a body in motion strikes another at rest or moving in a different direction.

In considering this question, however, it should not be forgotten that the phenomena of light, and certain disturbances in the motion of comets, point to the existence of an ethereal medium pervading space and filling up the intervals between the particles of ponderable bodies. Such a medium can scarcely be without influence on the electric state of a body; and, admitting its existence, it is by no means improbable that it may have a translatory as well as a vibratory motion, the former giving rise to the phenomena of electricity, the latter to those of light.

DEVELOPMENT OF ELECTRICITY BY MECHANICAL ACTION.

1. **By Friction.** The development of electricity by the friction of two solid bodies, one at least of which is a non-conductor, has already been considered (pp. 376, 377). We have now to notice the electric effects produced by the friction of pulverulent bodies, of conducting solid bodies, and of liquids.

Powders projected from a pair of bellows, become electrified by friction against the tube. Bennett made the curious observation, that powdered chalk, blown from a bellows against the cap of an electroscope, exhibited $+E$ when the cap was

about 5 inches from the nozzle of the bellows, but $-E$ when the distance was 6 inches. The powder is in fact positively electrified by friction against the tube of the bellows, negatively by friction against the cap of the electroscope, the one or the other of these effects predominating according to the distance. Pounded ice and very dry snow become electrified when blown from a bellows.

Powders become strongly electrified by passing through sieves. Pulverised earths and a large number of solid acids acquire negative electricity when sifted through organic tissues. Many powders become electrical when stirred. Dry oxalate of calcium stirred with a rod of glass or platinum becomes positively electrical in so high a degree that it is lifted out of the containing vessel on removing the rod (Faraday). Powders are also strongly electrified by rubbing against each other. When sealing wax and sulphur in powder are rubbed together, the wax becomes positive, the sulphur negative. When pounded resin (colophony) and red lead are rubbed together, the resin becomes negative, the red lead positive. A good way of exhibiting the opposite charges thus acquired by two powders, is to project them from a caoutchouc bottle having a glass tube inserted into its mouth and a piece of flannel tied over the tube, against two brass knobs (the knobs of two Leyden jars for example), oppositely electrified; the resin is then wholly deposited on the positive, the red lead on the negative knob. If the powders are projected against a resinous cake two points of which have been oppositely electrified, they collect round the points in very remarkable configurations, called *Leuchtenberg's figures*, the resin being deposited round the positive point in beautiful arborescent forms, the red lead round the negative point in round patches, or sometimes in concentric circles, altogether destitute of arborescent character. The difference is of the same kind as that between the positive and negative brush in air; it would be interesting to observe how the figures would be modified in atmospheres of different gases.

Friction of Good Conductors.—Metals and other good conductors do not exhibit any signs of electricity when rubbed together and then brought in contact with an electroscope, because the opposite electricities recombine more quickly than the surfaces can be separated. If, however, one of the metals, in the form of filings, is made to fall over the surface of the other, signs of electric charge become apparent, because the fine division diminishes the conducting power of the metal. Becquerel finds that when filings of any metal are projected against a plate of the same metal, the filings become negative, and the plate positive, the effect being stronger as the metallic powder is finer and more rapidly projected. When the plate and the filings are of different metals, the effect is complicated by the electric charge resulting either from simple contact of the two, or from chemical action exerted on one of them by the moisture in the air (p. 414), so that the effect due to friction cannot be exactly ascertained. Copper filings become negative when projected against plates of zinc, lead, tin, iron, bismuth, and antimony; zinc filings positive with plates of platinum, gold, silver, copper, and tin,—negative, with plates of zinc, bismuth, antimony, and iron. Pulverised metallic oxides and sulphides are positive with respect to the corresponding metals.

To exhibit the electricity developed by rubbing together solid pieces of good conductors, it is necessary to make use of the galvanometer. Solder a narrow strip of copper plate to one end of a galvanometer wire, and a similar strip of iron plate to the other end, and enclose the junctions, together with a portion of the plates, in corks, to serve as handles, so that no heat may be communicated from the hand to the metal. If the two plates are then simply brought in contact, no electric effect will be apparent; but on rubbing one plate lightly over the other, taking care to separate the rubbed parts as quickly as possible, but still maintaining the contact, the needle of the galvanometer will be deflected, its direction indicating the passage of a current of positive electricity from the iron through the wire to the copper, and therefore showing that the iron has been rendered positive by the friction, and the copper negative. Of the bodies in the following table, each one, when thus treated, becomes negative with all those which follow, positive with all those which precede it: *Bismuth, palladium, platinum, lead, tin, nickel, cobalt, copper, gold, silver, iridium, zinc, iron, cadmium, arsenic, antimony, anthracite, peroxide of manganese*. This is the same as the thermo-electric series (p. 412); nevertheless, the effects do not appear to be due to heat; for, if two cylinders, about 4 inches long, one of copper, the other of iron, are attached to the ends of the galvanometer wire, and rubbed together in such a manner that the same points of the one may traverse the entire length of the other, whereby these points are heated much more strongly than the surface, the same current is obtained, both in direction and in intensity, whether the iron be rubbed in this way over the copper, or the copper over the iron. The degree of heat evolved in either of the metals is, therefore, without influence on the result.

Friction of Liquids.—It was formerly supposed that electricity is not developed by

the friction of liquids against solid bodies. Subsequently, however, it was found that liquids, in the form of very small globules, either alone or mixed with air, yield a considerable quantity of electricity by friction against solids; alcohol, ether, and liquid resins, projected in this manner against rough glass, render it strongly positive. Mercury may be rendered highly electric by friction. When a small quantity of mercury, contained in a foot-glass, is connected by an iron wire with a gold-leaf electroscope, and a solid body, such as a glass rod, partially immersed in it, no signs of electric excitement are manifested during the immersion; but on gradually withdrawing the solid body, the leaves of the electroscope diverge, the excitement increasing as the solid body is withdrawn, and reaching its maximum at the moment when it leaves the mercury. With organic substances, such as paper, linen, wool, woollen cloth, silk, sarcenet, feathers, and felt, the mercury takes a positive charge; with feathers and felt, when very dry, it sometimes gives sparks. Most mineral substances (*e.g.* rock-crystal, sulphur, and glass), render the mercury negative; amber and sealing-wax give it a strong positive charge.

Very large quantities of electricity are developed by the friction of water, in the form of minute globules, against solid bodies. Steam escaping from boilers often exhibits positive, and the boiler, if insulated, negative electricity. If one hand, or a plate of metal, or a bundle of wires with numerous points, be held in the stream of vapour, and the other brought near the boiler, a spark may be obtained from the boiler. This effect, accidentally discovered by a workman in Sir William Armstrong's factory at Sighill, near Newcastle, was carefully investigated by the latter (*Phil. Mag.* [3] xxii. 1), who found that the intensity of the electric charge increased with the pressure of the steam, and that the steam was in most cases positive, the boiler negative. Armstrong attributed the electric excitement to the expansion of the vapour; but Faraday, by a very careful analysis of the phenomenon (*Experimental Researches*, ser. 18), has shown that electricity is never excited by the passage of pure steam, and is manifested only when water is likewise present. Hence he concludes that the effect is altogether due to the friction of the globules of water against the sides of the opening, or against the substances opposed to its passage, as the water is rapidly moved onwards by the current of steam. Accordingly, it is found to be increased in quantity by increasing the pressure and impelling force of the steam. The immediate effect of this friction is, in all cases, to render the steam positive, and the solids, whatever they might be, negative. A wire placed in the current of steam at some distance from the orifice, exhibits the positive electricity acquired by the steam, of which it is then merely the recipient and conductor. The results may be greatly modified by the shape, nature, and temperature of the passages through which the steam is forced. The electric charge is greatly increased by causing the jet of steam to issue from a tube of hard wood. With an ivory jet, on the contrary, very little electricity is produced. Heat, by preventing the condensation of the steam into water, likewise prevents the evolution of electricity, which, however, speedily appears on cooling the passages, so as to restore the water which is necessary for the production of that effect. The phenomenon of the evolution of electricity in these circumstances is dependent also on the *quality* of the fluid in motion, more especially in relation to its conducting power. Water will not excite electricity, unless it be pure: the addition of any soluble salt or acid, even in minute quantity, is sufficient to destroy this property. The addition of oil of turpentine, on the contrary, occasions the development of electricity of the opposite kind to that which is excited by water; each particle of the water then becomes covered with a thin film of oil, so that the friction takes place only between that external film and the solids along whose surface the globules of liquid are carried. A similar but more permanent effect is produced by the presence of olive-oil, which is not, like oil of turpentine, subject to rapid dissipation.

Compressed air, when pure and dry, does not exhibit any sign of electricity when issuing from an orifice; but if damp, it acquires positive electricity, and renders the vessel negative, the effect being due to the particles of water condensed by the cold arising from the sudden expansion of the air. The escaping air likewise becomes electric if it is impregnated with fine dust or powder of any kind. Thus, when air, containing finely divided sulphur, issues from a mouth-piece of metal, wood, or sulphur, the air acquires $+E$, the vessel $-E$; powdered resin renders the vessel negative if the mouth-piece is of metal, positive, if it is of wood; starch-powder renders wood negative; very finely divided silica imparts $+E$ to metals or to wood. The discharge of a dusty air-gun in the dark is attended with a flash of light, which is probably due to electricity developed in a similar manner.

The general conclusion to be drawn from the experiments above described, is that electricity is excited by friction between two solid bodies, or between a solid and a liquid; but that the friction of gases against solids does not produce any development of electricity.

The electric excitement resulting from the friction of water is applied to the construction of an electrical machine of great power, called the **HYDRO-ELECTRIC** machine. It consists essentially of a cylindrical boiler *a* (fig. 397), a set of escape-tubes *c*, partly

Fig. 397.

enclosed in a condenser *b*, and a conductor *d*. The boiler, which is usually about 15 inches in diameter and 30 inches long, is heated by an interior fire-place fed with charcoal; *f* is the fire-door, *g* the chimney. The boiler is supported on four strong glass legs *v*, fixed to a frame which stands on castors *u*; *s* is the safety-valve; *r* a cock for letting off the steam, and setting the machine in action, the steam first passing into the tube *t*, thence into the three small horizontal tubes passing through the condenser *b*, and issuing by the mouth-pieces *c*. The condenser *b* contains cold water, not, however, reaching to the level of the horizontal tubes, but supplied to them by cotton wicks hung over them, and dipping into the water; the wicks thus become moistened by capillarity, and cool the tubes just sufficiently to condense a portion of the steam. The steam which

forms within the condenser escapes into the chimney by the tube *g*'.

The construction of the mouth-pieces is of great importance; in fact, the power of the machine mainly depends upon them. The escape-tubes near their extremities are widened in the form of a cone (fig. 398), and within this cone is introduced a piece of

Fig. 398.

hard wood *p*, having the form of a truncated cone, the smaller base of which is joined to the piece of metal *m*. The current of vapour striking against this piece of metal is divided, and forced to enter the slit; where it is again divided and passes into the tube in the axis of the wooden cone; the screw ring *n* serves merely to keep the different parts of the mouth-piece together.

As the steam passes through the condenser, part of it is reduced to minute drops of water, which pass on with the steam, and it is by the friction of these drops of water against the wood that the electricity is developed; in fact, the drops of water correspond to the rubber of an ordinary electrical machine, the wooden mouth-piece to the plate or cylinder, and the steam is merely the motive power serving to produce rapid friction.

The steam, as it issues from the tubes, impinges against a number of metallic points at the top of the conductor *d*, and charges the conductor with $+E$; this conductor is insulated, and sparks are taken from the ball *K*.

The tube *xy* serves to introduce different pulverulent substances into the course of the steam in order to study their influence on the nature of the electricity developed.

The hydro-electric machine yields large quantities of electricity, and of very high intensity. A gigantic machine of this kind, exhibited a few years ago at the Polytechnic Institution, having a boiler $3\frac{1}{2}$ feet in diameter and $6\frac{1}{2}$ feet long, charged a battery containing 36 square feet of coated surface in half a minute, and gave sparks 22 inches long, which instantly set fire to tow filled with pounded resin, and to a heap of wood-shavings,—effects which, with the ordinary electrical apparatus, can only be produced by the discharge of a large jar.

The hydro-electric machine is not, however, very well adapted for general use. It cannot be used in an ordinary apartment, as, besides the inconvenience of the fire, it

is necessary to provide some means of carrying off the steam, otherwise the atmosphere soon becomes quite unfit for electrical experiments. Moreover, to get up the steam to the required pressure, the fire must be kept up for several hours, and to keep the machine in a proper state of efficiency, the interior must be cleansed from time to time by heating a solution of potash in the boiler, blowing it through the tubes, and then washing out with pure water.

2. By Pressure. Friction is not the only kind of mechanical action by which electricity may be developed; indeed, every molecular movement of a solid body, however produced, appears to be attended with a disturbance of the electric equilibrium.

Solid bodies become oppositely electrified when merely pressed together and afterwards separated.

When two parallel faces, natural or artificial, of a mineral are pressed between the fingers, the mineral frequently becomes electrical on these surfaces, generally showing positive electricity. Calespar retains the electricity thus developed from three to eleven days, topaz and fluor-spar several hours, mica one or two hours, and rock-crystal for a shorter time. Talc must be insulated in order to render it electrical; heavy spar and gypsum are not sensibly electrified (Haüy).—According to Becquerel, not a trace of electricity is perceptible while bodies are being pressed together; it is not till they are separated that the one appears positively, the other negatively electrified. A slice of cork becomes positively electrified when pressed against a slice or plate of caoutchouc, orange-peel, retinasphalt, coal, amber, zinc, copper, silver, kyanite, or heated double refracting spar, these substances at the same time becoming negative. On the contrary, the slice of cork becomes negative with all dry animal substances, with heavy spar, gypsum (which must be freed by drying from hygroscopic water), fluor spar, and double refracting spar, not heated,—those substances at the same time becoming positive. Two good conductors pressed together exhibit, when separated, no other electricity than that developed by mere contact. Two similar bodies do not become electrical by pressure, unless one of them is at a higher temperature than the other; and then the hotter body always becomes negative, the colder positive. The strength of the electricity thus developed depends upon the nature of the bodies, the state of their surfaces, the intensity of pressure, and the rapidity of separation. Cork produces more electricity with calespar, when the pressure is exerted on one of the faces parallel to the cleavage-planes, than with heavy spar; with the latter more than with polished rock-crystal, and with this more than with gypsum, or with the polished surface of calespar; and when pressure, temperature, dryness, and polish of the cleft surfaces are equal—three times as much with calespar as with gypsum. The intensity of the electricity varies directly as the pressure; so that when the latter is doubled, the former is doubled also. Lastly, if the two bodies which have been pressed together are slowly separated, the two electricities have time to reunite, and a much smaller quantity remains in the free state after the separation. Bodies rendered electrical by pressure retain the electricity for a longer time, in proportion as their insulating or non-conducting power is greater.

3. By Cleavage and Separation of Surfaces. When two laminæ of a crystal of mica are suddenly torn asunder, there is not only an appearance of light produced, but one lamina becomes positively, the other negatively electrified; if again pressed together and subsequently separated, they again appear electrified. Also, on the cleavage of calespar, fluor-spar, heavy spar, topaz, tale, and dry warmed gypsum, and on tearing a playing-card into its two sheets, the separated laminæ appear oppositely electrified. In topaz, whose cleavage takes place parallel to the terminal faces of the prism, the cleft surface belonging to one end of the prism exhibits sometimes one kind of electricity, sometimes the other. When melted shellac is poured upon glass and pulled off after cooling, both become electrified. Non-crystalline bodies, such as sealing-wax or glass, exhibit no electricity when broken.

Two sheets of paper stick fast together when rubbed with india-rubber, and, on being pulled asunder, appear strongly charged with opposite electricities, often sufficiently to give sparks.

The electric effects obtained in the solidification of fused substances depend, like the preceding, on a disaggregation, or forcible separation of particles. When melted sulphur is poured into a short glass vessel of conical shape, and a glass rod is inserted into the sulphur before it solidifies, no electricity is apparent so long as the sulphur remains in the glass, but on lifting out the solid cone by the glass handle, the sulphur exhibits $+E$, the inner surface of the vessel $-E$. Similar effects are exhibited by chocolate and glacial phosphoric acid when melted and left to solidify in glass vessels. The development of electricity in these cases depends on the separation of the two surfaces by the contraction of the melted mass; substances which expand on

cooling, like fusible metal, exhibit no electricity when left to solidify in glass vessels. Hence Gay-Lussac concluded, that the change of state from the liquid to the solid is not a direct source of electric excitement, but merely serves in some cases to produce a molecular disaggregation, which is the true source of the electricity. If sulphate of copper and potassium be brought into a state of red-hot fusion in a platinum crucible, connected by a ring of wire on which it rests with a Bohnenberger's electroscope (p. 428), and then left to cool, no electricity will be apparent during the crystallisation; but as soon as the crystalline mass begins to contract with an audible decrepitation, and falls to pieces gradually and spontaneously, the formation of each new fissure is accompanied by a development of electricity, and the effect goes on till the whole crumbles to dust. (Böttger, Pogg. Ann. l. 43.)

4. By Vibration. When a metal rod having one of its ends coated with resin, is made to slide through an insulated metallic ring, so that vibrations may be produced in the metal, and communicated to the resinous coating, the rod and the coating both become electrical; the kind of electricity developed in each of them depending on the direction in which the rod is moved. When the rod slides through the ring with the covered end in advance, the uncoated portion of the rod, and therefore also the inner surface of the resinous coating, becomes negative: the outer surface of the coating at the same time becoming positive, as may be shown by hanging a small metal ring over it, and connecting this ring by a thin wire with a delicate gold-leaf electroscope. On reversing the movements, the electric charges are likewise reversed. If both ends of the rod are coated, and connected in like manner with electroscopes, they exhibit opposite electricities at each movement of the rod.

Different metals exhibit this effect in various degrees; brass and silver much more strongly than iron or steel. The effect is due to the longitudinal vibration produced in the rod, which sets the particles of the resinous coating also in vibratory motion, and seems to cause them to arrange themselves in a polar chain, so that the two surfaces of the layer exhibit opposite polarities. That it is not due to mere friction is proved by the fact, that the direction of the electric polarity remains the same as above when the ends of the rod are coated with sulphur, but is reversed when they are covered with pieces of glass tube; it is likewise unaltered when the inner surface of the ring is coated with various substances. When rods composed entirely of resin, sulphur, or glass are used, the effects are the same as when the ends of a metal rod are coated with these substances; glass, however, becomes much more strongly excited than resin or sulphur, because it is more elastic and vibrates better. It is remarkable that these effects are produced quite as strongly in a vacuum as in air. (Volpicelli, Compt. rend. xxxviii., 15 Mai, 1854.)

When the ends of a galvanometer wire are connected by a wire composed of brass and iron soldered together, and this compound wire is stretched and made to vibrate so as to give out a musical sound, the needle is immediately deflected, indicating the production of an electric current. A compound bar of antimony and bismuth soldered together, end to end, 25 centimetres long, 10 mm. wide and 7 mm. thick, exhibits this effect very strongly when connected with a galvanometer, and struck with a piece of iron. A similar effect may be obtained with a bar of a single metal, iron, for example, one portion of which is hard and crystalline, the other soft and fibrous, (Sullivan, *Archives d'Electricité*, x. 480). Ermann (*ibid.* v. 477) has also shown that when different metals are combined together, as for thermo-electric couples (p. 412) and rubbed slightly at the point of contact, currents are produced in the same direction as if heat were applied. The effect is not, however, due merely to heat developed by the friction, but is a direct result of the vibration or molecular disturbance thence resulting; for the current shows itself the instant that the friction commences, and ceases when the friction is discontinued, however long it may have been kept up.

When a long unannealed copper wire supported at intervals on props, is connected with a galvanometer, so as to form a closed circuit, and one part of it raised or lowered, and then released so as to throw the wire into vibration, an electric current is sometimes produced. If the needle does not move, it is probable that equal and opposite currents are produced in different parts of the wire; in that case, if one part of the wire be hardened by hammering or twisting, and the movement then repeated, a current will be produced. These currents are not due to the inductive action of the earth's magnetism; for they are produced in the same way whether the wire be placed parallel to the magnetic meridian, or inclined to it at any angle whatever. (Peltier, *Archives d'Electr.* i. 145).

It appears then that every molecular disturbance taking place in a solid body is attended with a development of electricity. Whether the electric polarity thus produced actually consists in a peculiar arrangement of the molecules of the body, or in particular movements imparted to them, or arises from a new arrangement of the

electric fluid or fluids associated with them, is a question which cannot at present be answered. But the whole of the phenomena just described appear to indicate that the electric polarity, whatever it may be, affects each separate particle of the body. We may suppose indeed that the separate particles of bodies are always in a polarised condition; but that when a body is in its ordinary state, the poles of the several particles are disposed without any regular order, so that their resultant action on any external particle is nothing, and that electric excitement consists in turning all the similar poles in one direction, —just as a glass tube filled with steel-filings acts like a bar-magnet when the filings are all regularly magnetised, but loses its polarity when the regularity of the arrangement is disturbed by shaking. The opposite electrification exhibited by two surfaces of a crystalline substance, like mica, when broken, may be compared to the effect of breaking a bar-magnet in two, and seems to show that the opposite polarities of the particles of the crystal neutralise each other when in contact, and manifest themselves when separated. The comparison must not, however, be carried too far: for if a crystal were made up of polarised particles symmetrically arranged, it would constantly exhibit opposite polarities at its two ends. The effect of motion, in allowing the particles of a body to assume the symmetric arrangement essential to electric polarity, is strikingly shown by the experiments of Volpicelli and by those of Sullivan and Ermann; the latter also indicate a close connection between the effect of mechanical disturbance and that of heat, which we now proceed to consider.

DEVELOPMENT OF ELECTRICITY BY HEAT.

1. *In Crystals*: — *Pyro-electricity*.—Many crystals, while their temperature is rising or falling, exhibit contrary electricities at their opposite ends, those extremities, or poles, which are positive while the crystal is being heated, becoming negative while it cools. The effect is altogether dependent on *change of temperature*, no crystal exhibiting any electric polarity while its temperature remains constant.

That pole of a crystal at which the algebraic sign of the change of temperature is the same as that of the electricity developed (*e. g.* which exhibits $+E$ while the temperature is rising) is called the *analogous pole*; the other, the *antilogous pole*.

The electric polarity of crystals appears to be essentially related to hemihedry, and in many instances to the non-superposable hemihedry exhibited by substances which possess the power of circular polarisation (see CRYSTALLOGRAPHY, p. 157). It was first observed in the tourmalin, which has long been known to possess the power of attracting light bodies when heated. This mineral usually crystallises in nine-sided prisms of the hexagonal system (*fig.* 399), which may be conceived to be formed from the

triangular prism $\frac{8P^2}{2}$ (CRYSTALLOGRAPHY, p. 143) having each of its edges bevelled by two small prismatic faces, and acuminated at both ends by three rhombohedral faces (denoted by P in the figure), which at one end, *a*, are set upon the faces of the triangular prism, and at the other end, *b*, on its edges. The end *a* is the analogous pole, becoming positive when the crystal is heated, negative as it cools.

The manifestation of electric polarity in the tourmalin is confined within certain limits of temperature, mostly between 10° and 150° C.; these limits vary, however, according to the length of the crystal.

A heated crystal of tourmalin suspended by its centre may be attracted and repelled by electrified bodies, just as a magnetic needle is attracted and repelled by other magnets; it further resembles a magnet in this respect, that on breaking it across, while still in the electrically polarised state, each of the fragments is found to have a positive and a negative pole, showing that the electric polarisation affects each individual particle, and that in the excited crystal all the particles have their poles symmetrically disposed.

In most crystals, the electric polarity is much less powerful than in the tourmalin, and in some cases can only be detected by the use of a delicate electroscope; but the general laws affecting it are the same in all.

In boracite, which crystallises in the form $\infty O \infty \cdot \frac{O}{2}$ (*fig.* 400), the four cubic summits which are truncated by shining tetrahedral faces, are antilogous poles; the other four, which are either not truncated at all, as in the figure, or truncated by dull tetrahedral faces, are analogous poles. Silicate of zinc, or siliceous calamine, which

Fig. 399.

The word "and" in this table is placed between two metals of equal thermo-electric power. The dash separates the thermo-positive from the thermo-negative metals (see below). The discrepancies in the statements of different experimenters induce the supposition that the direction of the current is affected by impurities in the metals, and varies with the difference of temperature. That the latter may really be the case, will appear from the following:

When iron is moderately heated in contact with copper, silver, gold, brass, or zinc, positive electricity proceeds from the iron through the galvanometer to the copper, &c., but when the heat is stronger, from the copper, &c., to the iron (Cumming). The reversal of the direction of the current takes place at a dull red heat, when copper and iron are the metals employed (Becquerel). Zinc and gold produce at 70° C. a feeble current which passes from the zinc through the galvanometer to the gold; at 150° , this current ceases; at 180° , an opposite current sets in, and becomes very strong at 275° . On the contrary, with zinc and silver at a low temperature, positive electricity passes from the silver through the galvanometer to the zinc. This current attains its greatest strength at 120° C., diminishes at a higher temperature, ceases at 225° , and is reversed at still higher temperatures. (Becquerel.)

The farther two metals are separated in the thermo-electric series, and the higher the temperature at the point of junction, the stronger is the current; but it is always small in quantity and of very feeble tension.

By combining a number of thermo-electric pairs into a *thermo-electric battery*, *chain*, or *pile*, a powerful thermo-electric current may be obtained: e.g. a number of bars of bismuth and antimony, or of platinum and iron, alternately soldered together

Fig. 402.

Fig. 403.

(figs. 402, 403), and heat applied to the first, third, fifth, &c., points of junction, whilst the second, fourth, &c., are kept cold. In this manner the thermo-electric current produces, not only deflection of the needle, but likewise chemical decomposition of liquids (Botto, Pogg. Ann. xxviii. 238), and heating effects, so that even when one of the conducting wires of the battery is cooled by immersion in ice, the point of junction of that wire situated without the ice becomes sensibly warmed (Watkins, Phil. Mag. [3] xiv. 82; also Pogg. Ann. xlv. 497). Melloni's *Thermo-multiplier*, or *Thermoscope*, is a pile formed in this manner of bars of bismuth and antimony, and connected with a galvanometer. The rays of heat fall on the first, third, fifth, &c., points of junction, whilst the second, fourth, &c., are kept cool. The smallest difference of temperature between the two sets of junctions suffices to produce deviation of the needle.

b. With one Metal.—A metallic wire connected with the two ends of a galvanometer gives no electric current when heated in the middle; but when each end of the galvanometer is connected with a wire, and the end of one of the wires is heated and then quickly pressed on the cold end of the other, an electric current becomes manifest by the deflection of the needle of the galvanometer. The direction and strength of this current vary with the nature of the metal employed. In the so-called *thermo-positive metals*, bismuth, platinum, gold, silver, copper, tin, lead, &c., the positive electricity goes from the cold piece of metal through the galvanometer to the hot piece; in the *thermo-negative metals*, zinc, iron, antimony, &c., from the hot to the cold end. The more one end is heated, the stronger is the current. According to Yelin, bismuth produces the strongest current with a given degree of heating; then follows antimony, then zinc, silver, platinum, copper, brass, gold, tin, and lastly lead; but, according to Nobili, this order is correct for certain temperatures only.

A simple platinum wire connected with a galvanometer also produces a current when heated, if it be tied in a knot at one point and heated near the knot; because the more rapid cooling through the knot causes unequal distribution of heat on the two sides; the positive electricity proceeds from the knot through the galvanometer to the heated part. Two copper wires do not produce so strong a current when clean as they do when covered with oxide or with a thin film of silver or gold, because the covering hinders the communication of heat to the cold end, and consequently interferes with its uniform distribution (Becquerel). Mercury is not thermo-electric, according to Matteucci and De la Rive; very slightly, according to Peltier.

DEVELOPMENT OF ELECTRICITY BY CHEMICAL ACTION—GALVANIC OR VOLTAIC ELECTRICITY.

Chemical action is always accompanied by a disturbance of the equilibrium between the molecules of a body, and may therefore be expected to give rise to electric excitement. It is, in fact, the most powerful of all causes of electric action, though it does not appear to be so in all cases, because the opposite electricities recombine, for the most part, as fast as they are separated, unless particular arrangements are made to prevent such recombination. In fact, in this, as in other modes of development, the quantity of electricity which becomes apparent, generally forms but a small portion of that which is actually set free.

The development of electricity by chemical action will be considered under the following heads:

1. Between a liquid and a solid.
2. Between two liquids.
3. Between a gas and a liquid or solid.
4. By combustion.

Of these the first is the most important, as it is that which forms the basis of the ordinary voltaic battery.

1. *Development of Electricity by the Chemical action of Liquids on Solids.*
VOLTAIC BATTERY.

When a metallic capsule containing a conducting liquid, viz. water or any aqueous solution, is placed on the cap of a delicate condensing electroscope (p. 386), and a piece of another metal held between the fingers is immersed in the liquid, without touching the capsule, the leaves of the electroscope diverge with $+E$ or $-E$ according to the nature of the metals and of the liquid interposed between them. If the capsule is of platinum, the electroscope shows that it has taken a charge of $+E$, whatever may be the nature of the liquid and of the metal dipped into it. A copper capsule on the other hand becomes positive or negative, according as the metal dipped into the liquid is more or less attacked by that liquid than the copper capsule itself. The result in all cases resolves itself into this, that when a metal is acted upon by a liquid, the metal becomes charged with $-E$, the liquid with $+E$. Thus, when zinc is plunged into water contained in a platinum capsule, the zinc takes $-E$, which passes into the ground, and the $+E$ taken up by the water is transferred to the capsule and thence to the upper plate of the condenser; consequently the gold leaves connected with the lower plate exhibit a negative charge. Similarly with zinc, water, and copper. If, on the other hand, a piece of platinum or gold is plunged into nitric acid contained in a copper capsule, the copper becomes negative and the leaves of the electroscope diverge with $+E$. If both metals are attacked by the liquid, the charge of the condenser is that which results from the difference of the two actions.

The effects just described are exactly the same whether the metallic capsule and the plate of the condenser on which it rests are formed of the same or of different metals; they cannot therefore be due, as is sometimes supposed, to electricity developed by the contact of dissimilar metals; in fact, as already observed, the kind of electricity taken up by the capsule depends altogether on the reaction which takes place between the two metals and the liquid. Moreover, it has been distinctly shown by De la Rive and others, that contact of dissimilar metals is not accompanied by development of electricity, unless one of the metals is at the same time chemically acted upon by the moisture of the air, or by some other liquid. See De la Rive (*Traité*, ii. 773-787), and Wiedemann (*Die Lehre vom Galvanismus und Electromagnetismus*, i. 17).

The signs of electric tension exhibited by the arrangements above described are feeble, even when the chemical action is highly energetic, and require a very delicate electroscope to render them visible. The cause of this apparent anomaly is that, the metal and the liquid which act upon it being both conductors and remaining in contact, the greater part of the opposite electricities recombine as fast as they are separated. Accordingly, the electric tension may be greatly increased by causing the liquid to evaporate at the instant that the chemical action takes place. Thus, when a capsule of any oxidisable metal, copper, zinc, or iron for example, is strongly heated, then laid on the plate of the electroscope, and a few drops of water either pure or slightly acidulated poured into it, the liquid attacks the hot metal and vaporises at the same time; consequently the $+E$ is carried off by the vapour and cannot reunite with the $-E$, which therefore passes into the electroscope, and produces a strong divergence of the gold-leaves, even without the aid of a condenser. If the quantity of water introduced is too great to be completely vaporised, scarcely any divergence is produced,

because the two electricities can then reunite, the $+E$ not being carried off by the vapour.

The development of electricity in this manner was observed by Volta and De Sausure, who ascribed it, not to chemical action, but to the vaporisation of the liquid. But it is easy to show that this view is not correct: for if a clean platinum capsule strongly heated be laid on the cap of the electroscope, and a few drops of water or any other liquid which neither acts upon the platinum nor is decomposed by the heat, be thrown into it, no signs of electricity are manifested. It is necessary, however, to use a shallow capsule with the lip not turning inwards; otherwise electricity may be developed by the friction of little globules of water carried away by the steam against its sides (p. 407). If the water contains any salt in solution, electricity will be developed by the separation of the water from the salt.

The development of electricity by the oxidation of a metal may likewise be shown without the aid of heat. If a small piece of potassium be spread on the bottom of a platinum capsule connected with a condenser, a drop of water let fall on the potassium, and the plate of the condenser lifted up as soon as the hydrogen-flame produced by the decomposition of the water has ceased, the electroscope gives signs of electricity, showing that the capsule has been charged with $-E$, the $+E$ having been carried away by the hydrogen and aqueous vapour evolved.

Fig. 404.

The electricity developed by chemical action may be made to show itself in the dynamic, much more easily than in the static form. When a plate of zinc and a plate of platinum are immersed in dilute sulphuric acid and connected outside the liquid by a wire (fig. 404), a current of electricity is immediately set up, continuing as long as the conducting circuit is complete and the action of the acid on the zinc goes on. This may be shown by placing a magnetic needle near any part of the connecting wire; the needle is then deflected, tending to place itself at right angles to the wire; and the position of its poles shows that the current of $+E$ passes from the zinc through the liquid to the platinum and thence through the wire to the zinc, as indicated by the arrow in the figure, this direction being in accordance with the charging of the condenser by an arrangement of zinc, acid, and platinum as before described (p. 414).

The greater facility with which the electricity thus developed shows itself in the form of a current is easily explained. The $+E$ taken up by the liquid and thence transferred to the platinum, can unite with the $-E$ of the zinc in two ways, either through the liquid, or through the connecting wire, and as the latter possesses greater conducting power than the liquid, the greater part of the opposite electricities recombine along the wire; whereas if the one or both of the plates are insulated, as when the arrangement is made to charge an electroscope, they recombine through the liquid, and only very small quantities show themselves on the plates in the state of tension.

The system of two dissimilar metals immersed in a liquid which acts on one of them is called a GALVANIC or VOLTAIC COUPLE. Its peculiar powers were first observed by Galvani, who found that the hind legs of a frog touched in different parts by a copper and an iron wire in contact with each other, were thrown into convulsions. Galvani did not however notice the necessity of having two metals to produce the effect; this most important point was discovered by Volta, who attributed the effect to electricity developed by the contact of the dissimilar metals, and by theoretical considerations founded thereon, was led to the invention of the pile or battery which bears his name. We now know that the electricity in Galvani's experiment was developed, not by the contact of the metals, but by the chemical action of the moisture on the frog's leg on one of the metals, viz. the iron. The necessity of having two metals in this or any similar arrangement is obvious; for if two plates of the same metal were immersed in a liquid, and connected by a wire outside, they would tend to produce equal and opposite currents, and no electricity would be apparent.

Of the two metals in a voltaic couple, that which is most attacked by the liquid is called the positive, the other the negative metal. It must be remembered, however, that it is the inactive metal from which the current of $+E$ passes into the conducting wire, and that this metal, though called negative, really corresponds, in its relations to the external conducting channel, with the positive conductor of the electrical machine, or the positive surface of a coated plate. The term positive, as applied to one of the metals of a couple, must be understood as denoting that which determines the direction of the current. The following experiments will show that

the direction of the current is really determined in this manner, and therefore that it owes its origin to chemical action :

When two plates, one of gold and the other of platinum, are connected with a delicate galvanometer and immersed in pure nitric acid, no current is produced ; but on adding a drop of hydrochloric acid, a strong current is excited, proceeding from the gold through the liquid towards the platinum, because the gold is attacked by the nitro-hydrochloric acid, while the platinum is much less acted on, if at all (De la Rive). When two gold wires connected with the ends of a galvanometer coil are immersed in pure nitric acid, no current is produced ; but on adding a small quantity of hydrochloric acid to the part of the liquid near one of the wires, a current is set up from that wire through the liquid to the other (Becquerel). In like manner a couple formed of platinum and palladium, which is inactive in dilute sulphuric acid, becomes active on adding a few drops of nitric acid, which produces an action on the palladium and renders it positive ; similarly, a couple of rhodium and platinum, inactive in nitric acid, becomes active on addition of hydrochloric acid, the platinum being then attacked. (De la Rive.)

Moreover, the direction of the current in a voltaic couple is in many cases reversed on changing the liquid in which the metals are immersed. Let a copper plate or wire be attached to one end of the coil of a galvanometer, and an iron plate or wire to the other end, and the plates immersed in dilute sulphuric acid ; the galvanometer needle will indicate a current proceeding from the iron through the liquid to the copper, because the iron is attacked by the acid and the copper is not. Now let the plates be taken out of the acid, washed in water, and then immersed in an aqueous solution of sulphide of potassium ; the needle will immediately move the contrary way, showing that the current is reversed, and that the copper is now the positive metal.

Mere dilution of the liquid is sometimes sufficient to reverse the current. The following table contains two columns in which the same metals are written one above the other, in such order that each metal is positive, or determines the direction of the current, with all those which precede it in the same column, the exciting liquid being strong nitric acid for the metals in the first column and dilute nitric acid for those in the second. It will be seen that the order of the metals is not the same in the two columns, but in all cases the direction of the current is determined by the metal which is most attacked : —

Strong Nitric Acid.

Oxidised iron
Silver
Mercury
Lead
Copper
Iron
Zinc
Tin.

Dilute Nitric Acid.

Silver
Copper
Oxidised iron
Iron
Lead
Mercury
Tin
Zinc.

The next table gives the results of Faraday's experiments with seven different liquids. It is arranged like the preceding, each metal being positive with regard to all those above it when acted upon by the liquid at the head of the column. The numbers in each column indicate the order in which the metals follow each other when the exciting liquid is a dilute acid :

Nitric acid, dilute.	Sulphuric acid, dilute.	Hydrochloric acid.	Nitric acid, concentrated.	Solution of caustic potash.	Sulphurate of potassium, colourless.	Sulphurate of potassium, coloured.
1. Silver	1. Silver	3. Antimony	5. Nickel	1. Silver	6. Iron	6. Iron
2. Copper	2. Copper	1. Silver	1. Silver	5. Nickel	5. Nickel	5. Nickel
3. Antimony	3. Antimony	5. Nickel	3. Antimony	2. Copper	4. Bismuth	4. Bismuth
4. Bismuth	4. Bismuth	2. Copper	2. Copper	6. Iron	8. Lead	3. Antimony
5. Nickel	5. Nickel	6. Iron	4. Bismuth	4. Bismuth	1. Silver	8. Lead
6. Iron	6. Iron	8. Lead	6. Iron	8. Lead	3. Antimony	1. Silver
7. Tin	8. Lead	7. Tin	7. Tin	3. Antimony	7. Tin	7. Tin
8. Lead	7. Tin	8. Lead	8. Lead	9. Cadmium	2. Copper	9. Cadmium
9. Cadmium	9. Cadmium	9. Cadmium	10. Zinc	7. Tin	10. Zinc	2. Copper
10. Zinc	10. Zinc	10. Zinc	9. Cadmium	10. Zinc	9. Cadmium	10. Zinc

The unvarying relation between the direction of the current and the relative force of the action exerted by the liquid on the two metals is quite sufficient to show that chemical action, and not contact of dissimilar metals, is the source of the electric excitement. A further and convincing proof of this statement is however afforded by

the fact, that a current capable of producing electrolytic decomposition may be obtained without any metallic contact. This is shown by the following arrangement (*fig. 405*), devised by Faraday. A plate of platinum, *b*, and a plate of zinc, *a*, bent horizontally in the upper part, are immersed in water acidulated with sulphuric acid; a piece of filtering paper moistened with iodide of potassium solution is laid on the zinc at *x*, and a platinum wire attached to the plate *b* is brought down to the upper surface of the moistened paper *without touching the zinc*. Immediately a brown spot of iodine shows itself on the upper surface of the paper at *x*, while the lower surface remains uncoloured, showing that the iodine is separated at the extremity of the conductor from which the $+E$ enters the solution, just as in the decomposition effected by the current of the electrical machine (p. 397). Here then we have additional evidence of a current in which the $+E$ passes from the zinc through the wire to the platinum, and then round the external conductors to the zinc. If the arrangement be somewhat modified so as to introduce a galvanometer, as at *g* (*fig. 406*), the deflection of the needle will indicate the same direction of the current. The effects are the same when a solution of potash is substituted for the dilute acid as the exciting fluid.

The strength of the current in these and all other voltaic circuits, depends partly on the exciting or "electro-motive" force, resulting from the action of the liquid on the zinc or other metal of the couple, partly on the resistance which the current meets with in the different parts of the circuit. In the particular arrangements now under consideration, in which the resistance offered by the conducting wire and other metallic parts of the circuit, is constant, the force of the current depends upon the relation between the electromotive force of the couple, and the resistance of the solution at *x* which is decomposed by the current. If the affinity between the elements of this liquid—the "electrolyte"—is too great to be overcome by the electromotive force of the couple, the current is arrested and the galvanometer needle returns to its natural position. Different electrolytes offer very different degrees of resistance to decomposition, and consequently some are decomposed by a given electromotive force, while others are not: thus a couple composed of zinc, dilute acid and platinum will decompose solution of iodide of potassium and fused chloride of silver, but not acidulated water. Hydrochloric acid, fused nitrate of silver, or fused iodide or chloride of lead likewise resist the electromotive force of the same couple, with dilute sulphuric acid as the exciting liquid, but are decomposed on adding a small quantity of nitric acid to this liquid, which increases its chemical action on the zinc.

The following table contains the results of a number of experiments by Faraday on the power of different voltaic couples in decomposing various electrolytes. Each horizontal line of this table contains the names of the four substances comprised in a circuit; the last column exhibits the comparative strength of the current, as indicated by the galvanometer:—

Active metal.	Exciting liquid.	Inactive metal.	Electrolyte decomposed.	Character of current.
Iron	Dilute nitric acid	Platinum	Sulphide of potassium	Full current
"	"	"	Red nitric acid	"
"	"	"	Pale strong nitric acid	Good
"	"	"	Green nitrous acid	Very strong
"	"	"	Iodide of potassium	Full
"	Dilute sulphuric acid	"	Sulphide of potassium	"
"	"	"	Red nitric acid	Good
"	Hydrochloric acid	"	Green nitrous acid	Very strong
"	" dilute	"	Red nitric acid	Good
"	"	"	Sulphide of potassium	"
"	Solution of common salt	"	Green nitrous acid	Very strong
"	Ordinary water	"	"	Good
Zinc	Dilute nitric acid	"	Iodide of potassium	"
"	Hydrochloric acid	"	"	"

Active metal.	Exciting liquid.	Inactive metal.	Electrolyte decomposed	Character of current.
Cadmium	Dilute nitric acid	Platinum	Iodide of potassium	Good
"	Hydrochloric acid	"	" "	"
Lead	Dilute nitric acid	"	" "	"
"	Hydrochloric acid	"	" "	"
Copper	Dilute nitric acid	"	" "	"
"	Hydrochloric acid	"	" "	"
Lead	Strong sulphuric acid	Iron	Dilute sulphuric acid	Strong
Tin	" "	Platinum	" "	"
Copper	Sulphide of potassium	"	Dilute nitric acid	"
"	" "	"	Iodide of potassium	"
"	Strong nitric acid	Iron	Dilute nitric acid	Very strong
"	" "	"	Iodide of potassium	"
Silver	" "	"	Dilute nitric acid	Strong
"	" "	"	Iodide of potassium	Good
"	Sulphide of potassium	"	Dilute nitric acid	Strong
Tin	Strong sulphuric acid	Copper	Dilute sulphuric acid	"

The liquid which unites the two metals of the voltaic couple likewise suffers decomposition during the whole time that the current is passing, and its elements are transferred in opposite directions, one to the active the other to the inactive metal. In fact, the exciting liquid is itself an electrolyte, and it is only a liquid capable of decomposing in this way that can act as the exciter of a voltaic couple, the decomposition which it undergoes being exactly similar to that which the current produces in any other electrolyte through which it passes; in the one part of the circuit as in the other, one set of elements, the electro-negative or chlorous elements, Cl, Br, I, O, S, SO⁴, NO³, &c., are transferred in the direction of the current of $-E$, and the others, the electro-positive or basylous elements, viz. hydrogen and the metals, in the direction of the current of $+E$ (pp. 397, 432).

In all the combinations mentioned in the preceding table, it will be found that, during all the time the current is passing, hydrogen is continually evolved from the liquid in the acting cell, at the surface of the inactive or negative metal, and at the same time the zinc or other active metal unites with chlorine, sulphur, SO⁴, NO³, &c., according to the nature of the exciting liquid, and dissolves. No evidence of commotion or action of any kind can be detected in any part of the liquid, excepting at the surface of the metallic plates; but as one of the elements is being continually transferred to the active and the other to the inactive metal, it is clear that a continued movement and shifting of particles must be going on. The nature of this movement we have now to examine; but first it must be observed that the active metal of a voltaic couple is usually subject to two kinds of action, one of which is essentially connected with the formation of a current, while the other is independent of it.

When a piece of ordinary commercial zinc is immersed in dilute sulphuric or hydrochloric acid, it immediately begins to dissolve and hydrogen is evolved upon its whole surface. Now let a plate of platinum or copper be immersed in the same liquid, and either brought in direct contact with the zinc under the liquid, or connected with it by a wire; immediately the greater part of the hydrogen is evolved at the surface of the latter metal, although this metal undergoes no change, and the zinc dissolves faster than before.

The effect of the inactive metal is still more striking when pure zinc, freed from foreign metals by redistillation, is used. A plate of this pure zinc immersed in dilute acid remains quite inactive, no gas being evolved at its surface; but as soon as a plate of copper or platinum is brought in contact with it, a brisk action is set up, the zinc dissolves, and hydrogen is evolved from the surface of the copper or platinum. It would appear from this that the establishment of an electric current is an essential condition to the solution of the zinc. When the zinc contains foreign metals, such as iron, lead, &c., these metals act just like an immersed plate of copper or platinum, establishing local currents within the liquid; and after the action has gone on for some time, these metals, especially the lead, are seen to separate from the surface in filaments. When, therefore, impure zinc (or other metal) is used to form the active metal of a voltaic couple, two kinds of action take place together, the solution of one part of the zinc being essentially related to the current which is established between the elements of the couple, and that of the rest depending on the so-called *local action*, due to the

presence of the foreign metals in the zinc. On making the connection between the two metals, the local action on the zinc is greatly diminished in amount, but does not cease altogether. Hence it follows that pure zinc is more advantageous for use in a voltaic couple than the impure metal, because a certain portion of the latter always dissolves without contributing to the production of the electric current.

Ordinary zinc may, however, be made to act with acids in exactly the same manner as distilled zinc, by amalgamating its surface with mercury. This is easily done by rubbing the surface with a rag dipped in dilute sulphuric acid, and at the same time spreading the mercury over it. The zinc then becomes uniformly amalgamated, not only on its surface, but right through, unless the plate is very thick. A plate of zinc thus amalgamated shows no signs of action when simply immersed in dilute acid; but on connecting it with a plate of copper or platinum, as above, hydrogen is briskly evolved from the surface of the latter metal, and the zinc dissolves. The mercury appears to act, partly by rendering the surface uniform, and removing the metallic impurities on which the local action depends, partly in a manner to be presently noticed (p. 420).

Theory of the Voltaic Couple.—The remarkable fact that a piece of pure zinc or of amalgamated zinc exerts no decomposing action on water or dilute acids when alone, but acts immediately on being connected with another metal not itself acted upon by the liquid, seems at first sight to favour the supposition that the action begins at the surface of contact of the two metals, and is essentially dependent upon that contact. The effect is, however, exactly the same when no actual metallic contact takes place, as when the conducting circuit is completed by the intervention of an electrolyte (p. 417). The zinc then dissolves, and hydrogen is evolved at the surface of the platinum as long as the current passes, but no longer.

Now we have seen (p. 404) that an electric current may be regarded as a succession of charges and discharges taking place throughout a series of polarised molecules; accordingly, the state of things in the voltaic couple may be represented as follows: Suppose a plate of pure zinc, *Z* (fig. 407), to be immersed in hydrochloric acid. We may suppose that its particles

polarise those of the acid which are in contact with them, in the manner shown in the figure, the atoms of chlorine becoming negative and turning towards the surface of the zinc, which becomes positive, while the atoms of hydrogen become positive and turn the contrary way. These molecules then polarise the next in a similar manner, these the next, and so on. At the same time the atoms of the zinc itself become oppositely polarised, each turning its positive pole towards the liquid, and its negative pole the other way; or probably the two elementary atoms in each molecule of the zinc (i. 187) are thrown into opposite electrical states.

When a plate of an inactive metal, such as platinum, is introduced into the same liquid as at *P* (fig. 408), its particles become polarised in like manner by the influence of the already polarised molecules of the liquid, turning their negative poles towards the liquid and their positive poles outwards. This state of tension continues till one of the plates, say *Z*, is connected with the earth. The negative electricity

is then discharged, and on connecting *P* with a condensing electroscope, the + *E* shows itself. At the same time, the chlorine of the molecule of acid in contact with the zinc

Fig. 407.

Fig. 408.

unites with it, their opposite electricities being thereby neutralised; the hydrogen of the first particle of acid unites with the chlorine of the second, the hydrogen of this with the chlorine of the third, and so on, till the hydrogen in contact with the inactive metal *P*, finding no chlorine to unite with it, is either set free, or more frequently, as the action in this state of tension of the couple is very slow, remains attached to the surface of the platinum plate.* This action goes on only till the tension of the charge on the insulated plate becomes strong enough to cause the two electricities to recombine across the liquid; and as the whole arrangement consists of conducting materials, the tension thus attained must necessarily be very low, and accordingly, the amount of chemical action which takes place is but slight; but on connecting the two plates by a wire or other good conductor, the particles of that conductor also become polarised, a regular series of charges and discharges taking place along it, as well as in the two metals, *Z*, *P*, and the intervening liquid. The action, therefore, becomes continuous, the atoms of chlorine being transferred towards the zinc, and those of the hydrogen in the opposite direction to the platinum, where they escape.

Fig. 409.

A precisely similar explanation will apply to every case of the development of electricity by a combination of two metals, and a liquid which acts chemically on one of them. The liquid must be an electrolyte, that is, a compound whose elements can be transferred in opposite directions, like those of the hydrochloric acid, *e. g.* H^+O^- , H^+SO_4^- , H^+NO_3^- , Cu^+Cl^- , Cu^+SO_4^- , PbI^- , K^+S^- , &c. The liquid state is evidently essential to the molecular transference.

The local action which takes place when zinc containing foreign metals is immersed in an acid, may be explained thus. Suppose *Z* (fig. 409) to be a plate of zinc, with here and there a particle of iron, *F*, on its surface. Local currents will then be established between different parts of the surface, the zinc forming the active, and the iron the inactive metal,

and between them polar chains of molecules will be formed, just as when a plate of another metal is placed in connection with the zinc.

The effect of amalgamating the zinc is partly, as already observed, to remove the foreign metals, partly, also, to enable the atoms of the zinc to polarise more regularly: for in a molecule of the amalgam, ZnHg , the atoms of zinc and mercury take up the opposite polar states more easily than the two atoms of zinc in a compound molecule of the metal, ZnZn ; and moreover, the semi-fluid condition of the amalgam enables the molecules to turn their poles easily in the direction which the polarising action tends to give them. The arrangement of a series of molecules of amalgamated zinc, hydrochloric acid, and platinum may be thus represented:

The precipitation of one metal from its solution by another, as of copper by iron, lead by zinc, silver by mercury, &c., affords an example of a simple voltaic circuit. When a piece of common zinc is immersed in a solution of acetate of lead, local currents are set up in the manner just explained, and the effect of such a current passing through the solution, is to precipitate a particle of lead on a point of the surface of the zinc, where a particle of any foreign metal, such as lead or iron, happens to be situated; the lead thus deposited forms a more distinct inactive or negative metal, and thus an increased electrolytic action is set up, more lead being precipitated on the surface of the first portion; and in this manner fresh particles of lead continually attach themselves to those previously deposited, the precipitated metal taking the well-known arborescent form called the lead-tree, or *Arbor Saturni*. Similarly, when iron is immersed in a solution of copper, there are always a few oxidised points, or small particles of carbon, on certain points of the surface, which favour the formation of local currents, and thereby determine the precipitation of the copper. The precipitation is of course greatly facilitated in the first instance by bringing the precipitating metal in contact with

* When a platinum plate which has thus been used, is placed in acidulated water, together with a clean platinum plate in its ordinary state, and the two connected with a galvanometer, the needle indicates the existence of a current, in which the first plate of platinum is the active metal. This effect is due to the film of hydrogen adhering to it, which in fact makes it act like a plate of zinc. (De la Rive.)

another which is not acted upon by the liquid, and in this manner many metallic precipitations may be effected, which would not otherwise take place. Thus, silver does not of itself precipitate copper; but on touching the silver under the liquid with a piece of iron, a current is immediately established in which the iron forms the positive, and the silver the negative metal, and the copper is then precipitated on the silver.

The protection of one metal from the action of a liquid by bringing it in contact with another, is also a case of the formation of a simple voltaic circuit; such was the method proposed by Davy for protecting the copper sheathing of ships by attaching to it pieces of a more oxidable metal, such as zinc. The zinc then formed the positive and the copper the negative metal, and consequently the oxygen and chlorine of the sea-water were directed to the zinc, instead of to the copper. The galvanising of iron by uniting it with zinc is another example of this mode of action. On the other hand, the corrosion of a metal by the action of air and water is sometimes accelerated by contact with another less oxidable than itself; thus iron railings are often found much corroded near their lower ends, where the iron is in contact with the lead which has been run in to fix it in the stone.

When the liquid in a voltaic combination acts in a similar manner on both the metals, *e.g.* when zinc and copper are immersed in nitric acid, the electric tension and current produced are such as result from the difference of the polarising actions exerted by the two metals on the liquid; if these actions are equal, as when two plates of the same metal are immersed in an acid, no current is produced. If, on the other hand, one of the metals or other conductors has an affinity for the positive element of the electrolyte, *i.e.* for the hydrogen if the electrolyte is an acid, while the other tends to unite with the negative element of the electrolyte, it is easy to see that the molecules of the electrolyte will be polarised by the sum of these two forces, and thus a much stronger current or a higher electric tension will be produced. Such a combination may be formed by zinc, acidulated water, and a plate of platinum covered with peroxide of lead; here the negative element of the acid (Cl or SO^+) tends to unite with the zinc, and the oxygen of the peroxide with the hydrogen of the acid, and the polarisation may be thus represented:

This combination charges the condenser and deflects the galvanometer much more strongly than the ordinary combination of zinc, acid, and platinum. A convenient way of forming it is to pack a quantity of the dry finely powdered peroxide into a rectangular cell of porous earthenware (such as those used for Grove's battery), introduce a thin plate of platinum having a wire soldered to it into the middle of this cell, so that it may be completely enveloped by the peroxide, and immerse the porous cell thus filled, together with a plate of amalgamated zinc, in an acid or saline solution. On connecting the zinc and platinum plates with two platinum wires terminating in acidulated water, the water is quickly decomposed, an effect which would not be produced by a single couple of zinc and platinum without the peroxide. The only use of the platinum in this arrangement is to act as a conductor. The strength of the current rapidly diminishes, however, chiefly in consequence of the reduction of the peroxide of lead to protoxide. Peroxide of manganese produces the same effect as peroxide of lead, but less strongly, and with even more rapid diminution. A similar effect, but also less powerful than that with peroxide of lead, is produced when the porous cell is filled with strong nitric acid and a platinum plate is immersed in it. In this, which is Grove's combination, the polarisation resulting from the affinity of the zinc for the chlorine or other negative element of the acid is intensified by that of the external atom of oxygen in the molecule $\bar{\text{O}}(\text{N}\overset{+}{\text{O}}^2\text{H})$ for the hydrogen.

The tendency of the peroxides of lead and manganese to deoxidation, by taking up the hydrogen of water or acids, is so strong, that very distinct indications of electric action are obtained, either in the state of tension or in the form of a current, on immersing in water a plate of platinum, and peroxide of lead or manganese, either in lumps or in fine powder, spread upon another plate of platinum. The uncovered plate of platinum then yields $-E$ to the condenser, the peroxide at the same time yielding $+E$. On connecting the two plates with a galvanometer, the current of $+E$ passes from the covered plate through the coil to the uncovered plate; but the current has not sufficient tension to pass through water. The addition of an acid, especially hydrochloric acid, to the liquid, greatly increases the force of the current, by facilitating the oxidation. A platinum wire covered with peroxide of lead and a gold wire, immersed in hydrochloric acid, yield a powerful current, proceeding from the covered platinum externally to the gold, the latter metal dissolving at the same time as chloride. Similar combinations with chromate of potassium, instead of the peroxide, yield very strong currents.

the chromic acid being reduced to chromic oxide. A copper plate oxidised on the surface forms with zinc and dilute sulphuric acid a more powerful current than a plate of clean copper.

Compound Voltaic Circuit. Voltaic Pile or Battery. The electric tension produced by a single voltaic couple is very small, because the opposite electricities can easily recombine through the medium of the liquid. It may, however, be increased by uniting a number of such couples together in regular order, the negative metal of the first being connected metallically with the positive of the second; and so on throughout the series. To understand how this increase of tension is attained, consider two couples of zinc, water, and platinum, connected in the manner just described (*fig. 410*). If

Fig. 410.

the second couple were inactive, the particles of the zinc, water, and platinum which compose it would be polarised to a certain degree of tension by the influence of the first; but, besides receiving this degree of charge, they likewise become polarised in the same direction, and to an equal degree, by the chemical action of the zinc and water in the second cell. These two actions, therefore, assist each other, and the resulting intensity in the second couple is twice as great as it would be if that couple were disconnected from the first. The polarisation of the second couple is also transmitted to the first, so that both couples have their electromotive force doubled. In like manner, the addition of a third couple will treble the electromotive force; and so for any number.

Hence when the opposite extremities or poles of an insulated voltaic circuit composed of a large number of couples are connected, each with an electroscope, the leaves of the two electroscopes diverge with opposite electricities. Moreover, by testing the different parts of such a series with an electrometer, it is found that when the whole is insulated, the tension of the opposite electricities is greatest at the two poles, and goes on continually diminishing towards the middle, where it is nothing. Now the electric tension of the different parts of the series cannot proceed from the intermediate couples, because the opposite electricities of each pair of zinc and platinum plates neutralise each other; it proceeds, therefore, from the opposite electricities accumulated at the extremities or poles, which are constantly tending to reunite, and are constantly renewed by the chemical action. On connecting one pole with the ground, and thereby discharging one kind of electricity, the tension of the other pole is increased.

The electric tension exhibited by the poles of a voltaic battery depends in a great measure on the nature of the liquid with which the cells are filled. The greatest possible tension would be obtained by an arrangement which should unite great electromotive power with imperfect conduction. Generally, however, the conducting power of a liquid increases with its power of acting chemically on the zinc.

The battery, whether charged with water, acid, or a saline solution, always takes a certain time to attain its maximum tension, that time being greater as the conducting power of the liquid is less; but with very good conductors, such as dilute acids, the maximum tension is attained almost instantly. In all cases, the statical, as well as the dynamical, effects of the battery are essentially dependent on the chemical action between the liquid and the positive metal. The stronger this action, the smaller is the number of couples required to produce a given tension. Gassiot has found that a Grove's battery (to be hereafter described) of 400 cells, well insulated in glass vessels, exhibits at the two poles a tension equal to that of a water battery of 3520 pairs.

The poles of a voltaic battery in a state of tension discharge to each other, just like two metallic rods connected with the positive and negative conductors of an electrical

machine. When the poles of the 400 pairs of Grove's battery, just mentioned, were placed in connection with two copper discs placed at the distance of $\frac{1}{50}$ of an inch from one another, a rapid succession of sparks was produced.

The wire along which the current of the voltaic battery is passing, either continuously or by intermittent spark-discharge as just described, exhibits the same effects as one which conveys the discharge of an electrical machine or Leyden jar. The wire itself, if not very thick, becomes warm, and a thin wire of platinum interposed in the circuit is heated to redness, or fused, according to the strength of the current; magnets are deflected, and iron and steel magnetised by it; and if the two poles of the battery are connected with two platinum wires or plates immersed in water acidulated with sulphuric acid, the water is decomposed, hydrogen being evolved from the wire connected with the negative pole, and oxygen from that connected with the positive pole. Any of the other electrolytes mentioned on page 397, as decomposed by friction-electricity, may also be decomposed with ease by the current, even of a small voltaic battery. The quantity of oxygen and hydrogen thus evolved in a given time affords, as we shall afterwards more particularly explain, a measure of the quantity of electricity evolved by the battery. Now the *quantity* thus evolved, whether measured by the amount of water or other electrolyte that it will decompose, or by the deflection of a magnetic needle (p. 398), is incomparably greater than that evolved by the most powerful electrical machine; a pair of thin wires of zinc and platinum dipped for a moment into dilute acid will produce a current capable of decomposing a larger quantity of iodide of potassium than could be decomposed by a large electrical machine working for a considerable time.

But the *intensity* of the charge of a voltaic battery, even of a very large number of pairs, is almost immeasurably below that of the electricity produced even by rubbing a piece of glass with the dry hand; in fact, the whole of a voltaic arrangement consists of materials possessed of considerable conducting power, and therefore the neutralisation of the opposite electricities takes place through the battery itself more easily than through even a very small stratum of air, or other insulating body.

The exact relations between the quantity and intensity of the voltaic current will be more fully considered hereafter. At present it may suffice to state that, with a conducting circuit not offering much resistance, the quantity of electricity developed in a given time increases nearly in direct proportion to the size of the plates in a single pair (not to the total extent of metallic surface in the battery), whereas the intensity, or power of overcoming resistance increases, as already observed, directly as the number of pairs. Hence when the current is to pass only through a metallic conductor of no great length—as for most electro-magnetic experiments, and for heating wire not extremely thin—a single pair of plates will act as well as a compound battery, provided all the connections are good. Hare's *calorimotor* for heating wires is an arrangement of this kind. A number of zinc and copper plates are fastened alternately and perpendicularly in a frame, all the copper plates being soldered to one common bar of metal, and all the zinc plates to another, so that the whole acts like a single pair of very large zinc and copper plates. With from 60 to 120 copper and zinc plates, each having a surface of 19 square inches, excited by dilute acid, a platinum wire $\frac{1}{4}$ of a line thick may be fused. Another mode of obtaining a large surface in a small space is to roll together a zinc and copper plate 6 inches broad and 9 inches long into a cylinder $2\frac{1}{2}$ inches in diameter, in such a manner that they never come into contact, but are always kept about a quarter of an inch apart. All the copper plates of a number of such rolls are united by soldering with a single metallic rod, and all the zinc plates with another.

Dry Piles.—The greatest degree of intensity is obtained by the so-called dry piles, which consist of a great number of pairs of two metals separated by paper instead of a liquid conductor, tinfoil being generally used as the positive, and peroxide of manganese as the negative metal. In these piles, as in the ordinary voltaic battery, the motive power is chemical action, the exciting liquid being the moisture in the paper, the oxygen of which is continually combining with the tin, and the hydrogen with the oxygen of the peroxide of manganese (p. 421); in fact, the pile acts only so long as the paper remains moist, so that the appellation *dry pile* must not be understood in its literal sense.

The best way of constructing a dry pile is to take a sheet of paper tinned on one side, and cover it on the other side with a paste made of peroxide of manganese mixed with milk and starch or gelatin, to make it adhere. The paper thus coated is left to dry, and then punched into a number of small circular discs, which are laid one upon the other in a glass tube, care being taken that the tinned surfaces are all laid the same way; when the tube is quite full, its ends are closed with brass caps, which must be metallically connected with the two extremities of the pile.

The tin end of such a pile exhibits $-E$; the manganese end, $+E$. A pile of

several thousand pairs produces strong divergence of the leaves of an electroscope, when one of its ends is brought in contact with the cap of the instrument, while the other is held in the hand; and, on connecting its two poles by a wire, small sparks are obtained. The pile does not produce a continuous current, since, in consequence of the imperfect conduction of the paper-discs, it takes some time to recover its maximum tension after being discharged. With a dry pile composed of a comparative small number of large discs, some of the dynamic effects of electricity may, however, be obtained; thus Delezenne succeeded in decomposing water with a dry pile composed of 300 pairs, each having a surface of 270 square centimetres.

The chief use of the dry pile is to assist in the construction of a very delicate electroscope, called from its inventor, *Bohnenberger's electroscope*. It consists of two

Fig. 411.

dry piles, C, D (*fig. 411*), placed vertically at a distance of four or five inches, with their poles in opposite directions; and of a single gold leaf, G, suspended just midway between them from a brass rod passing through the cap, A, of a glass receiver which covers the whole arrangement. The poles of the two piles, being charged with opposite electricities, attract the gold leaf in opposite directions, so that, if suspended exactly in the middle between them, it hangs vertically while not itself electrified; but as soon as the slightest charge is communicated to it, it moves towards the pile whose superior pole is charged with the electricity opposite to its own. The instrument is so sensitive that it is affected by an excited rod of glass or sealing wax at the distance of a yard; in fact, it is sometimes too delicate: for if the piles are placed too close together, and the leaf, from any slight disturbance is thrown a little out of the vertical, it will be drawn towards one pile or the other, even though not itself electrified. A pith-ball or a small disc of gilt paper suspended by a silk thread between the opposite poles of two dry piles, oscillates between them as long as the piles continue in action.

A well constructed dry pile will remain active for two or three years; but the action ultimately stops, either from desiccation of the paper, or from formation of a thin film of oxide on the surface of the tin-foil.

The older forms of the galvanic or voltaic apparatus, viz. the pile of Volta, Cruikshank's trough, and Wollaston's battery, are too well known to need particular description; moreover, they are now but little used. They all consist of a series of couples of zinc and copper, excited by an acid liquid, generally a mixture of water with $\frac{1}{40}$ of its bulk of sulphuric and $\frac{1}{60}$ of nitric acid.

Constant Batteries.—In all voltaic combinations consisting of two metals and one liquid, the force of the current continually diminishes, in consequence of the alterations which the chemical action produces in its component elements. Consider, for example, the ordinary combination of zinc, sulphuric acid, and copper. As the zinc dissolves, the action of the acid on the remaining metal becomes less energetic, and therefore the electromotive force, which depends upon that action, is diminished. But, besides this, the sulphate of zinc thus produced, and the water, are decomposed by the current, hydrogen and zinc being carried towards the surface of the copper. The zinc is there deposited, and tends to form a counter current, just as if a plate of zinc were substituted for the copper; and the hydrogen likewise diminishes the force of the current, partly by clinging about the surface of the copper, and forming a non-conducting film, which impedes the passage of the current, partly by acting as a positive element, in the same manner as in Grove's gas-battery (p. 430), and thereby also generating a counter-current. When common zinc is used, a further variation arises from the local action induced by the foreign metals present in the zinc, and continually increases as those metals are separated in larger quantity (p. 418). This last inconvenience is completely obviated by the use of amalgamated zinc.

The variation of power arising from the saturation of the acid may be prevented by gradually removing the spent liquid and replacing it with fresh acid, which, however, introduces considerable complication into the arrangement of the battery; this source of variation is greatly diminished by the use of amalgamated zinc, which acts only while the circuit is closed, and therefore does not saturate the acid so quickly.

The variation arising from the transference of zinc and hydrogen to the surface of the negative metal is prevented by immersing that metal in a liquid of different composition from that which acts upon the zinc, and capable of absorbing the hydrogen, the two liquids being separated by a porous partition, which prevents them from mixing, but does not interrupt the electric communication. This object may be effected by various arrangements, the most important of which are the batteries of Daniell, Grove, and Bunsen.

In *Daniell's battery*, each cell consists of a copper cylinder, *cc* within which is placed a cell *ab*, either of porous earthenware or animal membrane, filled with a mixture of 1 measure of strong sulphuric acid and 8 measures of water, and in this is immersed a cylinder of amalgamated zinc *z*. The space between the porous cell and the copper cylinder is filled with a saturated solution of sulphate of copper. On connecting the zinc with the copper by a wire, the zinc dissolves, and the particles of the two liquids become polarised in the manner represented below:

the sulphates, for greater simplicity, being supposed to be replaced by chlorides. The last atom of hydrogen, instead of passing on to the copper, unites with the chlorine of the first atom of chloride of copper beyond the porous diaphragm; the atom of copper thus set free unites with the next atom of chlorine, and so on, till the last molecule of cupric chloride is reached, the copper-atom of which is deposited on the surface of the copper cylinder in the metallic state. Thus the copper, instead of having its surface tarnished by a deposit of zinc, or polarised by adhering hydrogen, is kept continually bright by fresh deposits of metallic copper.

This is the action which goes on in a Daniell's cell, so long as the copper solution remains tolerably well saturated. It is clear, however, that in course of time it must become weak unless renewed; and when it becomes dilute, water is decomposed as well as the cupric salt, and hydrogen then passes on to the copper surface. It is important, therefore, to keep the copper solution saturated; and for this purpose a shelf of perforated copper is fixed round the interior of the copper cylinder at about an inch below its upper edge, and on this shelf are laid crystals of cupric sulphate, which dissolve as fast as the copper is removed from the solution by the action of the current.

A Daniell's battery thus fitted up remains nearly constant for a considerable time; but the acid of course becomes gradually exhausted. To preserve it at a constant strength, the copper cylinder *AB* was originally constructed as shown in *fig. 413*, with a siphon-tube *efg*, proceeding from its lower part and terminating within

Fig. 413.

Fig. 412.

Fig. 414.

the ox-gullet *a b, FE*, which formed the porous cylinder. By this tube an outlet was provided for the spent liquid as fresh acid was poured in at the top. This construction has, however, not been found to yield sufficient advantage in point of constancy to compensate for the additional complication which it involves. Buff has contrived a modification of the Daniell's cell, in which the zinc plate or cylinder is sustained by a counterpoise, and allowed gradually to sink in the liquid, thus presenting a greater surface to the action of the acid as that liquid becomes weaker.

Grove's battery.—In this battery (*fig. 414*) the positive-metal consists of amalgamated zinc immersed in sulphuric acid diluted with about 10 times its bulk of water, and the negative metal of platinum immersed in strong nitric acid. Each zinc plate, *Z*, bent

round, as in the figure, is contained in a rectangular vessel of glass or glazed earthenware A B C D, filled with dilute sulphuric acid. Between the two bends of the zinc plate is placed a narrow rectangular cell of porous earthenware, containing strong nitric acid, and in this is immersed a plate of platinum, bent at the top to meet the next zinc plate, against which it is pressed by a small split piece of wood, *a*. The action of this battery is similar to that of Daniell's, but stronger, because the hydrogen evolved by the decomposition of the water is rapidly taken up by the nitric acid, which, in fact, acts upon it like peroxide of lead, or manganese (p. 421), and tends greatly to intensify the polarity induced by the action of the zinc on the sulphuric acid. The battery is not, however, so constant as Daniell's: for the nitric acid is very quickly reduced to lower oxides of nitrogen, and, after the battery has been in action for about an hour, copious red fumes are given off, which cause great annoyance. This inconvenience may be diminished by using weaker nitric acid (acid of 1.40, mixed with half its bulk of water), or by mixing the stronger acid with one-third or one-half its volume of strong sulphuric acid; both these methods render the action less variable: but the former greatly diminishes the force of the current; the latter is, therefore, to be preferred.

Bunsen's battery (fig. 415) is the same as Grove's, excepting that the platinum is replaced by compact charcoal or coke. Each couple consists of a hollow cylinder of carbon enclosed in a glass vessel containing nitric acid, and encloses a cell of porous earthenware which contains dilute sulphuric acid, and a cylinder of amalgamated zinc. The upper

Fig. 415.

rim of each carbon cylinder is enclosed by a copper ring, to which is attached a riband of the same metal, serving to connect it with the zinc of the next couple, in the manner shown in the figure.

The carbon for these batteries is obtained as described at p. 760, vol. i. Its conducting power is somewhat less than that of platinum, and consequently the current produced on first closing the circuit is less violent than that of Grove's battery, and, on this account, somewhat more constant.

The platinum in Grove's battery may also be replaced by lead coated with gold or platinum (Callan, *Ann. Ch. Phys.* [3] viii. 28); also by iron rendered passive by immersion in strong nitric acid; iron in its ordinary state may be used as the positive metal, with passive iron as the negative, but amalgamated zinc is better (Schönbein). Callan has obtained good results with amalgamated zinc and cast iron immersed in dilute sulphuric acid, without the use of nitric acid.

The variation in the strength of the current arising from the adhesion of hydrogen to the surface of the negative metal may also be prevented, to a great extent, by covering the surface of that metal with a coating of finely divided platinum or gold. Plates of platinum or silver may be thus coated by immersion in a solution of chloride of platinum or chloride of gold. Metals thus coated with platinum are said to be *platinised*.

Snee's battery, which consists of a series of pairs of amalgamated zinc and platinised platinum, immersed in dilute sulphuric acid, produces a current of much greater constancy than might be expected from a battery of only one liquid, because the hydrogen does not adhere to the rough surface of the platinised platinum. The form of the plates is similar to that adopted in Grove's battery, the plates of zinc being bent double, and the platinum plates interposed between the two surfaces formed by the bend; but as there is only one liquid, and no porous cell, the two surfaces of each zinc plate may be brought much nearer to each other than in Grove's battery. The battery is charged with a mixture of 1 pt. sulphuric acid to 7 pts. water. The plates are attached to a frame, by which they can be easily lifted out of the trough when not required to act.

Platinised silver may be used instead of platinised platinum, but silver is not very easily platinised, on account of the high polish of its surface.

None of the forms of battery above described are capable of yielding a really constant current. Daniell's construction gives the nearest approach to constancy; but even in this, variations must arise, as it is impossible to keep the acid at a perfectly uniform strength. The only way of obtaining a perfectly constant current, is to interpose in the circuit, a conductor, the resistance of which can be made to vary inversely as the strength of the action in the battery. The mode of effecting this will be described hereafter (p. 464).

2. Development of Electricity by the Chemical Action of Solutions one upon the other.

When two conducting liquids act upon one another, a development of electricity takes place, the more acid liquid becoming positive, and the more alkaline liquid negative.

This may be shown by plunging two perfectly clean plates of platinum, connected with the ends of a galvanometer wire, one in nitric acid contained in a glass vessel *d* (*fig. 416*), the other in a solution of potash contained in another glass vessel *c*, and connecting the two liquids by means of a bundle of cotton or asbestos fibres *p m q*, steeped in a slightly acid or saline solution.

Fig. 416.

The acid and alkali then rise through the bundle of fibres, by capillarity, and as soon as they mix, a current is produced, the $+E$ passing from the acid through the galvanometer to the alkali. That this effect is really due to the mutual action of the acid and alkali, and not, as Davy supposed, to the different action of the two liquids on the platinum plates, may be proved by immersing the two plates in cups containing a solution of nitre, connecting these two cups by means of a bundle of asbestos or cotton fibres, one with the nitric acid, the other with the potash, and the acid and alkali by another bundle of asbestos as before. The current is then produced in the same direction as with the former arrangement, but somewhat weaker, on account of the small conducting power of the nitre solution. Another mode of operating, so as to obviate the objection above-mentioned, is to plunge the two platinum plates attached to the galvanometer coil into vessels containing nitric acid, connect these vessels by a bundle of cotton fibres about four inches long, moistened with water, then drop gently, by means of a tube, a small quantity of acid and of potash solution near the middle of the cotton. As long as these drops of liquid remain separate, no current is formed; but as soon as they mix, a current is produced in the same direction as in the preceding experiments, the $+E$ passing from the alkali to the acid, and thence through the connecting wire to the alkali again.

If, in the first arrangement, the cotton or asbestos is moistened with a strong solution of any salt, such as chloride or sulphate of sodium, a current is at first formed by the action of this solution on the acid and on the alkali; this current is, however, comparatively feeble, and is soon succeeded by the stronger current resulting from the mixture of the acid and alkali. Thus, nitric acid and potash connected by cotton containing sulphate of sodium, produced, at first, a deflection of 4° or 5° in the galvanometer, but after a few seconds a deflection of 20° , which remained constant.

Electric currents are also produced by the action of one acid upon another; thus, when strong sulphuric acid is carefully poured into one branch of a U-tube (*fig. 417*), and nitric acid into the other, so that the two liquids may meet in *m*, without mixing, and the platinum terminals *a b* of a galvanometer are made to dip into

the two acids, a current is formed, in which the $+E$ passes from the nitric acid directly to the sulphuric acid, and thence through the galvanometer back to the nitric acid, the latter acting, in fact, as a base to the sulphuric acid. Phosphoric acid acts with nitric acid in the same way as sulphuric acid, and with sulphuric acid in the same manner as the latter acts with nitric acid.

Fig. 417.

Of the conducting solutions in the following series, each is *negative* with those which follow, and *positive* with those which precede it; the term *positive* being here, as before, applied to the body from which the $+E$ passes directly to the others:

Phosphoric acid, sulphuric acid, nitric acid, hydrochloric acid, acetic acid, saline solutions, alkaline solutions.

Water is for the most part positive with acids and negative with alkalis.

In all arrangements like those above described, it is of great importance to clean the platinum plates before each experiment, by heating them to redness, then immersing them in boiling nitric acid, and, lastly, washing them in distilled water. They should then be tested by connecting them with a galvanometer, and immersing them in the same liquid—nitric acid, for example. If quite clean, they will produce no current; if, on the other hand, the needle is deflected, it may be concluded that the plates are *polarised*, by the deposition of a film of oxygen gas on the one, and hydrogen on the other, these gases resulting from the electrolytic action which has taken place in the liquids in which the plates were previously immersed (see the next section). The effect of these gaseous deposits is to produce a current in the direction inverse to that of the current by which they have been formed, and this current may diminish, or even completely neutralise, that which it is desired to produce.

To obviate this source of error, Becquerel contrived an apparatus called a *depolariser*, consisting of a mechanical arrangement by which each of the platinum plates is lifted out of the solution in which it has been immersed, and plunged into the other, their connections with the galvanometer remaining, however, unchanged. The result of this continual shifting of the plates is, that neither of them remains in either of the liquids long enough to become polarised, and therefore the secondary current above-mentioned is not produced. By means of this apparatus, Becquerel has been able to detect the production of a current by the mutual action of liquids, in many cases in which it would not otherwise have been apparent.

Fig. 418.

The intensity of the current produced by the mutual action of liquids may, of course, be increased by joining several couples together, the two liquids in each cell being separated by a porous diaphragm, or, if they differ greatly in density, simply laid one upon the other. The couples are connected by wires of copper or platinum, the extremities of which dip into the positive liquid of one cell and the negative of the next.

A very remarkable form of couple, composed of two liquids and one metal, is that which is known as *Becquerel's Oxygen-circuit*. *CD* (fig. 418) is a glass bottle, into the neck of which is inserted a glass tube *AB*, kept in its place by a cork. Over the bottom of the tube *B* is tied a piece of linen, on which is placed a layer of moist clay, about half an inch thick, and on this is laid a piece of cotton-wool, to prevent it from mixing with the supernatant liquid. The bottle is filled with nitric acid, the tube with solution of caustic potash. The two liquids come into contact through the moist clay, and are also connected by means of a wire, which may be that of a galvanometer, terminating in two plates of platinum *PN*, the former immersed in the potash, the latter in the nitric acid. On making this connection, a strong current is produced, the $+E$ passing from *N* along the wire to *P*, and at the same time the water of the potash solution is decomposed, its oxygen escaping in bubbles at *P*, while the hydrogen is transferred to the nitric acid, which it partly reduces to nitrous acid, thereby colouring the liquid around it red or green.

The current produced by this oxygen-circuit is of constant strength, because the plates do not become polarised; in fact, although the nitrate of potassium formed by the union of the acid and alkali is decomposed by the current, the acid being transferred to the plate *P*, and the alkali to *N*, the acid is immediately neutralised by the potash at *P*, and the alkali by the nitric acid at *N*, so that they

do not remain attached to the plates. This arrangement was the earliest form of a constant voltaic current. Its power may be considerably increased by making the plate *P* of amalgamated zinc instead of platinum; the zinc takes hold of the oxygen, and produces an electric polarisation in the same direction as that resulting from the mutual action of the acid and alkali. A single couple thus constituted decomposes water with facility, and by uniting several such couples a powerful battery is obtained.
